
# SCHIZOPHRENIA:
## Other Aspects; Psychotherapy

Silvano Arieti

Downloaded from www.dbraulibrary.org.in

AN ENORMOUS NUMBER of studies have been made in an attempt to determine the organic changes which cause, accompany, or are the result of schizophrenia. Their findings are not consistent, their interpretation controversial. We shall report here only those which at present seem to be the most important.

## Somatic Studies

### *Genetic Studies* of Schizophrenia*

The hereditary nature of schizophrenia has been suspected by many authors, who have tried to give statistical evidence. Rüdin's[149] work, based on a study of 701 cases, had considerable influence in an earlier period. Rüdin felt that his results pointed strongly to the presence of a Mendelian recessive factor. Bleuler[27] criticized Rüdin's work on the grounds that it did not include the latent, undeveloped, or mild cases of the disorder.

Among contemporary researchers, Franz Kallmann[98,99] conducted two of the most important investigations into the genetics of schizophrenia—the first on the relatives of over 1,000 patients of a Berlin psychiatric hospital, the second on 953 twins from psychiatric hospitals of New York State. He, too, concluded that single-factor inheritance of recessive type is the genetic cause of schizophrenia. He found that full sibs of patients have a higher expectancy (11.5–14.3 per cent) for the disorder than half-sibs (7.1 per cent), and half-sibs have a much higher expectancy than step-sibs (1.8 per cent). He found the highest incidence of schizophrenia in the children of two schizophrenic parents and in one-egg twins.

Kallmann's work was criticized by Bellak[15] on the grounds that he excluded from his studies "the schizoform psychoses," which lack hereditary traits, thus obtaining different statistical results; by Pastore[137] on the grounds of his statistical analysis technique; and by

* See Chapter 8 for a detailed review of genetic studies. The topic will be dealt with only briefly here.

Koller[104] on the grounds that, if simple recessivity is the hereditary basis of schizophrenia, the incidence should be higher among the sibs than the children of schizophrenics, whereas Kallmann's figures indicate the opposite.

As a rule, however, researchers in many countries who have investigated the genetic aspects of schizophrenia seem to feel, with Kallmann, that the disorder is based on a recessive mendelian factor. Those who approach schizophrenia from the aspect of its psychodynamics are reluctant to accept this position. The noteworthy exception is of Rado,[111] who accepts the distinction between genotypes and phenotypes in relation to schizophrenia. Genotype is the inherited cause of development; phenotype the actual outcome of development. The genotype, through its interaction with the environment, causes the schizophrenic phenotype (called also schizotype) to develop an abnormal organization.

## *Constitutional Factors in Schizophrenia*

In 1921 Kretschmer[100] published *Physique and Character*, a work that remained popular in psychiatric circles for about two decades. Advancing his theories concerning personality and constitution, he divided body build into three types: (1) the leptosomatic (or asthenic), characterized by angular profile, narrowness of muscles, small shoulders, flat chest, relatively long extremities, and little muscular development; (2) the athletic type, with strong skeletal and muscular development; and (3) the pyknic type, characterized by pronounced deposits of fat on the trunk, short extremities, and gently curved profile.

Kretschmer saw a certain correlation between schizophrenia and body build. According to his studies, two thirds of schizophrenics are leptosomatic or athletic and one tenth dysplastic.

Sheldon[155] and Lindegarde[116] refined Kretschmer's rather crude technique, and many authors have adopted their method generally to confirm that there is a greater incidence of asthenic constitutions among schizophrenics. Rees[112] and the present writer, however, unlike Kretschmer, have not confirmed a lower incidence of pyknic constitutions found among schizophrenics.

## *The Endocrine Glands and Schizophrenia*

Many authorities suspected an endocrine origin for schizophrenia because of the rarity of the disorder before puberty; frequent occurrence at or shortly after puberty, in postpartum conditions, and again at the time of the menopause; relatively high incidence of dysplastic body build; and high frequency of sexual dysfunctions.

In spite of this list of incriminating factors, no convincing evidence has been collected pointing to an etiologic correlation between schizophrenia and endocrine disorders. None of the classical endocrine disorders, such as acromegaly, hyperthyroidism, myxedema, Cushing's disease, etc., is found more frequently in schizophrenic patients than in the general population. Manfred Bleuler,[29] writing on endocrinological psychiatry, reached similar conclusions.

Studies on the thyroid gland by Witte,[173] Hoskins,[80] and many others have not reached any definite conclusion, although the opinion prevails that there is a moderate functional hypothyroidism. The adrenal glands in schizophrenics have been subjected to intense study, since these glands are involved in what Selye[138] calls "general adaptation syndrome" and states of stress. A majority of researchers have found a dysfunction of the adaptation syndrome (Pincus and Hoagland,[140] Parsons, *et al.*[136]), but uncertainties remain as to the specific mechanism of this dysfunction. Sands[150] found higher 17-ketosteroid excretion in paranoid patients, but is inclined to attribute this finding to "the emotional response of the organism to the paranoid thought."

In extensive research on the gonads of schizophrenics, Mott[134] found varying degrees of atrophy of the testicles in all cases of schizophrenia and a complete arrest of spermatogenesis in the majority of them. Morse[133] criticized Mott's work on the ground that the changes found in the testicles of patients may be the result of age, state of nutrition, concomitant disease, and may have nothing to do

with schizophrenia. Hemphill and his associates,[82] however, using biopsy rather than autopsy specimens, confirmed Mott's findings, with the exception that they did not find atrophy in paranoid patients.

At a clinical level, many authors have found hirsutism and other secondary masculine sexual characteristics in regressed female patients. Very common are also dysmenorrhea and amenorrhea. Ripley and Papanicolaou[145] found a correlation between the severity of the illness and the degree of abnormality of the menstrual cycle. An improvement in the psychological symptomatology was usually accompanied by a return to a more normal menstrual function.

Altschule[1] reported studies, not yet confirmed by others, according to which a protein-free pineal extract is beneficial in the treatment of chronic schizophrenia.

## *The Cardiovascular System and Schizophrenia*

The main alterations found in the cardiovascular system of schizophrenics may be grouped under four headings:

1. Decrease in the size of the heart. Lewis[108, 109] found a hypoplastic heart in schizophrenics who came to autopsy. He did not, however, find this hypoplastic condition in paranoids. Hypertrophy of the heart was never found, even in presence of valvular lesions.

2. Decrease in the volume of the blood flow. Finkelman and Haffron[61] found, in schizophrenics, a diminished volume of circulating blood in comparison to that of manic-depressive patients. Researchers have also studied the intracranial blood flow in schizophrenics, but the findings were so discordant that no conclusion was possible.

3. Decrease in blood pressure. The finding that the blood pressure of schizophrenics is generally lower than that of the general population of similar age is almost unanimously accepted. Freeman, Hoskins, and Sleeper[75] found, in a series of 180 patients, that the average systolic pressure was 104.5 mm. Hg. and the diastolic was 54.5. Rheingold,[143] too, found the blood pressure of 129 schizophrenics to be lower than that of the general population. There is general agreement that paranoid or relatively well-socialized patients have a higher blood pressure than the rest of the patients.

4. Exaggerated tendency to vasoconstriction and resulting diminished blood supply. Shattock,[155] in an accurate and informative study, reported lowering of the temperature, vasoconstriction, and cyanosis in the extremities of patients, especially female. Minski,[120] Stern,[158] and others have reported similar findings which have been interpreted in various ways.

## *Biochemical Changes in Schizophrenia*

Volumes could be written on the studies of metabolism that have been carried out on schizophrenic patients. McFarland and Goldstein,[117] who reviewed the work in this field up to 1938, concluded that the results of all these investigations were almost entirely negative, so conflicting were the reports. Bellak and Willson,[14] reviewing the literature on etiology of dementia praecox, in an article published in 1947, concluded the sections on the biochemical factors with the remarks that the only consistent difference of biochemical findings "from normals lies in the greater variability of values for almost any factor investigated."

Space limitations permit the report of only a few of the most important findings. The reader who is particularly interested in this subject should see References 15 and 90.

*Hoskins*[90] *found that the output of urine* was twice as large in the schizophrenic as in the normal population, but attributed this to the fact that, generally, schizophrenics drink more water than the average person. A low hippuric acid excretion, suggesting dysfunction of the liver, was found by many authors, but the Quick test, on which these works were based, cannot be considered a reliable method. Buscaino,[33] too, incriminates the liver. Buscaino is one of the staunchest European supporters of the theory that schizophrenia is the result of a metabolic disorder. In a number of papers, summarized in his report at the First International Congress of Neuropathology, he tried to prove that there is, in schizophrenia:

Downloaded from www.pdfbooksworld.org.in

1. Evidence of functional insufficiency of the liver (bilirubinemia, detoxication power impairment, as shown by deamination test, hippuric acid test, santonin test, etc.). Buscaino states that other researchers failed to get the same results because they relied on only one test, whereas, in order to study the liver properly, one must use a battery of tests ("hepatic constellation" or "instantaneous picture of liver").

2. Evidence of insufficient reactivity of the hepatic and extrahepatic reticuloendothelial system.

3. Evidence of gastroenteric function, as shown by findings of gastroenteritis. Buscaino reports that he has found pathologic amines in the blood and urine of schizophrenics and concludes that schizophrenia is an "aminotoxicosis." One of the disorders of metabolism investigated by Buscaino concerns aromaturia. McGeer *et al.*[118] have also reported that schizophrenics excrete a higher than normal concentration of aromatic compounds in the urine.

In studies of carbohydrate metabolism in schizophrenics, it has been found that, although the blood glucose level is generally normal, the glucose tolerance curve is often abnormal. For a review of glucose metabolism in schizophrenics, see Shattock.[156]

Deficient oxidative processes in schizophrenia have been reported widely.

Like Buscaino, Heath and his associates[80] believe that schizophrenia is primarily a metabolic disorder which manifests itself in varying degrees, "from a very minor deficiency in the so-called mild schizotypes up to a marked deficiency in the chronic overt psychotics." The metabolic disorder, according to Heath, hinges on the formation of a substance he and his collaborators isolated, "taraxein." "The present operational concept" of these authors is that taraxein is a manifestation of a defect in the oxidizing enzyme system.

## *Electroencephalographic Findings*

Early authors reported that the EEG was normal in schizophrenia. Davis[47] described what she termed a "choppy activity," which is a disorganized pattern of low voltage ranging from approximately 26 to over 50 cycles per second. This pattern could not be related to age differences or to menstrual deterioration. Davis did not consider this EEG record specific for schizophrenia, but much more common in this disorder than in others. In fact, she found it in 61 per cent of the records of schizophrenics in contrast to 39 per cent of manic-depressives.[46] Denis Hill[83] found the "choppy pattern" in only 20 per cent of schizophrenics.

Walter[168] observed slow wave changes in catatonic stupor. He found that the alpha activity shows instability and slow activity at 2 to 6 cycles per second. Low voltage was also apparent. These findings were not constant and could not be interpreted.

Hill,[83] who has made an excellent review of the literature on this subject, concludes that the EEG is abnormal in a proportion of patients suffering from schizophrenia, particularly of the catatonic type, but that no specific pattern is found in these patients. Subcortical type discharges, similar to those found in some epileptics, are found, particularly in young catatonics, but are not interpreted by the author as evidence of an organic-pathologic process. Hill states that the available EEG data "do not provide adequate evidence for a genetic progressive pathological cerebral process in schizophrenia."

## *Neuropathology of Schizophrenia*

Schizophrenia has been the object of much neuropathologic research, for the organicists have hoped to repeat for this disorder the history of the development of our knowledge of general paresis. From the time of the founding fathers of neuropathology, such as Nissl, Spielmeyer, and Alzheimer, to the present, these hopes have remained unfulfilled.

The brain of the schizophrenic has not revealed anything more definite than have the other organs. Many alterations were found, but not consistently, and their significance is disputed.

Alzheimer[2] found a local disappearance of ganglion cells in the outer layers of the cerebral cortex. Winkelman[172] found instead diffuse nerve-cell loss. Josephy[92] described cell sclerosis

Downloaded from www.chtelibrary.org.in

and fatty degeneration in cortical layers. Buscaino[36] reported so-called grapelike formations in the brains of schizophrenics. Other authors could not confirm these findings, which were considered artifacts. Klippel and Lhermitte[193] described areas of focal demyelination (later denied by Adolf Meyer and by Wolf and Cowen[174]). Bruetsch[31] found rheumatic foci in brains of schizophrenics. He feels that the incidence of these foci was greater than in the general population and that rheumatic fever must have played an important etiologic role. (Lidz[112] denies the importance of this role.)

In an effort to overcome the technical defects that many authors criticize in the neuropathological studies of schizophrenia, C. and O. Vogt have adopted a refined technique, which consists of a serial study of the cerebral hemispheres in slices eight microns thick. Quantitative computations of the alterations are made and control studies in normal people of the same age are carried out. The Vogts[165] have concluded that they have been able to find anatomical alterations in all cases of schizophrenia that they have studied. The localization, intensity, and histologic aspect of the lesions were found to vary considerably. The most important features were:

1. So-called wasting cells (*Schwundzelle* in German, *cellule fondante* in French). In these cells there is a progressive disintegration and disappearance of the tigroid substance, increase in fat content, and decrease in volume. The nucleus becomes pale at first and then disappears (karyolysis).

2. Alveolar degeneration. The cells lose the Nissl substance and undergo vacuolization of the cytoplasm.

3. Liposclerosis. The cells are shrunken and presumably filled with fat.

Other alterations (such as cell shrinkage, balloon cells, and senile alterations) seem to play a less important role. This impressive work has not yet been completed. All the alterations described by the Vogts are found to some degree in many pathological conditions and even in the so-called normal. The only finding that would be significant would be a quantitative difference from normal. But again even then, there would remain the problem of whether the quantitative change is part of the basic schizophrenic process or the outcome of the abnormal schizophrenic way of living, especially in patients who have been sick for a long time.

Several researchers have studied biopsy material, in an attempt to avoid the artifacts liable to be found in post-mortem specimens. Papez[135] and his associates reported inclusion bodies, presumably microorganisms, like zoospores. The significance of these findings was disputed by Wolf and Cowen and by Alfred Meyer.[127]

Roizin[146] made morphological and biochemical studies of biopsy specimens from twenty-four patients who had undergone topectomy, and electric shock (or insulin coma, or both) prior to psychosurgery. He found several alterations in the medium and large sized pyramidal neurons. He also found changes in the activity of indophenol-oxidase, cytochrome (oxidase) peroxidases, and acid phosphatases.* Roizin's work is an excellent piece of research but, as the author himself admits, inconclusive, because the findings might have been the results of the therapies to which the patients were subjected. (See Chap. 82.)

Dunlap,[52] Spiehmeyer,[157] Wolf and Cowen,[174] Alfred Meyer,[127] and Ferraro,[59] among many distinguished researchers, reached negative conclusions about these neuropathological findings, minimizing their importance on various grounds: these changes are not specific, are of mild intensity, and may be found also in control brains of normal persons; they may be the result of age, malnutrition, concomitant disease, or abnormal way of living of the patient.

Other authors feel that the relatively primitive techniques of traditional neuropathology have led to the negative findings and look forward with great anticipation to the results of new techniques, such as electronic microscopy, tissue culture and microchemistry.

## *Experimental Reproduction of the Psychosis*

Many investigators have administered to humans and to animals pharmaceutical agents

* See Chap. 82: Fig. 6, p. 1660; Fig. 7, p. 1661; Fig. 8, p. 1662.

Downloaded from www.dbraunton.org.in

which seem to engender syndromes identical with, or similar to, schizophrenia.

In Chapter 84, the effects of two drugs—mescaline and lysergic acid—which are frequently used for this purpose, will be illustrated in detail. Here we shall mention briefly the other drug which, until a few years ago, stimulated much research, namely, bulbocapnine.

Bulbocapnine is one of several alkaloids obtained from the plant *Corydalis cava*. Its chemical formula and its structural formula are related to that of apomorphine. Many authors—beginning with Mode in 1892[131]—have reported paralysis, catalepsy, and apparently "catatonic symptoms" in animals which had been intoxicated with this drug.

In 1921 DeJong[49, 50] started a series of investigations, later continued with the collaboration of Baruk. These authors found that moderate doses of bulbocapnine were producing absolute catalepsy in the experimental animal. The animal became immobile, with a complete loss of motor initiative. If the experimenter imposed certain attitudes upon the limbs of the animal, the animal would retain such attitudes, exhibiting something similar to the waxy flexibility of the catatonic.

DeJong and his co-workers were impressed with the similarity with the catatonic picture to such a point that they considered this intoxication an "experimental catatonia" and attributed it to the action of the bulbocapnine on the neocortex.

Ferraro and Barrera,[60] in an interesting monograph in which they described bulbocapnine intoxication in cats and monkeys, failed to see any psychic component in the production of the phenomenon. They found these symptoms—namely, loss of motor initiative, maintenance of passively impressed postures, maintenance of posture against gravity, resistance to passive movements, and variations of muscular tonus in various degrees—irrespective of the surgical removal of various portions of the central or peripheral nervous systems. The symptoms occurred even when the cerebral cortex had been removed.

The authors concluded that bulbocapnine intoxication reproduces only one important component of human catatonia—that is, the motor component, or catalepsy—but catalepsy alone does not constitute catatonia.

## *General Conclusions about Somatic Research on Schizophrenia*

1. Although Kraepelin himself thought that dementia praecox was due to a metabolic disorder, no consistent findings to corroborate this assertion have so far been obtained.

2. Findings such as those by Heath, Altshule, and others are too recent and are still in need of confirmation from other authors.

3. A great deal of cautiousness must be exercised by all researchers in evaluating their findings lest some of the results or outcomes of the schizophrenic process are mistaken for causes or pathogenetic agents. In the opinion of the present writer, no one has clarified this point better than Horwitt.[88] In his article, "Fact and Artifact in the Biology of Schizophrenia," he writes:

> We are now entering a period of renewed interest in biological research on schizophrenia. Nothing can be more harmful to this rejuvenation of the investigation of the biology of mental health than the publication of reports based on techniques of patient selection which do not meet the minimum standards accepted by other disciplines. The manner in which the patient chooses to manifest his difficulties may not be a function of his physiological status.
>
> Symptoms that are usually considered artifacts in other studies are often erroneously accepted as biological aberrations in the evaluation of the schizophrenic patient. Year after year, papers appear which purport to distinguish between the state of schizophrenia and that of normalcy. The sum total of the differences reported would make the schizophrenic patient a sorry physical specimen indeed: his liver, brain, kidney, and circulatory functions are impaired; he is deficient in practically every vitamin; his hormones are out of balance, and his enzymes are askew. Fortunately, many of these claims of metabolic abnormality are forgotten in time with a minimum of polemic, but it seems that each new generation of biologists has to be indoctrinated—or disillusioned—without benefit of the experience of its predecessors.

Downloaded from www.uratuba.org.in

Horwitt gives the following examples of procedural mistakes made in organic studies of schizophrenia: Basal metabolism during emotional stress is not basal at all but may be a reflection of metabolism during intense adrenergic stimulation due to the stress itself. Comparing data from blood samples of schizophrenics and normal people is like comparing samples from soldiers on the battlefields and people in a relaxed, basal condition. He also stresses that the vagaries of psychotic behavior are such as to affect food intake. In many cases this abnormal food intake is responsible for nutritional disorders and metabolic changes. He writes, "Having studied such changes in mental patients for more than fifteen years, I am at a loss to understand how some studies of urinary excretion or of blood constituents can be performed without recourse to nutritional controls." In the same article he gives many more illustrations, which cannot be reported here, of mistakes commonly made in biological studies of schizophrenia.

## ¶ Psychosomatic Studies

The physical changes that may be found in schizophrenics, particularly those who have been sick for a long time, are many, but research reveals that these changes are not constant and that no primary pathogenetic role can be attributed to them.

In an article published in 1945, the writer hinted at the possibility of a psychosomatic involvement in schizophrenia, and subsequent studies reinforced this point of view.[4, 6, 7, 10] These studies involve the central nervous system and the soma.

The psychosomatic approach to schizophrenia is based on the premise that the psychodynamic factors which lead to the psychosis may have a disintegrating effect on the functions of the central nervous system, where they must be mediated. The central nervous system is to a large extent the creator, or at least the interpreter, of psychogenic stimuli, and this theory assumes that the central nervous system may be disturbed by what the central nervous system itself interprets or creates. This seems to the writer the real psychosomatic interplay, much more so than that intervening between the central nervous system and other organs.

Carl Jung[91] was the first to advocate the hypothesis of the psychosomatic involvement of the central nervous system in schizophrenia (1903), when he thought that perhaps the emotional difficulties which lead to the psychosis may produce toxins which damage the brain.

Ferraro[59] too feels that the histologic changes found in some cases of schizophrenia may be the expression of a psychosomatic mechanism. But these changes are very inconsistent, as we have seen.

Although the present writer does not deny that the disorder is ultimately mediated by biochemical and electrical changes, he believes that under emotional stress, which in the schizophrenic is not adequately coped with by other defenses, functional disintegrations of neuronal patterns, or a disharmony of microscopic spatiotemporal patterns of activity in the neuronal network, or, more simply, an alteration of the normal functional relations between nerve cells, take place. In other words, a neurophysiologic dissolution of activity would take place mainly at the level of high cortical organization and not through the mediation of the autonomic nervous system, as is generally the case with other areas of psychosomatic medicine. This point of view does not exclude, of course, a subsequent but important involvement of the autonomic nervous system.

The symbolic nature of schizophrenic symptoms, at least at the beginning of the illness, seems to indicate that the disintegration or dysfunction has to be connected with the cerebral cortex, but not with those parts of the cortex that mediate motor, sensory, language, functions (because we know that such functions are not impaired in schizophrenia).

If we exclude these areas, only three cortical areas are left to be considered:

The first is an ill-defined area, including a large part of the temporal lobe (Brodmann's areas 20, 21, and 37) and small parts of the occipital and parietal lobes (parts of Brod-

Downloaded from www.dbraulibrary.org.in

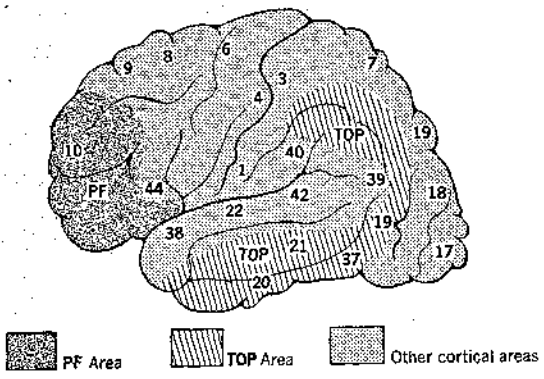

FIG. 1

mann's areas 7, 19, 39, and 40) (see Figure 1). I have designated this the TOP area, from the initials of the words temporal, occipital, and parietal. As I have reported elsewhere[6] this area may be considered the fourth or highest of four levels of the great posterior area of the brain, which consists of the parietal, occipital, and most of the temporal lobes. In this great posterior area, stimuli are received from the external world and progressively transformed in higher mental constructs. Presumably, the fourth level or TOP area, which is the last to appear in phylogeny and to myelinize in ontogeny,[62] is needed, in addition to the other lower levels, for the mediation of abstract thinking and for the high symbolism of interpersonal relations.

It is possible to assume that under the stress of the preschizophrenic anxiety one of two things, or both, may occur:

1. If the phenomenon is interpreted deterministically, the overpowering anxiety may be seen as impairing the intricate and delicate functional neuronal network, which mediates these functions (some kind of mechanical autoimpairment, although functional);

2. Teleologically, the organism in its adaptational strivings avoids the functions which elicit overwhelming anxiety. But these are the functions which require long circuits with participation of the large number of neurons which are in the TOP area.

These two mechanisms may be reconciled, as cybernetics attempts to do. The effect of these mechanisms may be seen as a psychosomatic return to a lower level of integration. Psychodynamically, we may consider this level one which does not permit long-circuited anxiety or difficult interpersonal relations, a level which corresponds to one at which long childhood dependency on others is not needed. Neurophysiologically, the process may be seen as a process of *dysencephalization*. Neurophysiologists give the name encephalization to the process by which functions that in lower species are mediated by lower or more caudal centers shift toward higher centers. Dysencephalization may be seen as the opposite process, which may occur in schizophrenia in a functional way. There is not only a return of the functions of the released lower centers but also a tendency for the functions of the higher centers to be mediated by the lower centers. We have seen, for instance, how anxiety-loaded concepts are reduced to perceptions and to hallucinations. In other words, especially at the beginning of the illness, we have predominantly not a loss of the abstract, but a transformation of the abstract into the perceptual and concrete. This mechanism may be seen as mediated neurophysiologically by a process of functional dysencephalization.

The other great area primarily involved in the symptomatology of schizophrenia is the prefrontal area (PF in Figure 1).

The prefrontal areas permit planned thinking in a sequence of logical processes, make possible anticipation of the distant future, maintain a steadfastness of purpose against distracting impulses from the environment,[119] and enable the focusing of attention, thus permitting elaboration of data obtained from the posterior brain. They also preside over the making of choices and the translating of ideas into actions. These are the functions which are capable of evoking the greatest amount of anxiety. Greenblatt and Solomon[77] also feel that the circuits occurring in the frontal lobes sustain the emotional tension in psychotic individuals. As was said about the TOP area, complex functional prefrontal neuronal patterns may be disturbed by the anxiety they themselves produce; consequently, they may be avoided or impaired, and neuronal patterns of lower orders substituted for them. The archipallium (plus a subcortical structure, the hypothalamus) is a third area, which plays an important role in schizophrenia. A state of

Downloaded from www.thealibrary.org

severe hypofunction of the neocortex (that is, of the PF and TOP areas) may have important repercussions upon the archipallium, in that it may disturb the balance between the neopallium and archipallium.

Some experimental studies on cats[12] have demonstrated that the removal of the neocortex releases the inhibitory functions of the rhinencephalon over the hypothalamus. If the same things apply to human beings, we may conclude that a severe hypofunction of the neocortex (no matter whether organic or functional, provided it is very extensive) releases the archipallium, and consequently the functions of the hypothalamus are inhibited. But a release of the archipallium and inhibition of hypothalamus may engender other abnormal reverberating mechanisms, involving the thalamus and especially the visceral brain. These mechanisms may fail to feed back adequately the neocortex. A pathological vicious circle is thus produced, which started with a psychogenic dysfunction of the neocortex (Figure 2).

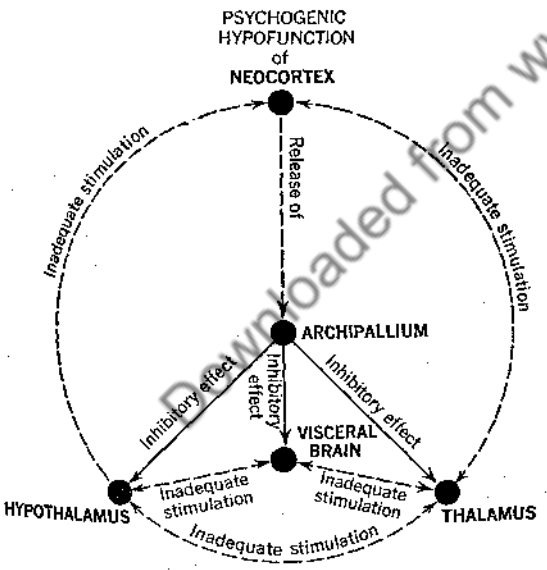

FIG. 2

From this point of view, it is possible to explain many of the somatics and biochemical alterations found in schizophrenia. These alterations would all be consequences of the functional alterations of the hypothalamus and of the encephalic vegetative centers which, in their turn, would be an indirect consequence of a primary dysfunction of the neocortex. But, in its turn, the neocortex is adversely affected by the dysfunction of these other structures.

In addition to these functional neural mechanisms, which are the most important, another simpler mechanism may have some effect on the somatic changes of the schizophrenic. The changed way of living of the schizophrenic, which forces withdrawal from stimulation and marked hypoactivity, may explain some of the alterations observed in the endocrine and vascular apparatuses.[4, 88]

## Psychotherapy

### *Choice of Treatment*

The methods of treatment for schizophrenic patients may be divided roughly into two categories: physical therapies and psychotherapies.

The physical therapies will be described in detail in other chapters (insulin shock therapy in Chapter 74, convulsive shock treatment in Chapter 75, psychosurgery in Chapter 76, drug therapy in Chapter 77, and miscellaneous other therapies in Chapter 78). This chapter is limited to a description of the basic principles of psychotherapy.

One finds, first of all, marked disagreements as to treatment of choice. My own marked preference, in the average case, is psychotherapy, although many authors and practitioners do not share this point of view.

My "bias" is based on the belief that physical therapies, as far as we know or can infer, produce only a symptomatic improvement, whereas psychotherapy tends to: (1) remove the basic conflicts which led to the disorder, (2) correct the psychopathologic patterns, and (3) permit the regenerative psychological powers of the organism to regain the lost ground. These assertions, however, should not be interpreted as a condemnation of physical therapies. On the contrary, I have found physical therapies, with the exception of psychosurgery, useful, at times, in a variety of situations:

1. When psychotherapy for psychotic pa-

Downloaded from www.brainlibrary.org.in

tients is not available (and, unfortunately, it is not available to by far the majority of patients), physical therapies should be administered.

2. Psychotherapy is not effective in every case. Although in the last few years we have made great progress in this field, our technique is still not completely satisfactory. We often encounter patients (fortunately, in decreasing number) who do not improve and a few who are actually made worse by any psychotherapeutic attempt. We are forced to the conclusion that, in these cases, every interpersonal relation, even that with the experienced therapist, increases the anxiety of the patient to such a point as to enhance his psychological disintegration. Perhaps, with the refinement of technique, such cases will eventually be extremely rare; but, for the time being, if more than two therapists have been unsuccessful, and the condition is worsening (especially in cases of rapid disintegration or those in which no contact at all is made), an attempt should be made to arrest the process, at least in a symptomatic way.

3. Finally, shock and drug therapies must be used in cases which are urgent because of a concurrent physical illness. Here quick results must be obtained before they could be achieved with the long psychotherapeutic procedure.

Even when shock or drug therapy is used with apparently successful results, psychotherapy is important in order to prevent relapses. Contrary to what some psychotherapists believe, I have found that the majority of patients who have undergone shock or drug therapy are still accessible to psychotherapy.

An increasing number of patients today are being treated with a combination of drug therapy and psychotherapy. The drug therapy decreases the anxiety and makes them more accessible to (or less fearful of) the interpersonal contact. In my experience, this combination does not shorten the treatment but does have the advantage of making hospitalization unnecessary for many patients. In many cases a full-fledged schizophrenic is transformed into an ambulatory schizophrenic. This transformation is not to be disregarded, as many patients are in this way able to work while undergoing effective treatment.

## *Historical Review of the Development of Psychotherapy of Schizophrenia*

Freud's concept that the libido of the schizophrenic is withdrawn from external objects, making it impossible to establish transference, for many years discouraged therapists from attempting to treat patients suffering from this disorder. Actually, psychoanalysis opened the road to the psychotherapy of schizophrenia after some modifications of the classic method were made.

Paul Federn, one of Freud's first pupils, pioneered in this field.[55] He is also known for two major theoretical concepts which underlie his therapeutic applications: (1) the concept of ego-feeling—that is, the ego is normally endowed with a certain quantity of libido, which does not come from other sources, but is autonomous; (2) the concept of ego boundaries. These boundaries are seen as defective in the schizophrenic, so that material from the external world and from the id becomes mixed with the ego. The most important goal of therapy is to establish normal boundaries. Reversing a famous sentence of Freud, Federn said that, as a result of therapy in the schizophrenic, "There where id was, ego must be."

Federn stressed the fact that it is possible to establish transference with the part of the patient which has remained healthy, and strongly suggested that the therapist have a helper to be with the patient in the intervals between sessions. Fundamentally, in Federn's method, the patient is guided to understand that a part of his ego is sick and that that part is not trustworthy.

Gertrude Schwing,[151] a nurse who was analyzed by Federn, applied her analyst's concepts to hospitalized patients. In a straightforward and honest but not fully convincing little book, *A Way to the Soul of the Mentally Ill*, she describes the schizophrenic as a person who has been deprived of the experience of having a real mother, a person who loves her child at any cost. The psychiatric

Downloaded from www.adpsychology.org.in

nurse must offer that love to the patient. She describes several techniques which establish continuity of contact with the patient and stresses the point that the patient must have the feeling that this new mother is there and does not intend to abandon him. Schwing considers her treatment a preliminary one, to be followed by Federn's method.

Hinsie[58] is one of the American pioneers in the psychotherapy of schizophrenia. As early as 1930 he published a book devoted to this topic. He studied patients in the adolescent period, who voluntarily sought treatment, had insight into the fact that they were sick, and were communicative and willing to follow the directions of the therapist. Thus, Hinsie selected the easiest patients to treat. He relied predominantly on the clinical psychoanalytic method of "free association."

The method instituted by John Rosen was called, at the suggestion of Federn,[57] "direct therapy."[148] (Direct, because the therapist aims at a direct communication with the unconscious of the patient). Others—Ellenberger, for instance—have called it "the psychological shock method," because of its apparent lack of cautiousness and softness.

Rosen too believes that the schizophrenic is the victim of a mother who was suffering from a perversion of maternal love, and tries to offer to the patient what he did not have. The patient must experience in the therapist a powerful, protective, benevolent person, as he wished his mother would have been in his early childhood. The therapist at times assumes the role of the persecutor and tries to convince the patient that he will have a beneficial rather than persecuting effect. The analyst must spend a long time with the patient—up to sixteen hours a day—and, like Federn, must often resort to an assistant. The patient is showered or shocked with interpretations which follow the language of the unconscious and explain the classic Freudian mechanisms. Such overwhelming, all-embracing treatment will often solve the acute episode in a few weeks and must be continued by the second stage of treatment which follows a technique more similar to classic psychoanalysis. During the treatment the analyst enters the psychotic world of the patient, who immediately feels better because he is finally understood. The therapist should not even avoid becoming one of the imaginary persons who appear in the delusions.

Rosen believes that there are not several mental diseases, but only one mental disease, characterized by hebephrenic, catatonic, paranoid, manic-depressive, obsessive, hypochondriac, and psychosomatic stages. Patients who recover go through these different stages.

Rosen's method has been the object of much criticism. Even his admirers point out the fragility of his theoretical framework and attribute his therapeutic successes to his personal qualities: lack of hostility, perseverance, physical endurance, etc. Others feel that the interpretations he gives the patients are arbitrary, not even necessary, and that his success is due simply to the fact that he is able in some way to establish contact with the patient. Others (Horwitz, *et al.*[89]) doubt even his results. They state that his claims of many recoveries were exaggerated; that some of his patients were misdiagnosed; that others who were undoubtedly schizophrenic had relapses and were later treated with physical therapies.

I, too, feel that Rosen's early assertions, like those of any pioneer, seem to suffer from enthusiasm. Also some of the theoretical bases of his technique seem unsubstantiated. Nevertheless, it is beyond question that Rosen obtained at least temporary results and that he was able to inject enthusiasm into many workers at a time when the prevalent opinion was that psychotherapy with schizophrenics was an impossibility.

In contrast to the dramatic, shocking, and perhaps not too consistent aspect of Rosen's method is the calm and steady flavor of Frieda Fromm-Reichmann's technique.[69, 70, 71, 72, 73, 74]

Fromm-Reichmann derived her technique from the theoretical premises of Freud and from the modifications which Sullivan made on those premises. She called her technique "psychoanalytically oriented therapy," not psychoanalytic therapy, to indicate that some modification from the traditional psychoanalytic method had been made.

Fromm-Reichmann thought that only quan-

Downloaded from www.dbraulibrary.org.in

titative differences exist between normal, neurotic, and schizophrenic patients.

The schizophrenic is not happy with his withdrawal, as some psychiatrists used to believe, and he is ready to resume interpersonal relations, provided he finds a person he trusts, a person who is capable of removing that suspiciousness and distrust which originated with the first interpersonal relations.

In order to establish the atmosphere of trust, the patient must be treated with kindness, understanding, and consideration, but not with smothering attitudes or as a baby. There is a part of the patient which has retained an adult state and which would resent being treated in a babyish way. Profusion of love or of exaggerated friendship are also out of place. They would be considered bribery and exploitation of dependency attitudes.

Fromm-Reichmann relies much less than Rosen on the therapeutic effect of interpretations. She makes use of them, however, and emphasizes that the symptomatology is susceptible of many interpretations, all correct, and that at times it is useful to give even partial interpretations. As a rule, her interpretations resort much less than those of other authors to symbolism of repressed sexuality. Fromm-Reichmann emphasized the role that fear of closeness plays in the patient's attitude. At times the warmth of the therapist may actually frighten the suspicious patient and precipitate a relapse.

But, according to Fromm-Reichmann, even more important than his fear of closeness is the patient's hostility. Because he overrates his negative destructive qualities, he must be reassured by the therapist and shown how to handle this potential anger.

Fromm-Reichmann stresses the importance of the countertransference which, according to her, is of crucial importance in the treatment of schizophrenics. Often, she states, the difficulty in communication or in the handling of the situation originates from the therapist's problems. The anxiety of the therapist is the greatest handicap and may jeopardize the whole treatment. Mild degrees of anxiety, however, may be an asset in helping the therapist to recognize which problems of the patient arouse his own anxiety.

These brief notes cannot give an adequate account of the details of Fromm-Reichmann's technique. They are completely inadequate also in describing those qualities of Frieda Fromm-Reichmann herself—her courage, her warmth, her humility, her unassuming genuineness—which undoubtedly played an important role in her therapeutic successes—qualities which to a certain extent she was able to infuse in all those who learned from her.

Sechehaye developed the new method of "symbolic realization" in connection with the successful treatment of her patient Renée. Sechehaye has devoted three books to this treatment, which remain perhaps the best-documented study of a single patient.[152,153,154]

Sechehaye accepts many of the traditional psychoanalytic and existentialistic methods of psychotherapy, and to them she adds her own method, which consists of helping to overcome the initial trauma by presenting the patient with a level of interpersonal relations which is corrected and adjusted by the therapist to the weak state of the psychotic ego. Like Rosen, Sechehaye enters the psychotic world of the patient, accepts his symbolism, and attempts "to realize" (that is, to materialize) at a symbolic level the patient's fundamental needs which, through their frustration, led to the psychotic conflict.

Eissler[53] has stressed the importance of early psychotherapy during the acute episode. The way in which the case is handled at the beginning, he claims, often determines the whole course of the illness. He distinguishes the acute phase from "the phase of relative clinical muteness."

Wexler[171] reported the successful treatment of a patient whom he treated by assuming the role of a tyrannical super-ego.

Bychowski has provided, in addition to important studies on schizophrenic thinking, important details on the manifestations, dynamics, and therapeutic handling of hostility.[37,38]

Hill, again, emphasized the crucial role of the mother in the development of schizophrenia and gave details of technique in handling patients.[84]

Bowers[30] applied hypnosis to the treatment of schizophrenia, although the general opinion

Downloaded from www.cbpahilibrary.org.in

is that such treatment is not suitable for psychotics. She hypothesizes that, in hypnosis, the therapist rapidly establishes contact "with the repressed, healthy core of the patient." She points out that the problems of resolution of the symbolic relationship require the utmost skill, but long remissions have been secured. A successfully hypnotized schizophrenic is moving toward recovery, as he is able to reincorporate the other, the therapist, and thus re-establish interpersonal relations.

Benedetti,[17,18] an Italian psychiatrist who studied with Rosen and now teaches and practices in Switzerland, accepts a great deal of Sullivan and Fromm-Reichmann, as well as some existentialistic concepts. He feels that the two basic tools in the treatment of schizophrenics are sharing of the feeling of the patient and interpretation.

## *Psychotherapy in Practice*

In this section a few more details will be given about psychotherapy of schizophrenics, as practiced by the author of this chapter. This technique is the result of the study of the contributions made by all the authors mentioned in the previous section, as well as of my personal experiences.

### General Attitude and Feelings of Patient and Therapist

More important than the technique of a therapeutic session is the establishment of a general attitude, an emotional tone and interchange of feelings between patient and therapist (transference and countertransference). These are intangible and indefinite entities, and therefore difficult to describe and almost impossible to prescribe. It will be sufficient if the reader gets the general flavor of this relationship; more specific technical problems will be discussed later.

When the patient comes for therapy, he feels unaccepted and unacceptable, suspicious, and distrustful of any interpersonal contact to the point of being delusional. His contacts with the therapist must make him feel that he is no longer alone in the world, that he is accepted as a human being, and that this acceptance will not be at the price of his remaining immature or dependent or overcompliant or driven to do things he cannot do, or inhibited sexually or otherwise.

According to Sullivan,[161] therapy must offer the patients a "relationship of security beyond what they have ever had." According to Fromm-Reichmann,[71] therapy must offer a "specific way by which they can trust the world and themselves." Using a terminology applied by Buber[33] and Erickson[55] in a different context, I feel that a relationship of *basic trust* must be established between the therapist and the patient.

It is futile to pretend offering to the patient the love he wants in order to compensate for what he did not have early in life; the therapist cannot love all of his patients, as only mothers can do, but he can offer trust. Basic trust is an attitude or atmosphere of hopeful expectancy. The patient relies on the therapist and feels that the therapist relies on him and that, if anxiety and mistrust disappear, the basic potentialities of the patient as a human being will develop and reach realization.

It is obvious from the foregoing that the countertransference is the most vital tool in the treatment of psychotics, and a necessity for the establishment of basic trust. The therapist likes the patient, and since he cannot like all of them, he must limit the treatment to those for whom he has positive feelings, and in whom perhaps he sees an exaggeration of his own unsolved conflicts.

Although some therapists, such as Wexler,[171] establish this atmosphere of basic trust by assuming a strict, reserved attitude, the majority tend to assume the benevolent, warm attitude of the loving mother. It does not really matter what specific type of attitude the therapist holds—what matters is that it must be consonant with the personality of the therapist and capable of conveying the feeling of basic trust.

Most therapists maintain an attitude of acceptance, warmth, kindness, and consideration. The expression, the gesture, the voice of the therapist should convey these feelings. In some cases the therapist must be somewhat reserved, particularly at the beginning of the treatment, especially with those patients who react with mistrust and fear to manifestations of warmth.

Downloaded from www.ohiolink.edu

No matter whether the therapist is overtly warm or reserved, however, he must be convincing, consistent, intensely involved, and, as Betz says,[19] able to communicate to the patient his strength, his fairness, and his kindness.

Of course this general attitude should not degenerate into a smothering oversolicitousness which the patient will perceive as a reproduction of the maternal anxiety which prevented psychological growth and enhanced dependency habits.

The handling of the hostility of the patient is difficult in some cases, as the closeness with the therapist may elicit such hostility. The patient fears that rejection inevitably will follow so much closeness and will consequently be more painful. Thus, he wants to be the one who rejects and hurts first. Whenever possible, the therapist must explain these vague feelings to the patient. At other times he must explain how the hostility is misdirected, not really directed to the therapist but to what he represents. If the hostility persists or cannot be handled in this way, the presence of an attendant or nurse may help psychologically to restrain the patient. If the therapist is afraid of the patient, and unable to solve the fear, he should not treat the patient. If the patient feels that even the therapist is afraid of him, he will become more resentful, distrustful of himself and of the therapist, and consequently more hostile.

Symbiotic tendencies, that is, complete dependency on the therapist for any kind of initiative, are very common during therapy. These tendencies may be useful only at the very beginning of the treatment, when every means must be used to make contact with the patient, but will be harmful later if not checked. The patient must recognize that the therapeutic situation is not a symbiotic bond, similar to the old one with his parents, but a new type of relationship which permits growth, without being accompanied by guilt and stultifying dependency. Related, but not identical, to the symbiotic tendencies is another important tendency which occurs at a later stage of treatment, in a much more pronounced form than in the neurotic: a gradual entrance of the therapist into the self of the patient. The social self craves to be rebuilt, not by the old significant adults, but with the help of the new meaningful other or *Thou*: the therapist.

What some authors call incorporative processes or identification with the therapist occur to a very pronounced degree. Although this is a necessary and useful event at a certain stage of therapy, it nevertheless must be fought gradually and from its very beginning in order to combat excessive imitative habits.

### THE TECHNIQUE OF THE SESSION

The couch should not be used, as the patient is very much in need of closeness even in a physical sense. The best method in my experience is that of sitting next to the patient. If the patient refuses to look at the therapist, he should not be forced to do so. If he prefers to look in an opposite direction or to walk around the room, he should be allowed to do so. These attitudes should not be interpreted as rejection of the treatment on the part of the patient but as ways to decrease the intense anxiety caused by the interpersonal relation.

Sessions should be numerous, in some cases one a day at the beginning of the treatment, especially if the episode is acute. Later, they may be reduced to an average of three a week. If the patient is in a hospital he should be visited by the therapist in the interval between sessions. If the patient is ambulatory, the therapist should insist that the patient come punctually. No time should be made up if the patient is late. Although the therapist must be permissive in many ways, he must be strict on the question of punctuality. The young therapist will soon realize how common it is for ambulatory schizophrenics to come just ten minutes before the end of the hour, or at a different time entirely. They test the analyst, in a certain way, to see whether he would allow this lack of discipline to continue. The patient wants limitations to be imposed on him, in an attempt to reorganize his confused life, and the insistence that he come on time is important. Since, however, many of these ambulatory schizophrenics have an inversion of diurnal-nocturnal rhythm of activity—that is, they stay up until late at night and sleep during the morning hours—it is better to help them by

Downloaded from www.freepsybooks.com

assigning them afternoon hours. This holds true, also, for hospitalized patients in acute stages.

The length of the session has to be regulated to the individual patient. As a rule, I find that the best length is a little shorter than that of the psychoanalytic session with neurotic or normal people. Generally, 40 to 45 minutes is as much as the patient can stand during the initial stage of treatment. Later, however, the session may be lengthened.

The technique of the session varies of course according to the stage and condition of the patient. If the patient is in an acute condition, frightened, and wanting to tell his troubles, the therapist must listen patiently and reassure him warmly. But if the patient does not desire to talk about himself or anything else, he should not be asked questions. Each question is experienced by the schizophrenic as an imposition, or an intrusion into his private life, and will increase his anxiety, his hostility, and his desire to desocialize. The request for information is not seldom interpreted by the patient as "an attempt to take away something from him." Even the therapist seems to him "to take away," not to give. And yet we must convince him of our desire to give to him because he is so much in need.

This technique of not asking questions is a difficult one, especially for a therapist who has been trained in a hospital where patients must be legally committed. The administration of the hospital requires that information be collected directly from the patient which will show that the patient is psychotic and legally detained. The administration also requires a complete physical examination to exclude infective or other acute conditions. Of course, these procedures are necessary, but I feel that the therapist should not carry them out. Perhaps another physician could take care of these physical and legal requirements before the patient is assigned to a therapist. Although there may be some disadvantages to this procedure and some physicians might resent this division of jobs, this is, as a rule, the best way to avoid the negative feelings that the patient would immediately develop for the therapist. Whenever it is possible, the contemporary treatment of a nonpsychotic member of the family (sibling or parent) can lead to a fuller understanding of the family constellation.

If the therapist is not supposed to ask questions of a reluctant patient, what is he to do? Again, various techniques are indicated according to the various cases:

1. It may be advisable for the therapist to take the initiative and talk about neutral subjects, conveying to the patient the feeling that a sincere effort is made to reach him, without any strings being attached to this effort.

2. If the patient is a mute, or almost mute, catatonic, the therapist must talk to him, expressing sympathy and a desire to break the incommunicability. He must tell the patient that he (the therapist) realizes how frightened the patient is, so frightened that he cannot talk. The therapist knows, however, that he feels and understands. At times, however, it is better not to talk at all to the catatonic if he seems to resent talking and withdraws more. The therapist must then "share" a state of silence without being disturbed by it. Even a simple state of proximity without any talk may disclose to the sensitive therapist almost imperceptible ways of nonverbal communication which are specific for each patient and therefore impossible to report.

3. If the patient is very disturbed, or incoherent, and his speech consists of word-salad, the therapist should not pretend to understand him, when he does not, but listen patiently. Soon it will be realized that the word-salad too makes some sense. Some themes recur frequently, and the atmospheric quality of the patient's preoccupations is transmitted.

4. At a more advanced stage of treatment, the patient will be able to talk more freely about himself and about his life. The gaps which still exist either in the knowledge of his life history or in the understanding of his production are often filled in easily by the therapist's knowledge of the psychodynamics of schizophrenia and of its formal mechanisms. The therapist must, however, always be alert to the possibility of uncommon and unpredictable dynamic and formal mechanisms.

5. If the patient is a verbose, apparently well-systematized paranoid, who fanatically

Downloaded from www.bharatiyapsychology.org.in

speaks about his delusions, an attempt must be made to detour his attention and re-establish his interest in the other aspects of life.

When the patient speaks to the therapist about his own delusions and hallucinations, the latter must not pretend that he accepts them but must explain to the patient that there must be reasons why he sees or hears or interprets things in a different way (Fromm-Reichmann[72]).

Interpretations are not very important, especially at the beginning of the treatment, although they may be beneficial later on.

If the anxiety is decreased to the point that acceptance of the psychotic world is no longer immediate or automatic, it is possible to explain to the patient how he concretizes and symbolizes. A patient of mine could recognize that the olfactory delusions about a bad odor emanating from his body were only concrete representations of what he thought about himself.

Patients who have been made less anxious by the new interpersonal relationship with the therapist are also able to understand and correct their auditory hallucinations. They are able to recognize that the anxiety state makes them anticipate the occurrence of certain things and situations they fear, for instance, that people are talking about them. But, almost simultaneous with that anticipation is the hallucination itself—they hear people talking about them. In the process of treatment they learn to recognize these stages and to catch themselves at the stage of the listening attitude, before it transforms into a definite hallucination.

Goldstein feels that the patient must be exposed to a concrete atmosphere and spoken to in concrete terms, in order to find himself in a comfortable environment where anxiety is decreased (Chapter 65). I have found this to be true to a certain extent, especially at the beginning of treatment, and with patients who show chronic forms of schizophrenia. In my opinion, however, the treatment does not consist only of presenting to the patient a concrete world: he cannot be treated as a defective person who has to learn to live with limited horizons. When his anxiety is decreased, the patient learns that he himself concretizes and he will recognize many of his delusions as actual active processes of concretization.

I found it thus possible and beneficial to explain to some paranoids, in language which they could understand, that the feeling of persecution was a re-externalization and concretization of the hostile feeling they experienced in early childhood. I was also able to explain in many cases how the feeling of having thoughts controlled by an external force was a reactivation or a concrete representation of the childhood feeling that thoughts were being crushed or controlled by those of the surrounding adults.

Quite often, when the patient is still confused, the therapist, who by now has learned much about the patient's life, may be able to summarize and simplify the understanding of his life situation without necessarily resorting to a concrete level of communication. This simplification will permit the patient to remain within a logical and realistic framework without the necessity of deviating toward the paleologic and delusional.

Another recommendation concerns the vacation time of the therapist. The patient must be prepared long in advance for it, especially if the treatment is still at the initial stage.

### General Participation in Patient's Life and Assignment of Tasks

**Use of a Therapeutic Assistant.** The treatment of schizophrenics must consist not only of the sessions but also of a general participation in the patient's life. The patient must feel that the therapist, like a deeply and warmly involved parent, shares many events of his life. This does not mean, of course, taking the initiative, which should be left to the patient whenever possible. The patient wants tasks to be given to him and demands to be made on him, contrary to the way he felt at the beginning of the treatment.

Now that he trusts the therapist and himself, he will consider himself trustworthy of the tasks the therapist assigns to him, and this will increase his self-esteem. Of course, the assignments must not be out of proportion to the capacity of the patient. Many schizophrenics disclose artistic inclinations. At this stage, it may be worth while to encourage them.

Downloaded from www.kabarulibrary.org.in

Some of my patients during treatment started to study painting, music, and dancing with considerable success.

Even one patient requires much attention, so much, in fact, that in difficult cases it is impossible for the therapist alone to treat the patient. In several instances it is good practice to resort to a *therapeutic assistant* who will stay with the patient between sessions. The therapeutic assistant should not only create a warm general atmosphere of acceptance but also help the patient to share feelings and do things together with another person. The therapeutic assistant should always be there, near the patient, as a person on whom the patient may depend whenever it is necessary. Federn at times used a relative as a therapeutic assistant. In my opinion, a relative, especially a close relative, such as parent or spouse, is too involved in the emotional problems of the patient to be a good assistant. I have successfully used nurses, social workers, and people in related professions. Before assigning the patient to the therapeutic assistant, the therapist must have had a few contacts with him and be sure that his personality will be acceptable to and accepting of the patient.

## ¶ The Concept of Schizophrenia

Several authors have expressed doubt about the existence of an entity to be called schizophrenia. Szasz, for instance, calls schizophrenia a *panchreston*, a term coined by Hardin[78] to denote dangerous words which are purported to explain everything, but which on the other hand obscure matters.

Szasz adds,[163] "The problem of schizophrenia which many consider to be the core-problem of psychiatry today, may be truly akin to the 'problem of the ether.' To put it simply: there is no such problem."

Szasz's is probably one of the strongest attacks ever made on the Kraepelinian concept of dementia praecox (schizophrenia). Although I admit that in what we call the schizophrenic syndrome there is still much that is indefinite, variable, inconstant, accessory, I feel nevertheless that there is a more or less homogeneous core which makes us recognize the schizophrenic person as such and leads us to some conclusions, some of which have pragmatic value. The fact that the nature of this core has not yet been fully or uncontroversially determined points to the incompleteness of the concept of schizophrenia but does not prove it is a fallacy.

Psychodynamic studies, although useful in understanding the factors that lead to the psychosis, have helped to make the concept of schizophrenia even less distinct, because of the similarities in the dynamics of these cases and those of other conditions. If we should concentrate on dynamics, almost every seriously disturbed person, child or adult, could be called schizophrenic. In that case, Szasz would be right in calling this word a panchreston. But, if we limit the name schizophrenia to those cases in which the psychodynamic conflict assumes the form of a progressive teleologic regression, then a relatively clear delimitation of the syndrome can still be maintained.

A definition I have found useful (but one which is by no means unanimously accepted) is the following:

*Schizophrenia is a specific reaction to an extreme state of anxiety, originated in childhood and reactivated later in life by psychological factors. The specific reaction consists of the preponderant adoption of mental mechanisms which belong to lower levels of integration. Inasmuch as the result is a regression to, but not an integration at, lower levels, a disequilibrium is engendered which causes further regression.*

Even this definition is not complete. For instance, it does not mention the hypothetical psychosomatic mechanisms of the central nervous system which mediate the regression.

Any attempt to define and redefine schizophrenia, and any satisfaction we may receive from theories that seem to fit our present knowledge, should not make us unaware that there is still much to learn about this syndrome, the most important in the field of psychiatry and yet, as it has been said, the Cinderella of the medical field.[48] More research is needed not only on the nature of the disorder and its treatment but also on its prevention. Promising signs are rising, however, for example, the founding of RISE (Research in Schizophrenia

Downloaded from www.arabpsychology.com

Endowment), an organization which has the purpose of focusing attention and helping research on "one of the most prevalent and neglected of all major diseases of our time."[48]

CHAPTER 25

# PARANOID CONDITIONS AND PARANOIA*

Norman Cameron

Downloaded from www.dbraulibrary.org.in

THE CONCEPTS OF PARANOID STATE and paranoia have had a capricious past, and they face a most uncertain future. In the current official classification of psychiatric illnesses they are included as distinct entities, but in actual clinical practice the task of differentiating between them and schizophrenic or manic-depressive psychoses often seems hardly worth the effort. Diagnostic difficulties have, in part, been met by setting up compromise groups, such as depressions with paranoid trends, paranoid reactions with depressive trends, paranoid schizophrenia, paranoid personality, etc. But, although such compromises do make room for many of the nonconformities that living patients always exhibit in relation to arbitrary classifications, they also leave the field in confusion.

Many psychiatrists today cut this Gordian knot by simply abolishing the group of paranoid reactions altogether. They assign most psychotic cases with marked paranoid manifestations to paranoid schizophrenia, and distribute the rest among the manic-depressive psychoses, the involutional reactions, and the sociopathic personality disturbances. This may very well be the future of the diagnostic group. On the other hand, no less a person than Freud has urged that paranoia be kept as a separate clinical type for dynamic reasons, no matter how often it is complicated by schizophrenic factors,[35] and he retained the designation throughout his later publications (for example, Refs. 30, 34, and 36). Most textbooks still include a chapter or a section on paranoid reactions,[39, 47, 66] and articles on paranoid disorders appear every now and then in the current journals. In the present chapter we shall follow Freud's recommendation and the official classification without, however, becoming enmeshed in nosological problems.

Historically, the term "paranoia" must antedate Hippocrates, since it appears as an already familiar word in writings attributed to him. In ancient times it seems to have been used roughly as the equivalent of "insanity" today.

* This chapter was prepared with the help of a grant from the Foundations' Fund in Psychiatry.

The term virtually disappeared from medical literature around the second century A.D., but it reappeared in the eighteenth century as the name for delusional and delirious disorders. In the nineteenth century "paranoia" was used in a variety of senses until Kraepelin, in 1893, made his distinction between paranoia, paraphrenia, and paranoid dementia praecox. He defined paranoia in terms of an insidiously developing, unchangeable delusional system, accompanied by clear and orderly thinking outside of the system, and without hallucinations. This is essentially the definition accepted in psychiatry today.

It was Freud who transformed the problem of paranoia and paranoid delusions from one of description and classification into one of genetic development and personal significance. He formulated a case of paranoid psychosis as a defense psychosis, and from this new standpoint compared it with hysteria and obsessions. The psychotic development he pictured as a gradual weakening in the defenses against self-reproaches, which returned to consciousness, but were now ascribed to other people in the form of delusions. For this process he introduced the term and the concept of "projection" (1896).

Fifteen years later Freud expanded and greatly enriched his original formulation in analyzing the paranoid mechanisms involved in the autobiographical account of psychosis written by a gifted psychotic jurist, Schreber.[74] In this analysis Freud[35] linked denial and projection as defenses against homosexual wishes. These wishes, he pointed out, had emerged when Schreber's sublimated homoerotism became resexualized, during a severe regressive episode. He also gave a new interpretation to delusions which he recognized as reality reconstructions, or restitutions, that is, as attempts at self-cure, as signs of recovery rather than as merely symptoms of disease (see also Freud, Refs. 28, 29, 33, and 36). In later years, after he had established the basic importance of aggressive drives and had evolved the ego-id-super-ego topography, Freud[30] gave much greater prominence to aggression in the genesis and structure of paranoid delusions. He stressed the importance of early sibling rivalry, and he reformulated the conversion of love into hate in terms of a reactive shift in cathexis at a primitive ambivalent level.

These newer leads have been pursued in more than one direction. Knight,[57] for example, focused attention upon hate as the basic problem in paranoid delusional development—hate directed against a father figure or a brother figure. The strong homosexual drive, he said, was an attempt to erotize and neutralize the patient's destructive hostility, which failed because the basic hate was too powerful. Following Nunberg,[67] Bak has redefined the paranoid reaction as delusional masochism.[3] Melanie Klein[54,56] pushes the crucial oedipal conflicts back to the first and second postnatal years, and dates from the same period the origin of a cruel, persecuting super-ego which she considers the source of later paranoid delusions.

Glover[39] has given an organized presentation of paranoid reactions in which he emphasizes regression, and both the defense against homosexual wishes and the reactive cathectic shift from homoerotic attraction to extreme hostility. In spite of a descriptive bias at the time, N. Cameron[11,12,14,15] was able to extend the concepts of paranoid denial and projection into fields of social interaction and reciprocal role taking. Finally, Waelder[82] reformulated the structure of paranoid ideas by giving first place to denial rather than to projection. He suggested a schema for delusion formation which closely parallels the generally accepted one for psychoneurotic symptom formation. These developments will be discussed further during and after presentation of the clinical material.*

## Official Classification

The official classification of the American Psychiatric Association[20] defines *paranoid re-*

* This brief historical introduction skips over many valuable contributions to our present-day conceptions of paranoid reactions. There are good historical reviews of nineteenth- and early twentieth-century developments.[47,50,63] Outstanding among contributors early in the century are Abraham,[1] Bleuler,[6,7] Brunswick,[9,10] Ferenczi,[25] and Jung.[51] All these, except one untranslated monograph by Bleuler, refer to publications in English.

Digitized from www.library.org.in

*actions* as psychotic disorders which exhibit persistent delusions, usually persecutory or grandiose, without the presence of hallucinations. Intelligence is well preserved; behavior and emotional response are consistent with the patient's ideas. Paranoid schizophrenia is specifically excluded from this group. Under paranoid reactions, two subgroups are distinguished, paranoia and paranoid state.

*Paranoia* is an extremely rare psychosis in which an intricate, complex, and logically elaborated delusional system slowly develops, without hallucinations. The paranoid system may be more or less isolated so that, superficially at least, the rest of the personality remains relatively intact, even though the course is chronic and protracted. Paranoiac patients often believe themselves to possess superior or unique abilities.

*Paranoid states* are psychoses characterized by paranoid delusions which are neither highly systematized and elaborate, as in paranoia, nor fragmented and bizarre, as in schizophrenia. There is no personality deterioration. The disorder may be of relatively brief duration, although sometimes it becomes chronic.

## ¶ Paranoid Reactions

Since paranoia is only a rare and extreme form of paranoid reaction, there is no point in complicating matters by discussing paranoia and paranoid state separately, as though the two had different origins and meanings. Instead, we shall speak of paranoid reactions throughout the chapter, and give a nod to history by adding a paragraph or so on classical paranoia near the end. It should also be clearly understood from the start that pure paranoid reactions themselves—ones which show no hint of schizophrenic thinking, no taint of depression or elation, and no evidence of psychoneurotic defense—are seldom encountered. Much of what we shall describe in this chapter—the defensive organization, the ego adaptations, and the imaginary pseudo-community restitution—may also be found entering into paranoid trends in other psychoses, in personality disorders, and in psychoneuroses.

### *Incidence*

The incidence of paranoid reactions, within the meaning of the official classification given above, is believed to be high in the general population. There is no way, however, of accurately estimating this. One reason is that they are often well defended and hard to recognize. Another is that mild paranoid characteristics are distributed widely among otherwise normal and psychoneurotic persons, who are in no danger of developing a psychosis. Everyone, for example, is at some time unjustly suspicious of his neighbor, or misidentifies some neutral happening as having special reference to himself. The mechanisms of denial and projection, which underlie all paranoid reactions, are also normal components of everyone's defensive system.

The question is to what degree such trends are dominant, how easily regression follows drive frustrations, and to what extent delusional beliefs can be corrected by experience. And even this last criterion is not infallible. Irrational beliefs, founded strictly upon personal need, fear, guilt, or unmanageable drive, are common among normal persons and social groups, and these beliefs resist correction by experience, with remarkable obstinacy. Nevertheless, to call such widespread phenomena paranoid reactions would be to reduce a useful psychiatric concept to mere nonsense.

Another barrier to an accurate estimate of incidence is the fact that paranoid persons do not usually consider their delusions pathological, and therefore do not seek therapeutic aid. They are often chronically suspicious individuals, who understand neither other people's motives nor their own, and who cannot trust anyone enough to confide freely and accept help. Moreover, when they fall ill, they are characteristically in better contact with their social environment, and better able to make use of it, than are manic-depressives or schizophrenics who are comparably ill. Hence they often weather mild and moderate psychotic episodes without needing hospitalization, and even without being recognized as ill by those close to them. And, finally, among eccentrics,

Downloaded from www.dbraulibrary.org.in

cranks, irascible neighbors, inventors, reformers, and persons committing crimes of violence, there are often found paranoid personalities who seem close to psychosis but do not reach it.

### *Heredity*

Since Miller's review of 400 hospitalized patients,[64,65] which included all psychotics with marked paranoid trends, little attention has been paid to the question of heredity as a factor predisposing an adult to paranoid developments. Miller found evidence of paranoid illness in the ancestors of only 8 of these patients, and only 44 were the direct descendants of persons suffering from nervous or mental disease. It is true, of course, that the possibility of hereditary factors—for example, susceptibility to stress,[75] inflexibility of adaptive organization, perceptual hypersensitivity, etc.—cannot be ruled out completely by such negative evidence. Moreover, what we have just said about the difficulties in recognizing paranoid illness and paranoid trends must certainly apply with special force to all studies of hospital records.

### *Sex and Marital Status*

Here again, the available data refer to hospitalized patients and are therefore of little value for our purposes. Tyhurst[81] reports that there is no good evidence concerning sex distribution of paranoid states, but that more recent evidence indicates that paranoia is nearly twice as common among women as among men, a statistic which reverses previously held opinion. Noyes and Kolb[66] state that an abnormally high percentage of paranoid psychotics have never married. They attribute this to a basic homosexual orientation and to chronic anger and hostility which make them undesirable partners.

### *Age*

According to Tyhurst,[81] there is no good evidence to show a characteristic age distribution of paranoid syndromes. He feels that specific paranoid delusional psychoses, without deterioration, appear in later maturity because this is when such disorders become socially intolerable, and not because this is when they begin to develop. As far as nonhospitalized persons are concerned, the point is debatable. Among clinicians who work with psychotics, there is almost complete unanimity that paranoid reactions—and even paranoid schizophrenias—appear a decade or more later in life than do nonparanoid schizophrenias.

Even in a study confined to a university student population, where the age spread to begin with is not large, the mean age of persons developing paranoid reactions was reported as being 11.6 years above that of persons developing any form of schizophrenia.[72] What Tyhurst says about the slow onset and the factor of social intolerance, in most cases, cannot be questioned. But slow onset and social intolerance are also important factors in schizophrenia, so that the reported difference in age of first hospitalization cannot be explained on this basis.

Assuming the widespread conviction to be true—that paranoid reactions develop significantly later than do schizophrenias—the meaning is still unclear. The difference may be an artifact, the product of our classification, which limits paranoid reactions by definition to more or less systematized delusions without personality disorganization. These qualifications tend to rule out the adolescent and postadolescent periods of stress and confusion, that is, periods of maximal drive, when an individual faces the challenges of his peer group alone, and when problems of self-identity,[22] career, marriage, and parenthood become urgent. It is logical, though not necessarily correct, to assume a fundamental difference in the personality structure of those who do not weather this phase (and become schizophrenic) and of those who somehow weather it but succumb a decade or so later to a paranoid reaction.

There are, objectively considered, some sources of frustration, conflict, and anxiety which are certainly more characteristic of the fourth decade, and after, than of the second and third decades. Some time toward middle age, when a person turns thirty, thirty-five, or forty, comes the dawning realization that his

Downloaded from www.dbraulibrary.org.in

life span actually is limited. With this recognition may also come fears that his lifelong hopes, overt or latent, will never be realized. Many people become suddenly aware of waning youth, attractiveness, ability, or vigor, and of dangers to what may suddenly seem a precariously held position of security or status. It is a fact that the actual range of choices in one's life does grow smaller with age, that one's commitments become deeper, and the accumulation of disappointment and disillusionment grows larger. To such threats, frustrations, and restrictions the vulnerable individual may react with regression and delusional restitution.

### *Social Milieu*

There is nothing to indicate valid differences in the incidence of paranoid reactions among different socioeconomic groups. Tyhurst[81] reports a higher percentage of hospitalized patients from urban than from rural areas, but the significance of this finding is unclear. He also reports a higher incidence among migration and minority groups, and states that hospitalized paranoids are perhaps better educated than other psychotics. Unfortunately for us, the important contribution of Hollingshead and Redlich to the problem of social class and mental illness[48] does not deal with paranoid reactions as a separate group.

In the end, of course, the question of whether or not there shall be a psychotic illness depends upon a complex interaction of biological, psychological, social, and cultural factors, all of which have a past history as well as vectors pointing to the future. The adult with an unstable or inflexible personality organization, and with relatively poor social integration, faces serious difficulties when he finds his achievements and gratifications falling further and further behind his ambitions and desires. He may react by redoubling his efforts, trying aggressively to meet new challenges, to overcome obstacles and prove himself, and, in his sex life, to spur himself on or look for new and untried sources of gratification.

If the efforts of such a person fail, the temptation increases to seek an explanation outside himself. His increased aggression is likely to arouse counteraggression in others, and this favors the development of delusions. If, as is sometimes the case, a paranoid individual should become disheartened and feel moved to give up, to submit to failure and to fate, he then runs the risk of reviving primitive fears for his own bodily integrity, fears that have been silent within him for decades. Let us turn now to a consideration of the major form of paranoid reactions, the development of persecutory delusions.

## ¶ Persecutory Paranoid Development

### *Personality Background*

We assume that anyone who develops a psychotic paranoid reaction, under the common stress of adult civilian life, has an adult personality structure that differs from the average in leaving him vulnerable to such a response. This circular statement is self-evident, but its referents are not. To what characteristics of the premorbid personality of paranoid psychotics are we referring, and how do they operate in bringing about situations which may be disastrous to the patient?

A simple answer to this question is not possible. The difficulty arises from the fact that a paranoid person, before his illness, may have been using almost any combination of secondary defenses and ego adaptations. The result is a variety of different premorbid patterns. Nevertheless, certain premorbid paranoid characteristics do appear with considerable regularity, however much they may be overlaid by reactive character structure or psychoneurotic defense, or handled through ego distortion, drive neutralization, and successful sublimation.

To begin with, the individual most vulnerable to paranoid psychosis is a tense, insecure, and usually fearful person, one who operates at high levels of anxiety. He easily becomes suspicious and distrustful.[53] He finds it difficult to confide in others, and if he does confide, as we shall see, he expects to be betrayed. If he has any close emotional relationships, they are

Downloaded from www.dtic.mil

likely to be limited to a very few individuals, and even these ties may not survive a personal crisis. Usually he is a person with lifelong tendencies toward secretiveness, seclusiveness, and solitary rumination, although these may be concealed behind a brittle façade of superficial social give and take.

The world in which such a person lives is a dangerous world where one must be always on the lookout for attack. People are unpredictable as well as untrustworthy; they must be watched. The paranoid individual, who needs more than the normal degree of understanding of motivation because he is so fearful and suspicious, has next to none. His social reality testing is grossly underdeveloped; therefore, he is easily taken by surprise and exposed to hurts and humiliations which ordinary persons foresee and discount, or avoid by preventive adaptations. The paranoid cannot understand another's motivation, or his own, because he does not have the other's perspective, as a reference point for his orientation, at the same time that he has his own. His failure in establishing adequate early identifications in infancy has left him unable to take the role of others realistically during later social interaction. As a result, he is forever socially incompetent in everyday situations that involve reciprocal role behavior—in ordinary cooperative, competitive, and complementary relationships. He therefore lives with endless tensions over mutual misunderstanding and misinterpretation, and is plagued constantly by ideas of self-reference.

Mild, harmless ideas of reference are familiar to everyone's experience. An occasional mistake in assuming that a critical remark or a compliment is meant for oneself, when actually it is not, lies within everyone's normal range, no matter how revealing it may sometimes be. Persons with well-compensated paranoid trends may even show this characteristic conspicuously without being in danger of psychosis. It is only when self-reference focuses upon some particular theme, or upon certain individuals who seem banded together, that it becomes a sign of beginning failure in paranoid defenses. The apparent self-sufficiency of paranoid persons, we have said, is usually a façade that hides their weakness. They are really over-concerned about what others think and feel about them, and at the same time much less able than the average to satisfy their need to know. When a condition of emotional stress increases this need, without increasing their ability to meet it, they do the best they can by increasing their vigilance and looking for signs that confirm their suspicions.

The persecutory paranoid personality is basically an extremely hostile one.[54, 56, 57] This is both because the individual feels surrounded by hostility, and because his personality organization includes major fixations at sadistic levels, with a preponderance of infantile defenses and an ease of partial ego-regression. The aggressiveness of the paranoid, however, is never aimless, excepting sometimes in an extreme panic reaction. Otherwise, he is always selectively reaction-sensitive, overready to react with defensive hostility to certain kinds of situations, personalities, and implied threats. And the directions of his reaction sensitivity, as we shall see, correspond to his own actual weaknesses, fears, guilt, intolerable frustrations, or ego-alien trends. In short, he is overready to react with what he considers counteraggression, to what he experiences as an assault upon his integrity, threatened from without. And this is true whether he conceives the threats as sexual or not, and whether what he fears is direct bodily attack or a danger to his freedom, his reputation, or his security.

On the defensive side, a major reason for calling the paranoid personality immature is that it must make excessive use of such infantile forms of denial and projection to bolster the characteristically inadequate repression. It is this preponderance of denial and projection that favors delusion formation in times of stress, to make good the lost aspects of reality. The immediate results are (1) to exaggerate normal tendencies to deny responsibility for failure or misdeed and ascribe it to others; (2) to deny unacceptable and unsatisfied sexual desires and attribute them to others; and (3) to deny one's own unmanageable hostility and project it onto others. The absence of realistic role representation in the personality structure[11, 15] leaves the individual with nothing

Downloaded from www.dbraulibrary.org

to oppose these drive-oriented attitudes. Needless to say, the denial and projection take place automatically at unconscious levels, so that the person is himself quite unaware of what he is doing. The effect of such unconscious maneuvers, however, is to create an atmosphere of tension and uneasiness, which makes others avoid the hostile person's company and increases his actual isolation. He feels unwanted and unloved, inferior or guilty, and pushed continually to overcome his multiple frustrations.

### *Premorbid Personality Stresses*

To offset these basic distortions, other defensive reinforcements, ego modifications, and adaptations are developed into one of a variety of adult patterns. The effect is usually to strengthen the total personality organization, but at the cost of making it more rigid. Indeed, a reactive rigidity, which renders normally flexible adaptation impossible, is a common and striking premorbid characteristic. The paranoid personality often gives an impression of self-sufficiency, superiority, and certainty. This impression in no way represents the basic internal situation but only a fixed inability to allow anything to enter which might upset a precarious equilibrium.

It is easy to understand why a person who must rigidly defend such a structure should be argumentative, insistent, and opinionated, unable to admit weaknesses, mistakes, and failures. The alternative would be to run the serious risk of precipitating a disastrous experience of inadequacy and guilt. Although reactive rigidity appears most clearly under emotional stress and in personal matters, it is also present chronically in some individuals, and in matters which seem impersonal on the surface—for example, a maddening insistence upon the literal application of rules, which expresses the individual's anxiety and not his strength.

Although he is unaware of the fact, such a person does not dare to recognize his weaknesses and failures or his ego-alien trends. Since he cannot successfully repress them, because of his defective defensive structure, he must engage in a continual process of getting rid of them through denial and projection. Now they appear as the real or fancied shortcomings, evil intentions, or misdeeds of others; and he is justified in his own eyes when he attacks these others with disparagement, denunciation, and condemnation. The more he defensively belittles another, the further he gets from seeing his own smallness. The more he points out others' mistakes and sins, the more he distracts attention from his own, and the less danger he runs of having to admit them to himself. By maximizing others' ego-alien or socially taboo aggressions and desires, the paranoid person automatically minimizes his own, to a point where what is left can be repressed. The unconscious guilt, which lurks behind every paranoid mechanism, is likewise denied and projected onto these others. This helps to get rid of still more of the disrupting aggression, which can now be justifiably vented upon the "guilty" ones in the form of contempt, indignation, or attack.

An ambitious paranoid person is likely to push ahead without due regard for others' feelings, which, because of his lack of reciprocal role representation and corresponding social perspective, he honestly does not understand. When he himself feels frustrated, he reacts with personal hostility because of these same defects. Such tactics further alienate people and provoke counteraggression. Now he may complain that people are against him—that he is being blocked, interfered with, discriminated against, or persecuted—all of which has some foundation in objective fact. What the paranoid person cannot see is that this outcome in the field of social operations is originally his own doing. He cannot afford to face this fact. If he cannot otherwise hide failure, temptation, or misdeed from himself, he calls in secondary rationalizations, misinterpretations, and distortions of recall, as a normal person might also do, but with far greater rigidity and determination. It is important to keep in mind that all these maneuvers are carried out under the pressure of urgent necessity, the necessity of defending an unsafe structure against disintegration, and of discharging libidinal and aggressive forces which cannot be otherwise channeled or controlled.

It should be said in passing that by no means

Downloaded from www.dbraulibrary.org.in

all paranoid personalities follow the path we are describing. Fortune smiles on some, and others hit upon effective compensatory adaptations. The more fortunate succeed in discharging much of their aggressive and libidinal energy in socially acceptable action, in enterprise and fantasy, and in setting up systems of reaction-formation capable of withstanding considerable stress. The most fortunate succeed also in establishing important sublimations and neutralizations which enable them to discharge otherwise inadmissable impulses wholesale in socially permissible ways—for example, in crusading vigorously against sexuality, depravity, cruelty, and crime, or in lining up actively with normal persons in promoting the constructive uses of brotherly love.

We are here concerned, of course, with the paranoid personalities who fail. Among those, three pathological characteristics are outstanding: an extreme sensitivity to certain unconscious trends in others, with manifest insensitivity to these trends in themselves; a marked tendency to self-reference within the areas of special sensitivity and an inability to correct mistakes through reality testing; and severe defects in reciprocal role representation, the result of defective identification and social interaction at infantile levels. When a paranoid person projects what he denies, we have said, he does not project at random. He ascribes hostile and erotic impulses to people who actually exhibit minimal signs of a corresponding unconscious impulse.[80] Since everyone has hostile impulses, and every heterosexual person has minimal unconscious homoerotic trends, it is not difficult for the selectively hypersensitive paranoid to find persons on whom to project. Thus there is always a core of truth in paranoid accusations. This fact, in part, accounts for the defensive hostility which the paranoid arouses in normal persons, hostility toward one who is stirring up their own anxieties over their own unconscious guilt.

The most obvious flaw in such paranoid accusations is that they assume these minimal unconscious impulses and trends in others to be maximal and conscious. And this gross misinterpretation of a correct, subtle perception can be a crucial step toward precipitating a psychosis. It then leads to the failure of a defensive maneuver and a return of the denied, as a new and imminent danger which seems now to threaten directly from external reality.[82]

### *Precipitating Factors*

The most important internal factor in precipitating paranoid reactions is a readiness to react with traumatic projective discharge when frustration provokes overexcitation.[89] An upsurge of hostile or erotic impulse may come as a result of the loss of major sources of gratification, in fact or fantasy; it may come as a compensatory reaction to the dangers of passive wishes or relative impotence; and it may come as a direct response to external frustration or temptation. The paranoid personality is especially vulnerable to ego disruption from super-ego attack, which may be experienced consciously, preconsciously, or unconsciously, as an increased sense of guilt. Whatever stimulates an increased sense of guilt creates an immediate demand for greater ego-defensive effort, and this means, for the paranoid personality, a sharp increase in denial and projection. Unfortunately, a sudden increase in projection is likely to make the environment seem suddenly more dangerous than ever, more malicious, and often more erotic.

Hostile and erotic impulses are likely to increase whenever new external challenges arise, when there is pressure from new or increased demands, and when one's status or security seems threatened. Rivalry can be dangerous for a paranoid personality, even in the presence of success. Close competitive situations may not only stimulate a vulnerable person to hostile aggression but also expose him simultaneously to homoerotic temptation, such as fantasies of who shall dominate and who submit. The same dangers can arise, even in the absence of serious competition, when a paranoid individual is thrown into close quarters with like-sexed persons for long periods of time. Paradoxically, increased social isolation can have similar effects for different reasons. Isolation leaves a person at the mercy of his fantasies and daydreams, without the safeguard of counteracting stimulation from outside, and

Downloaded from www.dbraulibrary.org.in

without such opportunities for reality testing as the talk and action of others may provide. Experimental work in sensory deprivation has brought this clinical factor into new prominence (see the review in Solomon, Leiderman, Mendelson, and Wexler[77]).

The internal stress is still further increased when a paranoid person experiences humiliation in actual failure and defeat. He has always relied for narcissistic support upon extravagant hopes and fantasies to offset his equally unrealistic fears and his deep sense of inadequacy. Now he feels unjustly exposed before the world as incompetent, weak, and degraded. It is easier to understand paranoid overreaction to humiliation if one realizes that, however inflated the patient's self-evaluation may seem, it is always defensive and compensatory. It is not just an expression of ambition and false pride; it is an essential bulwark against superego pressure that endangers ego integrity. Moreover, as we have intimated, failure and defeat may stimulate fantasies of passivity and helplessness, and these fantasies arouse vigorous defensive denial and hostile self-assertion.

The loss of a major source of security or gratification can take concrete external form, of course, as in someone's death or desertion; in actual rebuff, neglect, or deception; in economic loss; or in physical incapacitation. The real and the imaginary can support one another. Failing youth, strength, attractiveness, and health also belong in this group, as do the effects of severe fatigue and physical stress. It must be remembered that hypochondriacal trends are common in paranoid personalities and express, among other things, a conviction that the body is inferior, damaged, or vulnerable. Anything which justifies body overconcern will strengthen such trends. Accident and illness, including intoxication and brain damage, can have the same result, especially when they also place a susceptible person in a helpless, infantile position and decrease his opportunities for reality testing and social interaction.

In this section the discussion has been mainly about external reality situations and influences. This must not be taken to mean that adult paranoid reactions are *produced* by aggressive rivalry and erotic temptation, by failure and defeat, by sudden close contact or social isolation, and by major losses in security or gratification. These are only precipitating factors. They tip a chronically unstable balance, one dependent upon an infantile defensive organization, with defective reality testing, a selective hypersensitivity to unconscious processes in others, and irresistible tendencies to project and form pseudo communities. Nevertheless, these precipitating factors are dynamically and clinically important, since they can start off a process of paranoid development which the patient, because of his defective personality organization, may then become powerless to stop.

## *Onset*

The earliest phases of a psychotic paranoid development may be indistinguishable from the ordinary fluctuations of a paranoid person's life. In retrospect, however, it is often possible to say that in such and such a phase the habitual tendencies toward suspicion, blame, and self-reference became outright delusion. The change can often be related to some such precipitating factor as we have just discussed. We call the initial changes the onset of the psychosis. These changes may appear quickly, or they may incubate slowly and emerge so gradually that no one is sure when they started.

A sudden onset is sometimes analogous to sudden cardiac decompensation. The patient seems to have been functioning as usual up to a certain point, and then, almost without warning, he goes into an unmistakable psychotic episode. The precipitating stress is sometimes proportionately severe and suddenly applied. Sometimes, however, the premorbid equilibrium has been very unstable, and the new stress is only the last straw. In relatively rare instances, sudden onsets lead rapidly into acute panic.

Sudden onsets are not always as abrupt as they appear. Paranoid persons, we have said, often exhibit social behavior which, on the surface, seems maturely organized. They commonly build a rather rigid defensive structure, with extensive reaction-formations, and sometimes with fairly successful sublimations and neutralizations. A psychotic development may

Digitized by www.dtilibrary.org.in

proceed for some time behind such a façade before the patient finally goes past the point where he can control his impulses and conceal his illness from those around him. When his limits have been passed, the manifestations of psychosis may appear abruptly, even though its internal evolution has been gradual.

### *Early Phases*

In most psychotic paranoid reactions there is a more or less prolonged prodromal period. As a result of frustration, threat, temptation, rebuff, or loss—such as we have just described—the patient first withdraws his interest from his environment and loses interest in it. He becomes preoccupied and, in the process, undergoes regression. It is in this partially withdrawn, regressed, and preoccupied state that he begins the restitutional process, by means of which he will ultimately regain contact with his environment, but on a delusional basis.

At first the patient's experience may be only one of estrangement and puzzlement. Things have changed. They seem inexplicably different, and he tries to understand the situation without being able to do so. His growing anxiety, of course, comes from internal dynamic changes, but, to the patient, it seems related to things outside him. He becomes vigilant and uneasy. He begins to scrutinize his surroundings with more than his usual suspicion and misgivings. He does what he has always done—engages in solitary observation, searches for hidden meanings, asks leading questions, pondering over the answers like a detective, and listens attentively for clues in others' conversations to help him understand.

The patient—now anxious, puzzled, preoccupied, self-centered, and partially regressed—feels sure that something is wrong; something is going on that eludes him. With this fixed orientation he watches the little things people say and do, their glances and gestures, their facial expressions, frowns, smiles and laughter, their postures and movements. In this phase the paranoid patient shows a diffuse reaction sensitivity, that is, a sensitive readiness to react to any source of threatening stimulation within a wide range. We know that self-reference has always been his weakness, both because of his egocentric personality organization and because of his defective reality testing. Now, however, in his preoccupied, regressed, uneasy state, he finds that everything seems somehow related to him, although he still cannot understand what is happening.

It is obvious to us that the estrangement and puzzlement come from the patient's withdrawal of reality cathexes, his egocentric preoccupation, and his regression; but, of course, he does not and cannot know this. We know that the sources of his mounting anxiety lie not in the surroundings but in the patient himself; that they lie in the threat of a breakthrough of unmanageable unconscious impulses which he has already been denying and projecting. As with any suspicious, fearful person, the more vigilant and anxious the patient grows, the more things he will find in his surroundings to increase his uneasiness, feed his anxiety, and augment his defensive projection.

A patient notices, for example, that things have been disarranged on his desk or in his locker. At first he feels annoyed, and then he begins to wonder about it. He cannot find something in a desk drawer or at his bench, and he notices that things seem to have been disturbed. Some furniture has been moved around. Does this have some hidden significance? Clothes, newspapers, books, garden tools, or kitchen utensils seem jumbled up or missing. In the street, on buses, and in stores or elevators, people jostle him or crowd him or obstruct him, and he begins to feel furious. He overhears remarks that sound as if they might refer to him, and if there is laughter he feels this is directed at him. Someone spits on the sidewalk in front of him, or two people approach, smiling, and look at each other. This also seems directed somehow at him. Things are getting more and more mysterious.

### *Finding a Focus: Preliminary Crystallizations*

A situation such as this is too unstructured, too unstable, and too anxiety-laden to persist indefinitely. Even a normal person, feeling as threatened in a situation that he cannot understand, will automatically move on to hypoth-

Downloaded from www.dbraatbrain.org.ir

eses about it. Paranoid personalities are notoriously intolerant of suspense. They are driven irresistibly to form hypotheses, and this is where their incompetence in social reality testing trips them up. They are unable to represent realistically to themselves the probable points of view of other persons and are unable to confide, communicate freely, and share social perspectives when in desperate need.

The paranoid person is already caught in the web of his own projections. He cannot give up his projected fears and retrace his path, because the projected fears are themselves an integral part of his defensive maneuver against being overwhelmed and disintegrated by his own hostility. The only course open to him at this stage is to go on projecting and to move forward toward a more stably reconstructed "reality," which must include his defensive projections in its organization.

The preliminary crystallizations do not yet constitute a community of persons or a plot. They only express the patient's growing conviction that he actually is being singled out for some special reason which remains obscure. Things seem now to be done deliberately to confuse him, to test his intelligence, to express contempt for him, and make him look ridiculous. He finds signs that his effects are being searched. Objects are left around to try his patience or to communicate something about him, for example, that he is a fool, a pervert, or a criminal. Magazines and newspapers are left open so that he will notice a significant article, a story, or an advertisement. Now and then the food tastes strange; he wonders what is in it.

Things go from bad to worse. When the patient is driving, people saunter in front of his car as if to invite a serious accident; when he walks, drivers seem to drive right at him at street crossings. These are, of course, projections of his own denied murderous impulses and his fear of consequences. People seem to be watching him on the street and in the office; when he looks sharply at them they always look away. He goes to the window, and a man on the corner walks off; he is going to telephone a report about the patient. The patient is likely to believe that his telephone is being tapped and that hearing devices are concealed around his home and place of business. When he tries to divert himself by going to the movies or watching television, he sees and hears things which unmistakably refer to him and to things he never supposed were public knowledge about him. The net now seems widespread and inescapable.

Nearly all paranoid patients try more than once to communicate their misgivings to another person, to get help in understanding what is going on or in defending against it. The trouble is that, for the patient, everything is heavily loaded in the direction of his own projected fears and temptations, which his listener does not and usually cannot share. The layman, unless he falls victim to a rare *folie à deux*, is most likely to oppose the patient's drive-directed reasoning with some realistic evidence, or to expostulate frankly with him over his fantastic interpretations. The patient, unable to see things from any perspective but his own, may simply dismiss the other's reasoning as that of a coward or a fool, a person who will not or cannot face the frightening facts. He may also conclude, sooner or later, that the disbelieving person is really a party to some plot against him and is conspiring in order to throw him off his guard.

### *Final Crystallization: the Paranoid Pseudo Community*

Up to this point the projection, while by no means random, has still lacked a focus—some specific danger coming from some particular direction. The delusional reconstruction has still not built a stable organized picture of external reality that includes his expanding projections. If the patient has spoken of persecution, he has been able to say only that "they" or the "people" are doing things or planning things, without being able to specify who the "people" are and exactly what the plan is. It only remains now for him to conceptualize these dangerous "others" as a unified group, with some definite plot of which he is the intended victim, and he has structured his pseudo community with all his projections operating intelligibly within it.

*The paranoid pseudo community is an imaginary organization, composed of real and*

Downloaded from www.dbraulibrary.org.in

*imagined persons, whom the patient represents as united for the purpose of carrying out some action upon him.* The supposed "action" corresponds to his own projected libidinal and hostile impulses. The organization may be conceived of by the patient as a gang of underworld criminals or international spies, as a secret police force, or as a racial or religious group. In many cases the pseudo community is well organized and has specific plans, like the gangs in mystery stories. Some of the individuals in it may be identified by name as persons whom the patient knows. In many, the identity of all but the leading persecutor—actually a loved, feared, or hated acquaintance, or a public personage—remains obscure. They are only vague figures in the background.*

The formation of a projected pseudo community ushers in the phase of paranoid crystallization. This marks a final step in the restitutional process, in re-establishing relationships with external reality on a delusional basis. From a dynamic standpoint this step has considerable advantage for the patient. A known danger is easier to tolerate than an unknown one of equal magnitude, and the less diffuse a danger seems, the more effectively one can prepare to meet it. An acutely paranoid patient is forced to make massive projections merely to preserve his dynamic integrity. To have a more or less specific structured focus for this process makes it much easier to effect, with more economy and greater completeness.

This crystallizing out of the pseudo community, with its organization of projective processes in relation to it, is a movement in the direction of greater stability and precision—however false the crystallization itself may actually be. It represents a structuring of drive-directed, cognitive processes into something which can be used as the basis for meaningful, interrelated interpretations. These interpretations, of course, are also delusional. The patient himself often expresses the new stability in some such words as, "Everything became clear to me," an obvious experience of closure, which we have designated as sudden clarification.

* It is obvious that pseudo communities are not confined to paranoid reactions but may appear whenever delusional reconstructions include real as well as imaginary people.

The fatal flaw in this whole defensive maneuver is that what has been denied and projected seems now to return in external reality as an organized plot to ridicule, defame, or attack the patient, to subdue and exploit him, or perhaps to torture and kill him. The urgency of projection, and the patient's inherent inability to take the roles of others in imagination and see things from more than one perspective, leaves his cognitive operations at the mercy of the ongoing psychotic process. This process is itself powered by the unneutralized energy of his regressed, primitivized, dynamic organization.[46]

The result is that the patient's pseudo community organization moves forward irresistibly along the drive-determined vectors, often picking up momentum as it goes. Real happenings are distorted and reinterpreted to feed this ongoing process. Vague and trivial incidents are endowed with definite and important meanings. Contradictory evidence is scorned, ignored, or transformed to fit the over-all motivation of the pseudo community. This is the final picture of restitution, in which a delusional organization of active agents seems to threaten the patient in external reality. Many paranoid patients do not go as far as this; some do, and remain chronically fixed at such a level; others are able to replace some or all of this restitutional structure with more realistic relationships. The rare few go on to elaborate a classical paranoia (see p. 526).

## *Paranoid Action*

It remains for us to consider what course of action the patient follows in relation to what the pseudo community seems to be planning and doing. In many chronic cases this amounts to no more than a morose, suspicious, resentful, or aggressively hostile attitude toward the world, behind which the delusional convictions may be more or less successfully concealed. This group includes individuals who, no matter how they are treated, feel they never get a fair deal, and the many people who feel that no one can ever really be trusted.

In other chronically paranoid persons, with substantially the same attitudes, there are occasional outbursts of hostility or accusation,

Downloaded from www.psychiatrylibrary.org.in

which make others avoid too close contact and serve to isolate the patient. In this group belongs the litigious paranoid who repeatedly hales opponents into court to demonstrate to all the world that he has been wronged. The attempt always fails in the end, because the root of this urge toward litigation lies in the patient's unconscious sense of guilt. No court of law can ever silence accusations that stem from a pathological super-ego. In this group belong also patients who complain to the authorities about their supposed persecutors, or keep reporting the presence of prowlers and suspicious characters to the police, as well as the more fortunate persons who eventually seek psychiatric help to prove that someone else is wrong in claiming that they need it.

Some paranoid persons are driven to take more aggressive action. When their delusions crystallize, they abandon the role of observer and interpreter, and take that of participant in what seems to be going on in the malevolent pseudo community. The trouble is, of course, that what they imagine they are participating in does not actually exist as a construction in external reality, as we shall see in the case about to be described. The action the patient takes may be an attempt to escape by sudden flight, often with elaborate precautions to cover up the trail, in the best tradition of the mystery story.

Instead of fleeing, some patients feel driven to attack, to catch the enemy unawares and take revenge for what they have already suffered, and to forestall what they fear. It is obvious, in such a turn of events, that the patient has found another means of discharging his extreme hostility, without having to recognize it, and with the conviction that his attack is justified. The scapegoats, his victims, thus carry a double burden via his denials and projections—that of seeming to have what are really his own sadistic or erotic intentions, and that of shouldering the guilt for his actually unprovoked attack.

In all of this the paranoid patient is operating within an actual social field, in external reality. But he operates as a solitary individual who has reconstructed the behavioral elements and personal identities of this social field, in terms of his denied and projected delusional needs. His attitudes and interpretations are not and cannot be shared by the other individuals within the social field, since these others do not and cannot share his delusional reconstruction. Thus, if he takes action which, to him, seems just and reasonable, his behavior will almost certainly seem unintelligible and unprovoked to them—as, of course, in terms of the consensus, it is. The others are compelled, under these circumstances, to take protective action, which is almost sure to be aggressive and may be violent.

To the patient this counteraggression seems the final confirmation of his delusional expectation of assault. Thus, in the end he brings about a reality situation that corresponds to his psychotic reconstruction. The hostile world that he has built up in his imagination at last confronts him as external reality. The following case does not carry the patient to quite such an extreme as this, but its development is dramatic enough to illustrate the salient characteristics of a severe paranoid reaction.

## *Case Illustration*

### COMPLAINT AND IMMEDIATE BACKGROUND

An unmarried man, forty-nine years of age, was brought to the clinic by relatives after he had admitted his intention of committing suicide in order, he said, to escape being captured by gangsters and tortured to death. He gave the impression of being superficially friendly, polite, and cooperative. It was obvious that he was badly frightened and, behind his friendly politeness, very much on his guard. He told the story of his acute paranoid outbreak willingly and intelligently, although with no recognition of its delusional character. In all other matters, however, he took refuge in a degree of circumstantiality that amounted to a filibuster, and yielded little in the way of communication. What little could be gleaned about his mode of life was clearly of some importance in the background of his illness.

For several years he had been living alone in a cheap hotel, on a modest but steady income from investments. In spite of his comparative youth and good physical health, he lived idly and as though he were an elderly retired businessman

Downloaded from www.dbraulibrary.org.in

who had been unusually enterprising and successful. Every now and then he looked into new business prospects, but he never found anything that attracted him. He liked to sit around the hotel lobby and think, he said, from which one could draw the conclusion that he daydreamed and fantasied a lot. He conversed with other men there, played cards with them, read the newspapers, and, following a custom in that region, placed about a dozen small daily bets on race horses, through bookies and by telephone. This is all we knew about his life at the time the paranoid reaction erupted. We learned from him a good deal more of significance in his past, and there was probably much more than we know in his immediate background to make his violent outburst thoroughly intelligible.

### Acute Attack

The acute paranoid attack came the day after the patient had picked a violent quarrel with the racing bookies over a bet and had threatened to assault them. The circumstances were as follows. He had placed a number of bets by telephone one day, as usual, and one of the horses he had chosen, with the odds against it, had come in first. He went jubilantly to the bookies for his money, only to be told that he had not bet on the winning horse in that race, but on another one. He was very much taken aback. He went to a nearby bar and had a few drinks. As he thought about it, he "realized" that he was being deliberately cheated. He returned to the bookies, demanded the pay-off, and, when they still refused to give it to him, began shouting insults at them and invited them outside, so he could beat them up. They declined the invitation. For a time he paced up and down the sidewalk, until he cooled off a little, and returned to the hotel, still furious, where he sat and thought about the situation.

As he sat pondering alone in the hotel lobby, nursing his wrath, and probably imagining scenes of violent revenge—as people commonly do when they feel outraged—it flashed upon his mind, he said, that bookies were notorious for having national gangster "protection," which they paid for as a necessary business expense. This thought frightened him badly. He at once jumped to the conclusion that he had done a very dangerous thing in threatening and insulting people under gangster protection. The more he thought, the more he felt in danger of his life. The gangsters would get him. Here we see a man who quickly organized a provisional pseudo community of murderous persecutors out of his projected hostility and infantile fears. As we shall see, his more remote background will help explain why he was so ready with this response.

The very next day things began to happen. He noticed a number of rough-looking strangers hanging around the hotel lobby. They seemed to be watching him closely and waving signals to one another. The patient became himself watchful and apprehensive. At one time during that morning he saw an automobile filled with men stop in front of the hotel entrance. He was immediately convinced that these were gangsters coming to kidnap him, to torture and kill him because he had threatened and insulted the bookies. His vigilance grew, and with it seemed to grow the evidence on every hand that he was in deadly peril. He saw strangers and loiterers everywhere. They all seemed to be watching and shadowing him, wherever he went and whatever he did. There was no escape. He was convinced now that he was a man marked for execution, and, in a near panic, he barricaded himself in his hotel room against surprise attack.

### Flight

From his room the patient telephoned a relative and told him the whole story. The relative, who was well aware of the patient's intelligence and business acumen, accepted everything and agreed that the patient must somehow escape the murderers. The two arranged to leave the next morning secretly by car and take a long trip. But during a sleepless night the patient suddenly "realized" that the gangsters must have tapped the telephone wires and heard the whole plan. In a sudden access of fear, he packed a bag, slipped out of the hotel, and drove off alone without daring to notify his relative. He headed west for the home of another relative a thousand miles away. This sequence of first giving a confidence, and then feeling certain it would be betrayed, must have had a basic psychodynamic significance in this man's life, since it appeared again and again. It even led eventually, as we shall see, to his conviction in the clinic that he was about to be delivered into the hands of the pseudo community of gangsters.

Downloaded from www.pbookshop.com

As he fled across country from his persecutors, it became more and more obvious to the patient that escape was impossible. This was true, of course, but not for the reasons he believed. A number of trivial incidents and casual comments by strangers made him "realize" that he was caught in a great net which was closing in around him. Here are two examples from among a great many: He came out of a restaurant in Pittsburgh to find a policeman looking at his auto license. This meant, without question, that the police were in league with the gangsters and were keeping them informed of his movements. The organization of enemies now included all the police. In another town, when he stopped for a shoeshine, the man eyed him narrowly as he worked. "The grapevine was catching up," the patient related later. He now took precautions against having to live through the horrible torture that he knew inevitably awaited him. He hid razor blades in his suit, sealed a lethal dose of sedative in a chewing-gum wrapper, and carried a bottle of Lysol handy in his coat pocket. He slept in his locked automobile, hidden under coats, to avoid being kidnaped from motels.

Eventually, this desperate fugitive from his own projected sadism reached his relative's home alive. He was so terrified, however, and in such unendurable suspense, that he waited only for the moment when he would be alone to kill himself. He wrote a suicide note describing his terror, and speaking also of having suffered all his life from loneliness. The suicide note and the Lysol in his topcoat were discovered, and, with the help of the family physician, he was persuaded to return east by plane and get psychiatric help.

### CHILDHOOD

This man's reticence has already been mentioned. His past remained surrounded by an aura of vagueness and secrecy, which seemed to come, at least in part, from a lifelong inability to confide in anyone or trust anyone completely. The relatives, who were interviewed by an experienced senior resident, seemed also to be evasive. Either they knew next to nothing about the patient's past and recent mode of living (which seemed unlikely, as some of them were living in the same city), or else they did not want to convey what they knew. Enough came through these barriers to communication, however, to throw considerable light upon the dynamics of the present illness.

The patient's mother died when he was a small child. His father, whose work compelled him to move about frequently, boarded the children with relatives and friends, shifting them around "from farm to farm and from state to state." Sometimes the patient was with one or another of his siblings; often he was separated from them. There was stability neither in his past nor in his present, nor was there any security in his foreseeable future. He seemed never to have known mother love, and he certainly got nothing psychologically worth having from his father. He was never long enough in any one place to give him the chance to make lasting identifications with parent substitutes, or to build a sense of group loyalty and group identifications with children his own age.

This child lived as a chronically displaced person during nearly the whole of his personality development (cf. Pedersen on refugees, Ref. 70). He changed domiciles so often that it was impossible for him ever to feel at home. He grew up a lonely, insecure, brooding child in a solitary world devoid of genuine, lasting, dependable affection. In casual contacts he seemed to have done quite well. He had many fights with other boys, but he would not talk about these, and said he did not like to think about them. He always felt unwanted and with a great yearning "to confide and confess," neither of which he ever managed to do. It was never clear what burden of guilt lay behind this chronic urge, or whether the patient himself knew what it was.

### ADULTHOOD

There is a striking similarity between the pattern of life forced upon this patient in childhood and the solitary, footloose patterns he seemed to choose in adulthood. After a number of miserable failures, he finally drifted into a line of business in which one worked as a salesman for long periods of time completely on one's own. It was a highly competitive field, although one rarely met a competitor in person. But even within this relatively unrestricted framework, the patient was remarkable for his restless, roving existence, his frequent unexplained changes of employer, and his endless shifting of his own headquarters. From what we know of his childhood, it is not surprising

Downloaded from www.nbaubrain.org

that he never succeeded in identifying with any of the concerns for whom he worked, in developing any lasting loyalties, or in gaining either security or satisfaction from what he was able to achieve. He knew a great many people, but he had no close friends, and he was never interested in women.

His early retirement, which his success made possible but does not fully explain, was preceded by mutual distrust and suspicion between the patient and his employers. It was common practice in this industry for salesmen of one company to do a favor occasionally for a competing company, for which they were well rewarded on the quiet. It was also common practice for each company to put one of its own detectives on a salesman's trail from time to time, to check up on what he was doing. The patient made the serious mistake, for a person of his personality make-up, of shifting from selling to detective work. He later gave this up, because it made him too anxious and guilty. When, however, he returned to selling, he felt constantly watched and trailed.

The patient inevitably became involved in another profitable illegal deal on the side, and his sense of guilt and insecurity redoubled. He thought he recognized detectives in the street, and sometimes his things seemed to have been disturbed in his office or his room. If he thought he was being followed by someone, he would turn a corner and leap into a doorway or an alley, and then watch to see if this person also turned the corner and seemed in a hurry. He made sudden returns to his office and room, but he never caught anyone. When he felt sure—on the basis of rumination, solitary watching, and circumstantial evidence—that detectives were really on his trail, he would abruptly change office and room, even to another town. Eventually, he had himself transferred to a seaboard territory where he had never worked before. Here, however, his old fears and suspicions followed him, and his work dropped to such a low level that he was finally discharged.

This last was our interpretation, not his. The patient was convinced that enemies within the company—he could name them but he wouldn't—had trapped him into transferring out of his familiar territory where he had been so successful. They had sent instructions to the district manager on the seaboard, he said, to pull him down and get rid of him. It seems likely, from his account, that he had been suffering from a growing paranoid reaction for several years, while the acute episode and headlong flight were actually a sudden decompensation.

### Course in Clinic

Therapy was unsuccessful with this patient. Things went along smoothly at first, but he never got beyond what has been sketched above. He said several times that he wanted to get some things in his past cleared up, but he could never bring himself to indicate what they were. He was conspicuously noncommunicative about his sex life. When he made the offhand remark that he had never been interested in women, the query, "Or men?" brought only silence and a look of anger, and anger was rare with him. The first crisis came when a new patient made friendly advances to him. To these he at first appeared to respond with relief and gratitude. But the moment he discovered that this man had worked in the same industry as he had, the picture abruptly changed. He told the resident he knew this man was a detective, planted in the clinic to spy on him, and he now thought his company must have joined the conspiracy of gangsters.

The patient telephoned a local pastor, a stranger to him, and asked him to visit him at the clinic. During the visit he told his story, and made arrangements for another meeting at which, he said, he would go into other matters. After the pastor left, the patient had his characteristic reaction to putting trust in anyone. The pastor, he recalled, was dark-skinned and foreign-looking. Suddenly he "realized" what he had done. He had confided in a member of the underworld, disguised as a minister and sent in by the gangsters, who again must be listening in on his telephone calls. He became terribly frightened and made a suicidal attempt. It was impossible for him to conceive of any interpretation of these events other than his own, and his own, as we have seen, was the result of sudden "realizations" based upon his projected hostile and libidinal impulses. He now demanded, as a veteran, to be transferred to a government hospital, which was done. His ideal, he said, would be to spend the rest of his life in the center of an army encampment. In this statement he summed up his unconscious fears and wishes.

Downloaded from www.dbraum.org

The case illustrates a severe psychotic paranoid reaction in a man with no memory of having really loved anyone or of having been loved. His childhood seems to have given him no opportunity to build a stable personality system and a realistic picture of his world of objects. He had no chance of developing a normal repertory of realistic social roles; no chance to represent to himself how other people think and feel; no adequate means for matching his own feelings, wishes, impulses, daydreams, values, and expectations with those of other people. The wonder is not that such a person should become psychotic, but rather that he should have done so well for so many decades in a world of only half-intelligible strangers. The same deep personality defects which kept him from forming realistic object-relationships and identifications also helped defeat him in therapy.

Dynamically, the patient gives evidence of a persistent infantile lack of basic trust, a history of inadequate identifications and object-relations, and unquestionable signs of fixation at sadistic levels. His pattern of life and his conspicuous reticence point also to a possibly unconscious homoerotic fixation. His adult ego-adaptive operations, which brought him considerable financial success, were nevertheless carried on largely with the use of sexualized and aggressivized energy rather than with neutralized energy.[45,58] This helped keep him in constant turmoil and confusion, and ultimately tripped him up.

It is obvious that the patient used denial and projection to achieve what normal and neurotic persons achieve through repression and more mature defenses. Hence his continual preoccupation with watchful persons in his environment, to whom he ascribed primitive super-ego functions. Hence, also, his irresistible tendency to organize delusional pseudo communities, with himself as the focus of their supposed aggressions. With age, and the accumulation of frightening paranoid experiences, he tried to escape by retiring. This worked for a few years. Finally, a sadistic outburst stimulated violent projection, a regressive preoccupation, and then a paranoid reconstruction of object-relationships, in a world transformed by fixed delusions.

## ¶ Other Psychotic Paranoid Reactions

### *Delusional Jealousy*

Even normal jealousy, as Freud pointed out long ago,[36] is by no means rational. It is neither under conscious control nor necessarily proportionate to the external situation out of which it seems to arise. The elements that enter into it are grief over loss or threatened loss of a love-object, hostility toward both the rival and the love-object, and a severe narcissistic injury with a painful lowering of self-esteem.

Jealousy deserves to be called delusional when it exhibits the basic paranoid characteristics which we have already described for delusions of persecution. Delusional jealousy is not merely an exaggeration of normal jealousy but a psychotic restitution product. This is obvious even on the surface, from its fixed character, its exclusion of all contradictory evidence, and its inclusion of the most trivial and minute confirming evidence. The patient with paranoid jealousy watches for indications that he is right with the same intense alertness toward minimal signs of unconscious attitudes in others, and the same blindness to his own trends, that patients with persecutory delusions show. In other words, he gives evidence that primitive defensive operations of denial and projection are in the foreground. A brief case illustration will make this clear.

A thirty-nine-year-old lawyer was convinced that he was the victim of a conspiracy between his wife and her physician. Instead of going to the family doctor, as she previously always had, she insisted, in her second pregnancy, upon going to an obstetrician. This man was not only a friend of her family but also a member of the same minority group to which she belonged and to which the patient did not. His jealousy became marked as his wife continued to praise the doctor. She seemed pleased with the frequency and regularity of her visits to him, whereas the patient

Downloaded from www.dbraylibrary.org.in

felt she might have more appropriately objected. After the baby was born, he received a bill far smaller than he had expected. This made him certain that his wife had been unfaithful to him. He thought the baby looked like a little foreigner; it must be the obstetrician's and not his own.

The personal background of this case makes it more intelligible, though no less psychotic. The patient was the chronically insecure son of parents who were passionately devoted to appearances, conformity, and status—apparently as a reaction to their own humble beginnings. Against their wishes, he married the daughter of immigrants, in spite of the fact that he himself disliked and looked down upon his wife's family and friends. It was actually his own attitude that excluded him from this large and close-knit in-group, and, intellectually, he knew it. Nevertheless, he always blamed his feeling of exclusion on them. His wife's choice of obstetrician seemed to him just one more close relationship—too close—that left him out.

The patient had entered marriage with serious misgivings about his own potency and an expectation that a great deal would be demanded of him. It also came out rather late in therapy that he had had an extramarital affair during his wife's second pregnancy, partly as a spite reaction to what he imagined she and the obstetrician were doing, and partly to reassure himself. His affair, which involved a good deal of pregenital activity, made him feel exceedingly guilty, self-depreciatory, and fearful of discovery. It was evidently this which had reinforced the patient's suspicions and projections, and prepared him for his final delusional reconstruction of reality. In therapy he was able to work out some of the origins and meanings of his jealousy and to recover from his paranoid illness. His ease of projection, and his apparent readiness to withdraw from a love-object and regress, left him still vulnerable to similar episodes. He gained enough insight, however, to make a recurrence less probable.

In the case just given, there was evidence of certain feminine attitudes toward marriage on the patient's part, and a tendency to identify with his wife in imagining the obstetrical examination situation. In addition, there was some collateral preoccupation with boys' genitals, which came out in his incidental talk about sculpture, and with the whole topic of pregenital sex play. Freud's original account stresses unconscious homoerotic trends in the background of delusional jealousy, such as we see in this case. Freud[33] used a variant of his formulation of persecutory paranoid delusions to represent the unconscious mechanisms involved. It is as if the jealous paranoid patient defended himself by a denial, "I don't love him," and a projection onto the woman rather than the man—"*I* don't love him, *she* does." We shall return to these formulations later on.

## *Erotic Delusions*

There are paranoid delusions in which the patient believes that he is loved sexually by another person who, for one reason or another, does not make a direct avowal but does indicate his or her love in a thousand little indirect ways. It is most common among women and passive men. The individual selected as the delusional lover is usually of the opposite sex, and often a public figure—in politics, on the stage, in television, the movies, etc. These delusions are responsible for a good many police actions, since paranoid and paranoid schizophrenic persons with such delusions may eventually take action. They pester the supposed lovers with letters, come to see them, or demand an avowal at a public meeting or performance.

The love involved may be self-love, denied or projected onto another person, or it may be a defensive maneuver which substitutes a delusional heterosexual attachment for denied unconscious homoerotic trends. In the latter case, Freud's representation of the defensive maneuver is contained in the formulation, "I don't love *him*; I love *her* because she loves me."[35] For women, this would read, "I don't love *her*; I love *him* because *he* loves *me*." Fenichel maintains that the sex of the supposed lover seems unimportant in near-psychotic men. They sense vaguely an imminent object loss, he says, and because of this cling frantically to some love-object.[24] Many patients with this disorder express a narcissistic pleasure over their supposed predicament.

Downloaded from www.uratbal.org.in

Others, however, feel "persecuted by love" and protest indignantly, as in the classical case described by Tausk.[80] Persecution by love represents a special case of persecutory paranoid reaction.

## *Paranoid Grandiosity*

Grandiose delusions that are neither part of a manic elation nor sufficiently disorganized to qualify as schizophrenic may be included among psychotic paranoid reactions. They are encountered much less frequently than are delusions of persecution, and they usually characterize the more severe paranoid illnesses. The favorite themes, like those of persecutory delusions, are usually taken from the patient's surrounding culture, including its current folklore and popular literature. The manifest delusions range in complexity from relatively simple convictions that one is enormously talented, attractive, or inspired, all the way to the most intricately systematized convictions that one brings revolutionary conceptions to mankind, as a great inventor, scientist, or prophet.

Paranoid delusions of grandeur tend to be stable, persistent, and well organized. As a rule, the patient behaves earnestly in accordance with his leading delusional convictions. We occasionally see a grandiose paranoid person able to take a significant part in some social, artistic, or scientific movement and, in rare instances, to initiate and support reforms. It is much commoner, however, for grandiose as well as persecutory paranoid persons to attach themselves zealously to fanatical movements, which express and at the same time defend against their denied and projected impulses. Paranoid delusions of grandeur are restitutional in function and represent a partially successful attempt at recapturing lost object-relations.

The greater frequency of delusions of grandeur among severe rather than among milder paranoid reactions may stem from the fact that a greater degree of denial of reality is demanded in maintaining grandiose delusions than persecutory ones. Any insecure person can find danger more readily than comfort in his surroundings. It may also be that paranoid grandiosity involves a more profound regression. Freud[33, 85] felt that paranoid delusions of grandeur represent a retreat to infantile megalomania, and a sexual overestimation of the ego as love-object. He proposed the formulation to represent this process verbally, "I don't love *at all*; I don't love *anyone*; I love *myself*." Delusional grandeur is common in classical paranoia.

## *Classical Paranoia*

Classical paranoia is a rare form which represents the ultimate in systematization and fixity of delusional restitution. Perhaps its rarity is a function of the difficult combination of extensive involvement with preservation of relatively good object-relationships. That is to say, a patient with severe paranoia may be able to go about the ordinary business of life in spite of maintaining a complex fixed system of delusion, and without evidence of general disorganization and desocialization such as one sees commonly in extensive schizophrenic delusions. Sometimes this rare result is achieved by isolating the systematized delusion from the rest of the personality, thus leaving large areas free to operate normally.

The form and content of delusions in classical paranoia do not otherwise differ essentially from those in less severe paranoid reactions, excepting, perhaps, for the greater prevalence of grandiosity already mentioned. One meets patients who consider themselves, without question, great geniuses—inventors, scientists, and mathematicians on a cosmic scale; poets, writers, or artists; financiers; military or political leaders of mankind; gods, masters of powerful secrets and universal plans. It should be said that there has been an occasional genius whose delusional reconstructions and superior intellect have enriched mankind in actuality, for better or for worse. That is, there have been persons, apparently suffering from paranoia, whose fantastic plans have proved to be contributions which normal and neurotic persons could utilize.

It is obvious that the clinical picture of paranoia often reflects strength and superior intelligence. But the strength is one of rigidity,

Downloaded from www.objectivity.com

as well as organization, and the intelligence is usually pre-empted by a unique irrational belief, based upon *unsound* principles. The belief resists all potentially modifying influences. Experiences which might lead to reality testing and reorientation in a nonparanoid person are treated as nonexistent or beneath contempt, or else they are taken up in a distorted form to extend and support the system they should contradict. Great care and effort are often devoted to the task of maintaining the nuclear delusional structure intact, and of defending it insistently against anything that might weaken it. As might be expected, at the heart of this restitutional structure lie otherwise insoluble conflicts which, if they erupted, would plunge the personality into a regressive disintegration. Classical paranoia is generally considered to be incurable.

### *Folie à deux*

Baillarger reported, in 1860, the admission to a hospital, on the same day, of two members of the same family suffering from similar delusions. Lasèque and Falret introduced the term *folie à deux* in 1877, and, within a decade, four subdivisions had been described and named. Of these four, two are still commonly used—the induced and the communicated forms. In addition, where more than two persons are involved, a variant term, such as *folie à trois*, may be employed. According to Dewhurst and Todd,[19] the subdivisions are neither necessary nor well founded. These authors suggest the term "psychosis of association" to cover all such situations, including those which involve many unrelated persons, as in certain religious cults.[5] Perhaps they would also include the panic that once developed over a supposed invasion from Mars.[17]

The typical setup seems to be one in which a dominant, psychotic person provokes a delusional development in a relatively dependent, submissive one. The dependent one usually recovers within a few months after the two have been separated. Paranoid reactions and paranoid schizophrenia are the usual psychoses reported in *folie à deux*, and the majority of delusions are persecutory. In his excellent review and case reports, Gralnick[40] emphasizes the preponderance in *folie à deux* of persons who have been living together in intimate contact for a long time. He reports the following combinations in 103 pairs: two sisters, 40; husband and wife, 26; mother and child, 24; two brothers, 11; brother and sister, 6; father and child, 2. He ascribes the greater susceptibility of women to their being obliged to play a restricted, submissive role in society, with narrowed opportunities in educational, business, and social fields. He rejects the possibility that women are inherently more inclined than men to assume dependent, passive roles. Actually, these two sets of factors are not mutually exclusive, but complementary.

Gralnick points out that a relationship of dominance and submission is probably always involved, although this facet of the relationship may be wholly unconscious. It is generally agreed that the process of transmission from dominant to dependent person—and usually from older to younger—is never a simple one. Deutsch[18] interprets delusion formation in the dependent person as an attempt to recover a lost object through identification with it, or with its delusional system. The simple fact that two persons live together may itself express unconscious bonds between them which underlie their developing the same delusional structure later on. In the final restitutive organization, two persons share a common paranoid pseudo community, of which one is the major architect and the other the minor one.

## ¶ Psychodynamics and Early Childhood

All of the clinical evidence now available indicates that a special vulnerability to adult psychotic paranoid reactions has its roots in defects in the emotional relationships of early childhood. There is not yet complete and final agreement as to the exact character of these early defects and exactly when they first arise. As we shall see, some experienced and sophisticated clinicians ascribe the traumatic events confidently to conflicts over attitudes toward the like-sexed parent in the third to fifth years. Others, with equal confidence, trace the diffi-

Downloaded from www.PsychiatryOnline.org

culties back to the mother-child relationship during the first and second years, regardless of the child's sex. Some stress love and others hate; some stress sadism and others masochism. And these differences are of more than incidental importance for an understanding of paranoid reactions.

## *Difficulties in Reconstructing Childhood Origins*

It is not hard to understand how such fundamental differences can continue for decades unresolved. In the first place, adult paranoid psychoses are complex phenomena with many facets. Some patients throw light on certain aspects of the illness with exceptional clarity, and some throw light on different aspects. The clinician must make his studies more or less incidentally in a situation which is always primarily therapeutic. He cannot create, and he must not precipitate, paranoid psychoses in an experimental situation. He comes upon a patient now and then in therapy who communicates some fundamental aspect clearly, or who provides a basis for what seems to be a valid conceptual interpretation. The accumulation of such experiences establishes a trend for the clinical observer, and this inevitably influences what he later observes and interprets.

Therapists are always participant observers, and their personalities inevitably enter into the situation. Moreover, our theoretical conceptions of paranoid psychoses have already gone through a long evolution, which is still actively in process. As in all sciences, what has previously been observed and interpreted becomes a part of the heritage of later generations of observers and interpreters. Depending to some extent upon personal and professional experiences, upon special skills and preferences, the later student of similar phenomena will seek: (1) to preserve and further substantiate what has been discovered, (2) to place a greater emphasis than previously upon one or another aspect of it, or (3) to change the conceptual structure radically. We shall see examples of each of these trends in what follows.

A final barrier to the resolution of our difficulties is one that we encounter in all psychoses, not only in paranoid reactions. It is the obvious fact that we cannot get direct evidence from infancy, or completely dependable evidence from what the patient or his relatives "recall" about his early childhood. The phases which all of us assume to be crucial for psychotic development belong to periods of grossly inadequate verbal communication. Little children cannot conceptualize their feelings and communicate them, as most adults can; and infants in arms cannot verbalize at all. Our present-day knowledge about early nonverbal communication is relatively slight. Even infant observation is still itself an infant science. As for recall, we all know that it is emotionally biased[71] and culturally conditioned.[4] Accordingly, all inferences about the early childhood of paranoid psychotic adults must be based, for the present, upon a series of reconstructions.

The best way to gain an orientation in relation to prevailing attempts at reconstructing the early childhood of paranoid psychotics is to follow the early theoretical developments, and then consider a representative of each of several current trends. After a restatement of the peculiar position of paranoid reactions, as psychoses with psychoneurotic features, we shall proceed to round out the picture of the evolution of present-day conceptions which we sketched briefly early in the chapter.

We can begin with the fact that, from a dynamic standpoint, the position of paranoid reactions is an anomalous one.[39] The presence of frank delusions which are restitutional phenomena, their tendency to expand, and their resistance to correction by reality contradiction, make the condition obviously psychotic. On the other hand, the paranoid patient is not nearly as out of contact as a correspondingly ill depressive patient; neither does he suffer the degree of disorganization and desocialization found in equally sick schizophrenics. Some paranoid patients, in spite of serious unshakable delusions, still function reasonably well and are in good contact in all but a limited area of personal activity. They often give the outward appearance of a normal or psychoneurotic adaptation.

Downloaded from www.dbraulibrary.org.in

One of our patients, for example, required occasional brief periods of voluntary hospitalization because his fixed delusions got him into dangerous situations. Yet he managed to earn a large income, entirely through his own shrewd enterprise and realistic management, and to support his family in material comfort over a period of twenty-five years. Even his seeking refuge in a psychiatric clinic, which he did to keep from committing violence, was carried out in a well-planned manner, and in the face of his conviction that the clinic staff were blind to the "conspiracies" he saw around him. He continued to do business while living in the clinic, submitting his activities and correspondence to the censorship of a trusted staff member, but without ever being able to admit openly that he needed supervision. Many psychotic paranoid reactions, like this one, seem to be structured in most reality relationships like psychoneuroses.

## *Freud's Dynamic Interpretations*

Freud indicated this double orientation when he called, in the same paper,[31] a paranoid case both a defense neurosis and a defense psychosis. He made it more explicit when he described Schreber's illness in terms both (1) of a repressed inverted oedipal conflict, and (2) of object loss and delusional world reconstruction.[35] In the latter paper he made his classical formulation of psychotic denial and projection, bringing into sharp focus (1) the initial fleeting conscious wish to be a woman in sex intercourse, which Schreber reported, (2) Schreber's subsequent denial and projection of the wish, and (3) its return in the form of a conscious expectation of sexual assault.[34] On the basis of this study, and other clinical material, Freud proposed a verbal approximation for the paranoid denial, "I do not love him, I *hate* him," and another for the projection, "He hates (persecutes) *me*, which justifies my hating *him*."

The psychodynamic picture that Freud sketched at this time can be summarized as follows. Faced with frustration, the patient withdraws libido and undergoes regression, which comes to a halt at early, deep fixation points. These fixation points—of which there is a multiplicity—are the results of abnormalities in childhood development. They mark the failure of certain libidinal components to mature, and, in consequence, their current always behaves as if it belonged to the "system unconscious."[32, 37] Up to the time of psychotic regression, the repressive defenses have kept the derivatives of these fixations out of consciousness, along with all later-appearing ego-alien trends related to them. With the psychotic regression, however, there is a resurgence of previously repressed impulses, and the paranoid personality tries to deal with these by stepping up his already too active projection. The now-irresistible internal perceptions, or feelings, after some distortion are projected and appear in consciousness as external perceptions. The love is turned into hate, and the patient now perceives the previously loved person as a dangerous persecutor.

Freud postulated a continuum of libidinal development in everyone's childhood, from auto-erotic through narcissistic stages to homosexual and ultimately heterosexual object-love. On the basis of his clinical findings, and those of Jung and Ferenczi, Freud concluded that the chief fixation points in paranoid reactions are at homosexual levels.[35] It is the projective defense, against a return of wishes from these fixation points, that determines the symptom picture of persecutory delusions which finally emerges. Through delusional transformations, the patient builds a restitutional world that allows him to regain at least some kind of object-relations. The new object-relations may be intense, but they are never as successful as the lost ones, because meanwhile, profound internal changes have occurred in the patient's mental organization.

What we have summarized so far was written more than a decade before Freud arrived at his final topographical conception of ego, id, and super-ego, and before he had realized the full significance of aggression for his theoretical structure. His writings continued to show a preoccupation with the problems of distortion, projection, and delusion (for example, Refs. 28, 29, and 33). Then he introduced his concept of a death instinct[27] and placed

Downloaded from www.cbaindia.org

destructive drives on an equal footing with libidinal drives. Soon after this,[36] he traced the love of one's fellow men—whether sublimated or not—to reaction-formation against the early hate of siblings, who were rivals for the mother's love.

Finally, in *The Ego and the Id*,[30] Freud reformulated the transformation of love into hate and hate into love, in a new discussion of persecutory delusions, which may be stated as follows: Very early in childhood, the paranoid person must have developed intense hostility toward his sibling rivals. This intense hostility could not, of course, be gratified by assaultive action sufficient to discharge the angry child's destructive energy, but the intolerable tension thus built up had to be relieved somehow. The hostile attitude was, accordingly, replaced by a reactive loving attitude, because for the latter there was more possibility of gratification and relief by discharge. Both the strong hatred and the strong reactive love remain fixated, however, at infantile levels. Together, they form an intensely ambivalent attitude toward all love-objects, which the child carries with him into adulthood.

The account just given involves a paradox. It pictures the discharge of intolerable hostility through attitudes of love. Freud met this apparent paradox[30] by postulating a displaceable neutral energy, capable of joining forces with either erotic or destructive impulses.* In doing so, the displaceable energy makes it possible for a heightened cathexis and discharge, through a mere shift in energy. This is the process which he called the reactive shift in cathexis, and he applied this principle directly to the problem of persecutory delusions.

Something like a reversal of the reactive infantile shift seems to happen in the persecutory paranoid psychoses of adulthood. When a psychotic regression follows frustration, the original intense ambivalence reappears. The energy which is withdrawn from libidinal impulses, says Freud, is now used to supplement the hostile energy. A paranoid reactive shift in cathexis occurs, from love to hate in an originally ambivalent attitude. The hostility, thus reinforced by a shift in displaceable energy, is now projected as delusions of persecution. Whatever remains of this hostility, after projection, can be discharged in an attack upon the alleged persecutor.

## *Some Further Contributions Since Freud*

From this point in the evolution of the psychodynamics of paranoid reactions, a number of different emphases have carried the general trend in different directions. We shall give briefly a few representative examples from among those who still seem to retain paranoid reactions as a more or less distinct group.

### Excessive Love to Counteract Hate

Knight[57] carried this development further by stressing the intensity of paranoid love. The paranoid reaction, he points out, is *not* a new formation resulting from the projection of hate after love has been denied. Rather, the paranoid person suffers chronically from an excessive need for love in order to neutralize his tremendous unconscious hate. His love is actually dangerous; he is justified in fearing and denying it. At unconscious levels, the hate is already present in the patient before his persecutory delusions become manifest, and he already anticipates a retaliatory hatred from his love-object. The patient is caught in a net. He cannot keep away from the ambivalently loved person, because he desperately needs love to offset his ever-present hate. But the closer he gets to his love-object the greater becomes the danger of attack.

### Delusional Masochism

Bak,[3] citing a hint from Nunberg,[67] has followed Freud's general lead in a different direction by stressing sadomasochistic trends. He redefines the paranoid reaction as delusional masochism. He distinguishes four major steps in its psychodynamic development: (1) a first ego-defensive action, consisting in a re-

* The hypothesis of displaceable neutral energy has been used fruitfully in a much more inclusive sense by Hartmann,[42,43,44,45] Hartmann and Loewenstein,[46] and Rapaport.[72] See also the lucid summary by Anna Freud.[26]

Downloaded from www.pdfbooksfree.pk

gression to masochism; (2) a second ego-defensive action, consisting in withdrawal of libido for use against the masochistic threat, which now comes from the id because of the initial regression; (3) increased hostility toward the previous love-object, with sadistic fantasies; and (4) when mastery over this hostility fails, a final projection of part of the sadism as a delusional restitution. The inevitable result of projecting is that now the masochism returns. From his delusions of being mistreated and persecuted, Bak says, the patient obtains gratification of infantile masochistic wishes related to a father figure.

### Infant Sadism and a Very Early Super-Ego

Also pursuing Freud's newer emphases upon aggression, Melanie Klein[54, 55, 56] comes to her own conclusions regarding the origins of paranoid reactions and the depth of paranoid regression. Whereas Knight called attention to the patient's excessive need for love (to neutralize excessive hate), and Bak stressed masochism, Klein focuses upon sadism, and she goes back for its sources to fixations in the first and second years of life. It is impossible in a few paragraphs to do justice to the wealth of clinical material and the imaginative richness in the work of Klein and her co-workers. Neither would it be profitable to enter into the controversies to which this work has given rise. It is enough to say that even her critics, if they are engaged in intensive therapy with psychotic and borderline patients, are able to gain illuminating insights from Klein's publications. For our purposes, we shall restrict discussion to one or two points specifically related to the childhood origins of paranoid reactions.

Klein conceives of persecutory delusions as modeled upon a phase of development through which, according to her, every infant passes during his first or second year. In this phase the infant feels persecuted by cruel, sadistic objects which actually represent (1) its own projected sadism, and (2) its fears of retaliation for its own sadistic fantasies. During such a process a very early super-ego is formed which incorporates these distorted representations of father and mother and is characteristically cruel and persecuting in relation to the infant ego. The extreme anxiety produced by this primitive super-ego in the infant, says Klein, is the same kind as that which is basic to paranoid psychosis in adults. Ordinarily, in later infancy, between the third and fifth years, a less primitive super-ego supersedes the earliest one, says Klein. And, even though much more harsh than the parents actually are, it corresponds more closely to their attitudes and is far more realistic than the one which it replaces.

A predisposition to paranoid disorders, according to Klein, rests upon a failure to advance securely beyond this very primitive phase, in which all infants are beset with fantastic fears and threatened by a terrifying super-ego. The more beneficent, more realistic super-ego —which should be established during the third to fifth years—is inadequately developed and precariously held in paranoid personalities. The evolution of ego identifications, which is also closely tied up with super-ego development, is seriously impaired from the start in these vulnerable individuals.

When, in adulthood, paranoid psychotic regression occurs, the terrifying fears return under the influence of the primitive, earliest super-ego, which again becomes dominant. The patient now fears fantastically cruel attacks, such as our patient did who expected to be tortured horribly and killed. These attacks, says Klein, are feared both from the super-ego, now projected, and from real people whom the patient endows with the old fantastic cruelty. Thus she pictures the paranoid pseudo community as being organized on the model of the terrifying anxiety in relation to objects, which infants are assumed to experience in their most helpless and sadistic phases.

When we turn to Glover's account, we shall see that he also ascribes the paranoid adult's persecutors to projected super-ego figures—an interpretation which both Klein and Glover take from Freud.[33] But he characterizes the persecutors differently and refers them to a later phase of infant development. Klein, at

Downloaded from www.pdfbooksfree.pk

least by implication, rejects Freud's derivation of paranoid delusions from homosexual wishes,* and gives them a much broader, more diffuse, and more archaic origin (see, for example, Klein,[54] pp. 282–296).

### SUPER-EGO NUCLEI

Glover[39] has presented one of the most comprehensive, albeit condensed, accounts of paranoid reactions from a dynamic point of view. He follows Freud in placing the first formation of a super-ego somewhere in the third to fifth years. He does not accept Klein's early first- or second-year super-ego, but he does assume disconnected precursors which he calls super-ego nuclei. These become integrated eventually into an organized super-ego. Glover also follows Freud in ascribing a predisposition to paranoid reactions to failure in establishing strong, stable heterosexual object-relations. When psychotic regression occurs, he says, the patient first abandons all object-relations, and then succeeds only in re-establishing them at homosexual levels, usually in the form of persecutory delusions.

The delusional restitution is more successful in regaining effective reality contact than in other psychoses. This success, says Glover, is due to major fixations which involve well-defined drives at a crucial developmental phase; that is, paranoid regression carries the patient back to a phase of primitive but relatively good ego integration. But in his attempts to restore lost object-relations and gratify desires, the patient brings back, in projected delusional form, the homosexual wishes—always unusually frightening to paranoid personalities. Glover relates the paranoid watchers, listeners, and persecutors to introjected parental figures, now reprojected, and especially to the frustrating parent of the same sex. He regards this pseudo community of external spies and persecutors as evidence that regression has carried the patient back to a phase before super-ego integration, that is, to a phase when super-ego functions were still largely performed by actual external parents.

### DENIAL

As our last example we select Waelder's critique of theories of paranoid delusion and his attempt at a synthesis.[82] In all the preceding accounts it has been taken for granted that projection is the fundamental mechanism in delusions. Waelder comes to the conclusion that the fundamental mechanism actually is denial which, he says, plays the same part in psychotic symptom formation that repression plays in psychoneuroses. Projection is only a special form of denial. It is denial with a special countercathexis, a counterclaim which opposes the claim being denied.

Paranoid ideas are the result of unsuccessful denial. The denied returns in a distorted form, and fantasies are used to help strengthen the denial. But why are paranoid ideas inaccessible to reality contradictions? Because, says Waelder, they state an indestructible truth which has its counterpart in the indestructible power of instinctual drives. And the driving force in such a truth is an inescapable fear, the fear of being helpless in the face of dangers, unless one recognizes reality and watches it.

Waelder goes on to draw an interesting parallel, between the generally accepted formula for psychoneurotic symptom-formation (*conflict* between id drive and ego—*repression*, or similar defense, and *countercathexis—return of the repressed—compromise formation*), and a new one which he proposes for psychosis. In persecutory delusions we see the return of a denied drive. The resistance, however, is strong enough to prevent an undistorted breakthrough, and the result is that a violent delusional assertion appears instead. The warded-off drives return in forms that correspond to the original defense, for example, a denial returns as a related assertion (isomorphism). Waelder proposes the following formula for delusion formation: *conflict* between id and *ego—denial* and *countercathexis—return of the denied—compromise formation.**

* Among those who state their objections to this derivation more explicitly may be mentioned H. Klein and Horwitz,[53] Kant,[52] MacAlpine and Hunter,[60, 62] Grauer,[41] Sullivan,[70] and Ovesey.[68, 69]

* See also the discussion of denial and psychosis in Lewin[59] and Jacobson.[49]

## *Summary and Extension*

### Areas of Agreement

In the foregoing discussion we have focused upon the differences in emphasis among those concerned with psychodynamic problems in paranoid reactions, but there are also large and fundamental areas of agreement. For example, nearly everyone now agrees that paranoid adults must have experienced unusual sadism in their early childhood, and that such experiences are re-enacted in their psychotic delusions. To what extent these experiences were actual sadistic frustrations imposed by mother figures, and to what extent they were infantile exaggerations, it is not possible to say with certainty. Clinical evidence points in the direction of actually cruel treatment in a great many cases—if we include under cruelty such treatment as maternal neglect, coldness, "awayness," and actual absence for long periods, repeated active interference with ordinary freedom of action, failure to relieve excessive tension and anxiety, and the creation of an atmosphere of suspicion, resentment, watchfulness, and accusation. Often the current, contemporary interaction of parent and adult patient provides valuable clues to the probable situation in infancy.

When we come to the primacy of homosexual fixations we encounter less contemporary agreement. Few seriously doubt the correctness of Freud's original interpretation. But in the light of his later emphases upon innate destructive drives, there has been a growing interest in parent-child interaction before the crucial third to fifth years. We saw that even Glover, who can be ranked as moderately conservative, felt obliged to postulate "super-ego nuclei" as precursors of an integrated super-ego, and to shift his attention to earlier phases of ego development. On the other hand Melanie Klein, who is ranked in this country as radical, still traced paranoid development from original hatred of the mother to ultimate hatred of the like-sexed parent. In paranoid women this was a continuation of the original sadistic fantasies about the mother, or a return to them before the fifth year. In paranoid men the hate was transferred, she said, onto the father figure, and fixated there. These contrasting views are not as irreconcilable as their authors think. Both assume an intense ambivalence toward the like-sexed parent, and tendencies for this to erupt in delusions of persecution during an adult psychotic regression.

No one today seriously questions Freud's formulation of a sweeping regression and a subsequent restitution in paranoid psychoses. Some experience of traumatic frustration, or a series of such experiences, is generally accepted as the precipitating factor, and the first reaction is a withdrawal from object-relations, followed by the replacement of the more realistic object-relations by unrealistic ones—ones less mature, less determined by present circumstances, and more determined by unrealistic fears, hates, or loves. The fantasies openly expressed in paranoid delusions cannot be accounted for today without assuming, as Freud did, that a profound internal regressive change has occurred in the patient. The same can be said of delusional reconstruction. Objectively considered, there actually is a return to relationships with the environment which, however, now include delusional distortions. Freud's assumption, that delusional reconstructions are essential to the psychotic patient's regaining reality contacts, seems inescapable, in the light of the vigor and tenacity with which patients defend their delusions against contradiction.

### Mechanisms

What about the mechanisms involved in paranoid reactions? In their most simplified outline there is also general agreement, even though the directions of further elaborations differ. Whether or not we follow Waelder in giving denial first place, everyone seems to ascribe to denial and projection an abnormally large share in the defensive organization of paranoid personalities. Everyone agrees that repression in these individuals is seriously defective. When a psychotic regression carries the patient, in effect, back to primitive functional levels, repression becomes more than ever defective, while denial and projection become more than ever active. A general reduction in ego integration—which is inherent

Downloaded from www.dbraulibrary.org.in

in all regression—makes what is denied and projected seem much more real than when ego boundaries are relatively intact, as they are before regression. And finally, the return of intensely sadistic attitudes—whether one regards them as primary or as a defensive reaction—gives the projected drives and fantasies their cruel, unbridled characteristics.

### Social Interaction

The pseudo-community concept now comes into this evolution as an extension of the concept of reality reconstruction. Delusions of imaginary social interaction in a patient's surroundings are not a new group of delusions but an integral part of the restitutional process. In rebuilding his delusional object-relations, and trying to operate with them as a member of society, it is not enough for a patient to project his drives and fantasies onto appropriate individuals—who represent his own projected ego-alien trends and super-ego threats. It is inevitable that the synthetic function of the patient's ego should bind these individuals together into an interacting and interrelated organization, adding whatever imaginary persons are needed to complete the structure and to stabilize it.

The product of such paranoid ego synthesis and stabilization is an apparent community, the pseudo community which we described earlier in the chapter. Some of its members are always actual persons, to whom are ascribed imaginary functions, and some members are purely imaginary. The fantasied pattern of social interaction and interrelatedness does not correspond to social reality, that is, to the shared experience of the consensus. Instead, it corresponds to the needs of the patient's own internal dynamics—to his paranoid pattern of drives, threats, defenses, conflicts, fantasies, and solutions.[13] Against this fantasied social organization the patient may finally take action; or, as in the case we presented, he may try desperately to escape from it, even to the point of attempting suicide. It is usually some kind of overt action, or preparation for it, that brings the psychotic paranoid patient into therapy.

## ¶ Psychotherapy in Paranoid Reactions

The immediate therapeutic goal in paranoid reactions is the reduction of anxiety and the re-establishment of genuine communication. Excessive anxiety lies behind excessive paranoid projection, and both are intimately related to the regression and partial disintegration of personality which have occurred. The delusions are only the outcome and the indirect expressions of these fundamental processes.

It is often necessary, as in other psychotic episodes, to protect the patient from anxiety-provoking external stimulation. This may involve separating him from those relatives and friends who, for one reason or another, tend to raise his anxiety level, and from situations and places that increase his tension. Sometimes these objectives can be achieved without resorting to hospitalization; often they cannot.* But whether or not hospitalization is essential, there must be a clear policy of not interfering with the patient's freedom of choice and action any more than is absolutely necessary to prevent personal or community injury. Paranoid patients, more than any others, are sensitive to and humiliated by restriction of their liberty.

The process of re-establishing genuine communication goes hand-in-hand with tension reduction. As excessive anxiety and excessive projection begin to subside, the patient becomes, for a time, better able to express his fear and anger, the humiliations and misunderstandings he has experienced, the construction he places upon what seems to be going on around him, and his impulses to do something about it. What he needs most at this point is someone in whom he can safely confide, someone who is not driven by his own anxieties to belittle the patient's anxiety, to offer too much reassurance, or to argue.

It goes without saying that by this time all

* For criteria in evaluating the need for hospitalization, and for discussion of the special problems raised by hospitalized paranoid patients, see Noyes and Kolb,[66] Arieti,[2] and English and Finch.[21] Arieti also has an interesting discussion of milieu therapy.

Downloaded from www.dbraulibrary.org.in

of the usual common-sense methods for dealing with fear and suspicion have already been tried without success. Friends, relatives, and others have used reassurance, contradiction, reasoning, demonstration, and ridicule—often with skill and perseverance—but to no avail. Now something quite different from ordinary common sense is required. The patient needs help that is based upon a better understanding of his underlying pathology than the layman has.

The most important therapeutic need at this point is for a therapist who is available for communication, who can not only gain the patient's trust but retain it. Here certain questions about the therapist's personality and interpersonal skills become immediately relevant. Can he tolerate psychotic anxiety, fear, and hostility in a patient? Can he understand the patient's feelings emotionally, without sharing them to a disturbing degree? Can he tolerate mistrust and suspiciousness directed at himself? Can he be reasonably comfortable with the patient's extreme sensitivity to criticism and hidden meanings, with his readiness to be defensively hostile and aggressive?

If, for example, a therapist is made uneasy by the unconscious conflicts and fantasies expressed in paranoid anxiety and fear, he may unwittingly increase his patient's tension instead of helping it subside. If paranoid aggression arouses the therapist's hostility, and he does not recognize it, his relations with his patient will be distorted by his own unconscious denial, counteraggression, and reaction-formation. Such a patient-therapist interaction is actually antitherapeutic. It is not a disgrace to be unable to treat paranoid patients effectively, any more than it is a disgrace to be unable to do brain surgery, but it may be just as important to recognize one's limitations in the one as in the other.

What therapist attitudes are most helpful to a delusional patient? There are differences of opinion. Some experienced therapists counsel a warm, kind, helpful approach. Others, on the contrary, advise that one assume strict super-ego attitudes and, in effect, act out a part in compliance with the patient's need for self-restraint, which he is now unable to exert himself. Some therapists enter into a patient's delusional system deliberately and aggressively. Others enter into it for purposes of mutual understanding, but make it clear to the patient from the very start that they do not accept the delusions as fact. Some therapists keep rigorously out of the patient's delusional system without, however, making an issue of acceptance or rejection. Others maintain a detached attitude, in which their judgment appears suspended, until such time as therapist and patient understand each other better.*

The writer favors an interested, attentive, relaxed attitude initially, with a certain amount of detachment and suspended judgment. The initial detachment is essential, because paranoid patients are suspicious of an intrusive, friendly stranger, and frightened of too much closeness. The suspended judgment is necessary because one actually does not know how much of what one listens to is fact and how much fantasy. Many things complained of by a paranoid patient merit complaint, and sometimes fantastic things have actually happened. Within this general framework one should be able to feel friendly, considerate, sympathetic, and accepting, without being driven to express these feelings in words. If such feelings are genuine, the patient will usually sense them on nonverbal and unconscious levels; if they are not, the patient will sense any deceit behind a mask of fair words. There is no difference of opinion among therapists as to the necessity for scrupulous honesty, truthfulness, and steadfastness in working with paranoid patients.

What the patient needs in therapy is not, of course, merely a chance to talk, to express himself and "ventilate" his feelings. He needs to break out of his isolation and share his frightening experiences with someone who does not take sides, and who therefore may stand out as the only neutral person in his pseudo community. If such an exceptional relationship becomes established, the patient

* For discussions of therapist attitudes in treating psychoses, see Mann, Menzer, and Standish,[62] Fromm-Reichmann,[38] Semrad *et al.*,[76] Brody and Redlich,[8] and Stanton and Schwartz.[78]

Downloaded from www.dbtinbrief.nl

gains a new point of reference, and begins at least to catch glimpses of his world from another person's point of view. The therapeutic aim at this level is to replace a generalized suspicion with a specific trust—trust in the neutral therapist—which can become a base for further explorations.

If these primary objectives are realized, some of the origins and ramifications of the patient's basic problems can be worked through sufficiently to allow him a wider range of interpretation than his psychosis has left him. The pseudo community may be modified or replaced by something approaching the shared social community. Rigid, highly individualistic perspectives may give way to more flexible social perspectives. Through his work with the therapist, the patient can become better able to represent to himself realistically how other people feel about things and look at things. In an atmosphere of mutual respect, the therapist can express his suspended judgment or his disbelief in delusional misinterpretations, openly, without endangering the relationship. But one must bear in mind that it is not the delusion which stands in need of treatment, but the hostile, frightened patient.

It is obvious to everyone that paranoid patients are operating in relation to their own internal stresses, and that the stress patterns do not correspond to what is going on in the socially shared situation. We can gain a good deal of knowledge about the nature of these stresses, during the therapeutic process, by studying the patterns of imaginary social interaction which the patient ascribes to his delusional pseudo community. The components of his pseudo community are often actual people, whom we ourselves can also watch and hear. It is the imaginary patterns of social interaction among these real components which then reflect the internal stresses behind the psychotic restitution. The pseudo community thus provides us with a picture, half real, half imaginary, which may enable us to reconstruct the internal dynamic situation.

It should also be clear that the patterns of internal stress, set up by the patient's regression and delusional restitution, have their roots in the residuals of early childhood experiences, involving real and fantasied aggressive and libidinal situations. If a relationship of reasonably good communication and mutual trust can be established between therapist and patient, it is often possible to relate present fear and hate to the probable childhood situations that originally provoked them, or fanned them into flame. In such exploration, however, one must never lose sight of the fact that psychotic patients are always in danger of further regression, and that their greatest need is for a firm anchorage in present reality.*

What Freud said about deep interpretation is as true today as when he wrote it. The psychotic patient is often able to interpret unconscious symbolic meanings more immediately and correctly than can his therapist, whose intact defenses hide meanings from him. Such psychotic insight is a misfortune, not a gift. With it goes the additional handicap, already described, of reacting to minimal unconscious and symbolic material as though it were maximal, conscious, and literal. It is not so much the deep unconscious meanings that the psychotic paranoid lacks access to, but the socially valid, realistic ones. Too much has already come to the surface in the paranoid restitutional process.

The ultimate goal of treatment, of course, is that of getting the patient to the point where he no longer needs therapy. The ideal goal, often reached, is that of helping the patient to attain a more stable and satisfying equilibrium than his premorbid one, and to have him feel that it is possible to find someone trustworthy, neutral, and frank, in case of future need. This last may be a completely new discovery for him.

The prognosis in paranoid reactions is always guarded. Many patients regress further and become schizophrenic. Some remain static at a chronically delusional level. A small minority develop a classical paranoia. A great many recover partially or completely. The depth of the initial psychotic regression and the length of time during which active delusional recon-

* It is not the purpose of this section to describe, step by step, the therapy of psychotic paranoid reactions. The interested reader is referred to Fromm-Reichmann,[38] Federn,[23] and Arieti.[2]

Downloaded from www.dbraulibrary.org.in

struction has been going on will both affect prognosis. An insidiously developing, progressive restitutional process is more likely to have deeper roots, to be more stable and more difficult to remodel or replace, than a sudden delusional growth. Here, of course, we have to distinguish between a sudden change from relative health to paranoid delusion, and the sudden acute delusional attack which occurs in a long-standing, chronic paranoid reaction.

The most important limiting factor in the psychotherapy of paranoid reactions is the patient's basic personality organization—its ego-adaptive and defensive structure, its potentialities for change, for establishing fresh emotional relationships, for forming new ego and super-ego identifications. Self-evident as this statement is, it still deserves reiteration. There are wide individual differences among paranoid patients in these dimensions of personality, and the differences often do not become obvious until therapy is under way. The degree to which a patient can allow himself to communicate, to develop latent role-taking skills, and to include the perspectives of other persons in his own behavior will be a function of such individual differences as well as a function of therapeutic skill.

Today, more attention than ever is being focused upon the social settings in which patients develop psychoses and to which, if they are hospitalized, they return when they are well enough.[48] Community attitudes and community organization help determine the manner in which patients are introduced into therapy, the kind of therapy available, and the reception the patient experiences when he has recovered from his illness. We are still a long way from the development of intelligent public attitudes toward psychosis, and a long way from the development of adequate facilities for treatment. It is to be hoped that paranoid decompensation may one day receive as prompt and competent help as cardiac decompensation now enjoys, and that community attitudes and community facilities may one day reach the same level for the aftercare of compensated paranoid personalities as they already have for the aftercare of compensated cardiacs.

CHAPTER 26

# THE INVOLUTIONAL PSYCHOSES

Newton Bigelow

Downloaded from www.dbraulibrary.org.in

ALTHOUGH THE INVOLUTIONAL DISORDERS were originally decanted from the manic-depressive psychoses by Kraepelin, and, later, a direct relationship to schizophrenia was delineated for some cases of the group, they were formerly classified officially as "due to disturbances of metabolism, growth, nutrition, or endocrine function." Currently they lie under the broad heading, "Disorders of psychogenic origin or without clearly defined physical cause or structural change in the brain." Nevertheless—by insertion of the old subheading directly thereunder, and apparently to compound the ambiguity—present emphasis still seems to be placed upon metabolic factors. It will be perceived, however, as the etiological mechanisms are unfolded, that this group is comprised of preponderantly functional disorders.

Involutional psychoses affect women, beginning in the fourth decade, and men, beginning in the fifth decade, in a ratio of about 3 to 1. Patton[12] states that the rate of admissions to New York civil state hospitals per 100,000 of the general population has varied from 2.6 in 1926 to 8.8 for 1956. Henderson and Gillespie[6] refer to the larger number of cases from the rural areas of Scotland.

It has been held that the prepsychotic personality is a major etiologic factor in these disorders, whether the reaction is of the melancholic or the paranoid variety. Titley[15] concluded that anal-erotic characters seem to predominate among persons who later develop involutional melancholia. Rigid compulsives were described for the same group by Fenichel.[4] Generally, there are evidences of an inhibiting super-ego and strong feelings of insecurity. But this perfectionistic rigidity of the personality seems to be "undone" by the physical, physiological, hormonal, and psychic changes of the menopause. That the appearance of reality may very well change for the patient at this time must also be stressed. For such an individual the knowledge that life—with respect to work, recreation, love, and procreation—is fast ebbing away presents a major threat to the ego. The further realization that some of the physical symptoms are actually due to the menopause is also threaten-

ing. MacCurdy[7] goes on to say that such a personality, finding little satisfaction in life, turns the more strongly toward his own ego and body. As a consequence, there develops a coincidental preoccupation with, and revulsion from, death. This underlies some of the symptomatology, namely, the hypochondriasis, insomnia, and anorexia. That endocrine factors are not completely responsible is shown also by the current therapeutic ineffectiveness of endocrine preparations. The common headache, vasomotor symptoms, neuritides, and bladder disturbances do contribute substantially to the illness, however. With further reference to physical disorder, no fructose intolerance was found in schizophrenic, manic-depressive, and involutional patients,[6] as had been reported earlier. Finally, in considering etiology, one must recall the rather frequent occurrence of a precipitating factor, such as retirement, financial reverses, the death of a love-object, or illness of the individual himself. An excellent paper by Barnett *et al.*[1] links the typical prepsychotic personality with the precipitation of the depression. "The precipitating factors are considered to be traumata which prevent the maintenance of characteristically rigid ego defenses." In the view of the authors, this agitated depression may be seen then as "the decompensation of an anal character."

Depressive, paranoid, and mixed reactions are classified under the heading of involutional psychoses, although involutional melancholia is the prototype for these disorders.

## ¶ Involutional Melancholia

Classically, involutional melancholia is an anxious, agitated, delusional depression of the menopause.

A prodromal period of up to several months in duration is not infrequent. The early presenting symptoms may be considered neurotic. Occasionally, they may be attributed to the menopause, and, indeed, some may well be so founded. Anxious anticipation, restlessness, insomnia, fatigability, and irritability are common. Anorexia, weight loss, and constipation are often complained of. The mood varies from pessimism to frank depression. These symptoms blossom into a severe, agitated, delusional depression. No more profound depression is seen psychiatrically, and attempts at suicide are common. Although Muncie[10] says, "The patient slumps into a state of relative inactivity," the agitation is generally great enough to make him pace about restlessly, weep unrestrainedly, and pick unendingly at his body. The writer has seen patients brought into the hospital in former years with extensive lesions of their necks, or with their nasal septa largely destroyed in this agitation. Frequently, there are concomitant stereotyped utterances. Strecker[14] refers to catatonic phenomena, and English and Finch[8] call particular attention to the early-morning insomnia.

In the face of an unusually clear sensorium, depressive misinterpretations and delusions are almost invariably encountered, their content sometimes approaching the absurd, often in a picturesque way. Strecker's[14] case loudly insisted that "I am to be boiled to death in a *solid gold kettle*." Somatic delusions to the effect that the intestines are stopped up, that the brain has withered, or that the liver has turned to stone are not uncommon. In fact, some have held that the fixed delusion maintained firmly by a patient, to the effect that his bowels have not moved for five days, is a pathognomonic symptom. Nihilistic delusions, namely, "The world no longer exists," "There is no more food," often go hand in hand with ideas of guilt. Frequently, with these patients, one hears "the unpardonable sin" equated to "the trifling indiscretions of youth."[11] The unshakable belief that one is to be "boiled in oil" or "left to die in the frozen snow" are appropriate accompaniments. Not a few patients used to say that death would not end their suffering because they knew they would live forever in hell. Ideas of persecution then are also common. It may be repeated that the wish for, and fear of, death is reflected in the loss of appetite and in the insomnia. Hallucinations usually support the trend.

Milici's[9] description of the clinical picture is a graphic one.

In keeping with the danger of suicide that has been cited, Milici considers that the full classical symptomatology culminates in a

Downloaded from www.dbraintrauma.org.in

"death reaction." He traces its course from the early symptomatology, where the patient, overwhelmed by life's problems, begins to show

. . . signs of increasing dissatisfaction and distress . . . a growing moroseness . . . increasing introversion . . . difficulty in concentration and comprehension . . . complaints that the head "does not work right". . . .

With increasing depression . . . there is a sense of unworthiness, of uncleanliness and of wickedness. . . . He is dirty, filthy and he smells bad. . . . He has been false to God. . . . "I am a discredit to my religion. I am the scum of the earth. . . . I am not fit to live. . . ." Hostility comes increasingly to the surface. . . . "I hate everybody and everybody hates me. . . . Oh God, forgive me. . . ."

Increasingly vivid . . . is a feeling of unreality. . . . "My body feels as if it does not belong to me. It is like a piece of wood, of lead, of glass, a living stone." . . . At deeper levels, there are delusions of dying or of being already actually dead. . . . Finally the entire family, the neighborhood, the world, is dying or dead. . . .

The sufferer holds himself responsible for all this, feels that he is to blame for everything. He has infected, disgraced and harmed his family, has driven his loved ones "insane." . . . "I am the cause of all the ills of the world, for the death of trees and babies, for changes in the weather. . . . I barren things, the grass and the birds. I corrode the pipes. . . . I have killed the whole world. . . . Death would be better than a living death. I would be better off dead. I want to die. I am dying. I am dead. Everything is dead."

The following case is cited to illustrate the usual history:

After a suicidal attempt, E. D. entered the state hospital with an illness characterized by depression, self-condemnatory ideas, and somatic complaints of about one year's duration. She was then 58 years of age.

Her idolized father, a stern stonemason, enforced rigid discipline in the home. Owing to the father's attitude, the patient did not marry until forty-six. She is described as "dependable, honest, clean of mind and body, closefisted, hard to get acquainted with."

For this, her first psychiatric illness, several causes have been advanced. The patient later told of worry over early sexual indiscretions. Again she related her remorse that her husband's first coronary followed marital relations. However, her illness came soon after she had procured her sister's admission to the state hospital, after a long, agonizing, intense effort to care for her at home. For this she was berated soundly by another sister.

Filled with guilt over the course she had taken, this patient then voluntarily admitted herself to the observation hospital on the first of three occasions during the first year of her illness.

In general, she was agitated, depressed, distraught, and tearful on each admission. Loose stools, she believed, meant cancer, despite medical examination and opinion. She complained bitterly of insomnia, anorexia, dysuria, and sciatica. She was almost completely preoccupied with her physical condition and immediate need for medical attention. It should be added that, during her first admission, physical treatment of a leukorrhea and urethritis reduced her local and general complaints and rendered her generally more comfortable. In passing, one of her physicians commented upon the neurotic appearance of other expressed fears—that of riding on the bus or of leaving home. However, most prominent in her trend were the feelings of self-condemnation, inadequacy, and hopelessness. These led to a genuine suicidal attempt with an overdose of phenobarbital which took her into the observation hospital for the third time and on to the state hospital.

Electric shock therapy produced one remission. Thorazine seemed to give her good symptomatic relief. Its use was supplanted with Pyrrolazote at the state hospital from which she was released in four months, symptom-free.

Since then, the patient has done very well at home for more than a year, under care in the outpatient department on the same preparation. She has been discharged as recovered.

Upon most points—the prepsychotic personality, psychopathology, and clinical course—the history of this woman meets the usual criteria for diagnosis of the disease.

Formerly a number of types were described, and reference has already been made to those cases resembling manic-depressive psychosis or schizophrenia. Other types are seen rarely

Downloaded from www.brsubbiano.org.in

where, in the face of a profound depression, there is little trend and not too much obvious agitation. Earlier writers also gave prominence to a group complicated by the presence of arteriosclerosis—which hardly seems germane to the issue at hand.

The differential diagnosis of involutional melancholia is not difficult when there is a good history excluding earlier manic-depressive attacks. The patient with classical trends is not easily forgotten in making future discriminations between depressive states, psychoneuroses, and this illness. The absence of typical organic psychiatric signs and symptoms, and of the customary physical findings, should easily rule out psychosis with cerebral arteriosclerosis. As has been remarked upon by Henderson and Gillespie,[5] this writer, too, has seen a few young adults with clinical pictures indistinguishable from classical involutional melancholia. Despite the depressive cast of their symptoms, they appeared to belong to the schizophrenic group.

With respect to therapy, one of the first indications is for the prevention of suicide. This ordinarily means hospitalization with a full treatment regime. The introduction of electric shock therapy has transformed the entire outlook (and therapeutic plan) for this disorder, which was formerly chronic and caused untold human suffering. English and Finch[3] state flatly that in former days 25 per cent of these patients died by their own hands. Now, about 90 per cent of patients respond with remission to the usual course of fifteen electric shock treatments.

But psychotherapy is also strongly indicated in view of the underlying personality and the changing face of reality. English[2] puts it very well:

> This places a responsibility upon all those who treat the man or woman in the forties, to utilize an approach combining glandular replacement therapy and reeducational therapy in a ratio of 1 to 10. If one takes issue with this statement then more answers must come from the endocrinologist, internist, and practitioner who, having perfected their techniques in the use of internal medications, can use them objectively in practice and effect better cures.

Formerly it was held that only about one third of hospitalized cases "lived through their psychosis to survive." It should be repeated that we do not yet have in our therapeutic armamentarium an endocrine substance which ameliorates psychiatric symptoms in this disorder, although pure menopausal symptoms should be treated adequately by endocrine therapy. Nor do we have at this writing the ideal euphoriant drug to replace electric shock therapy.

Because most patients come promptly to successful treatment, persons with classical symptomatology are rare at the present time. Because of the clear-cut psychopathology which ordinarily stands out in high relief, such patients are most useful for clinical demonstration.

## ¶ Other Types

As the writer has said, paranoid and mixed states are also included in the involutional psychotic reaction. It must be confessed that this is an unsatisfactory grouping. Obviously, not all paranoid reactions occurring in the involutional age period should be included. Many are clearly schizophrenic, others are true paranoid conditions. These are discussed elsewhere. However, there are some individuals who present a paranoid trend in an involutional setting. There may even be some concomitant depression and somatic preoccupation. Here again, the prepsychotic personality can often be shown to be of considerable etiological importance, in that the individual seems to have been able to live behind his defenses until the climacterium, when his suspicious personality balloons into a paranoid state, with ideas of reference and actual delusions of persecution as the main trend. There is no deterioration here as may be seen in schizophrenia, however.

The following is an abstract of the record of a rather typical patient:

> At forty-nine years of age N. G., a married teacher turned factory worker, came to the observation hospital voluntarily, exhibiting an anxious, depressive, paranoid reaction.
>
> Eight weeks before admission she had become

Downloaded from www.brainlibrary.com

depressed, felt that fellow workers were plotting against her (hallucinations supported this trend), was tense, easily fatigued, and tremulous. Her physician had sent her to a general hospital for checkup, but beyond menopausal and psychiatric symptoms there were no findings.

At the observation hospital she wept, was seclusive, well oriented, and generally depressed. Among other things she said: "Everything seems too much. About last summer I went into panic. . . . I think that they have got my sickness mixed up in their products at [place of work]. It tires me to think of it. In the first place I don't know why I am that important. Why should they be fighting over me?" She thought that the people at her job were saying nasty things about her just as though they were appearing in her thoughts. She had guilt feelings saying that someone thinks she has done something wrong. "They are talking as though I was to blame for the layoffs."

There being no response to reserpine, she was placed on electric shock therapy (10) to which she reacted well, losing her trend and depression rapidly. She was discharged within six weeks at her family's insistence.

Five months later she was certified to the state hospital, presenting an agitated, paranoid reaction with little depression. She told of hallucinating the voices of the joint owners of her house from upstairs, to the effect that the wiring would affect her health to a degree that they would get her out of the way. She complained that "vibratory waves" from a generator "made her dizzy" and caused "a fire" in her head.

Later, as she improved, she handed her physician the following account of her trend partially in verse form (an avocation in which she had formerly been interested):

"The dead leaves clung upon the trees—they danced, they pleaded to be free—The wind came with a thousand tongues—He lipped, he lashed the vicious ones—Still dead leaves clung upon the tree—They danced, they pleaded to be free! A voice from her pillow, a babble scrabble of familiar voices, voices from upstairs—but why N. did not believe in voices from a pillow. Voices now came down in conversation—voices from upstairs! F. had put little fine wires in the pillow. R. from the shop wanted N. to think she heard voices. F. thought he could get the house—a sordid tale. N. lived in a dream world. F. said he had wired the house for Mrs. C. so he could investigate N.'s illness. It sounded impossible. Records played day and night. Records asking questions. One night a record told N. to lay on the studio couch. Then F. vibrated the studio couch. N. heard F. down cellar. One night voices said Mr. C. and Dr. R. were clearing up the investigation. They talked over a wire under the bed. It was just another trick of kids. It kept N. talking when she should have been asleep. It made a symptom. L. thought N. should go to Marcy [state hospital]. Her daughter was worried. One day two people came and took N. In the station wagon she heard voices. When she entered Marcy she heard voices. She thought it was a big setup. N. thought people were in a room upstairs. They were going to kill her with machines. She . . . with these people in her mind. Suddenly one day N.'s mind was free. She knew she had built a big story out of whole cloth."

Again she did not respond to reserpine but did well on Thorazine, being released during the fourth month. Despite an unfavorable home situation which includes an alcoholic husband and blind daughter, she adjusted well at work again, under outpatient clinic supervision for a year, when she was discharged as much improved.

This reaction was tied clearly to the menopause. It was noted that her prepsychotic personality was characterized as "easy-going but nervous and high strung." No obsessive-compulsive nor, for that matter, paranoid traits were described. The past history was negative. The diagnosis in this patient's case was that of involutional psychosis, paranoid type. The favorable response to treatment is not typical.

The case for the mixed involutional psychosis is still more tenuous, and this label should be employed only when there appears to be an almost equal admixture of depressive and paranoid features in an involutional setting.

The prognosis for both paranoid and mixed cases is much worse than that for involutional melancholia. Electric shock treatment, although less effective here, is still the method of choice. For the refractory mixed case Sainz[18] has proposed, in a preliminary report, the use of Pyrrolazote in gradually increasing dosage

Downloaded from www.dbraulibrary.org.in

up to 200 mg. q. i. d. For the same group, Mezer[8] gives an improvement rate of 40 to 50 per cent with prefrontal lobotomy.

CHAPTER 27

# RARE, UNCLASSIFIABLE, COLLECTIVE, AND EXOTIC PSYCHOTIC SYNDROMES

Silvano Arieti
Johannes M. Meth

Downloaded from www.dbraulibrary.org.in

ONLY AFTER CONSIDERABLE HESITATION was it decided to include this chapter in the *Handbook*. The hesitation stemmed from several factors. First of all, even a preliminary examination of several conditions to be described in this chapter (for instance, Ganser syndrome, collective psychoses, etc.), revealed that they cannot be considered psychoses without some reservations and that perhaps they should be more exactly termed "pseudo psychoses." Other conditions could be included in some already-known categories such as schizophrenia or paranoid states.

Original reports of collective psychoses are of historical or social character and lack clinical standards. In the case of the exotic syndromes the situation is even more difficult. Although one of us (J. Meth) had experience in the tropical part of South America, the account given here of the majority of syndromes comes not from direct experience but as a result of a compilation of the literature. The literature on exotic psychiatric conditions is scarce, inconsistent, and not too reliable. Some accounts are more anecdotal than scientific.

In spite of these deterring factors, it was decided to include the chapter, first, for the sake of completeness. At meetings and in discussions of atypical cases, mention is occasionally made of these rare conditions. It is thus worth while for the psychiatrist to have some acquaintance with them. Secondly, conditions such as the Ganser and Capgras syndromes present interesting theoretical problems as well as practical aspects. Although some of these are probably not psychoses, they have, nevertheless, a characteristic *psychotic flavor* of their own. Third, a brief account of

collective and exotic conditions may stimulate additional work in this field, which is needed for a better understanding of the nature-nurture problem as well as of many other aspects of social psychiatry. From an immediate, practical point of view we must also add that since the United States has extended her responsibilities into the farthest corners of the earth, American physicians are in increasing number called upon to diagnose and treat exotic conditions.

## ¶ Rare and Unclassifiable Syndromes

### *Ganser's Syndrome*

#### Clinical Picture

In 1898 Ganser[34] described a syndrome consisting chiefly of what he called *Vorbeireden*, that is, "talking past the point" or giving only approximate answers. This syndrome has received much consideration in European literature. In the United States, Weiner and Braiman[89] wrote on the subject.

Although relatively rare, the Ganser syndrome is interesting from psychopathological and legal points of view. It is generally encountered in prisoners who have to face trial but also, occasionally, in patients in the general population who have to face unpleasant conditions. Jolly[45] reported that one third of his cases were noncriminal civilians. Of the six cases reported by Weiner and Braiman, only one was a prisoner. Dogliani[30] reported one case occurring after a relatively minor automobile accident. It has also been reported as not infrequent among the Negro soldiers in Africa.[16]

One finds, in the Ganser syndrome, a more or less acute loss of the capacity to reason normally. Many cases present total or partial amnesia. The patient is disoriented as to time and space and gives absurd answers to questions. Often he claims he does not know who he is, where he comes from, or where he is. When he is asked to do simple calculations he makes obvious mistakes—for instance, giving 5 as the sum of 2 plus 2. When he is asked to identify objects, he gives the name of a related object. Upon being shown scissors, the patient may say that they are knives; a picture of a dog may be identified as a cat, a yellow object may be called red, and so on. If he is asked what a hammer is used for, he may reply to cut wood. If he is shown a dime he may state that it is a half dollar and so on. If he is asked how many legs a horse has, he may reply, "six."

At times almost a game seems to go on between the examiner and the patient. The examiner asks questions which are almost silly in their simplicity, but the patient succeeds in giving a sillier answer. And yet it seems that the patient understands the question, because the answer, although wrong, is related to the question.

Other symptoms found in patients suffering from Ganser's syndrome are, in order of frequency: (1) mild degree of mental defect (dull borderline); (2) hysterical symptoms of various kinds, such as amnesia, analgesia, incontinence, confusion, etc., and (3) epileptic-like convulsions, tremors.

#### Diagnosis

Ganser's syndrome may be confused with voluntary malingering in prisoners who want to escape indictment. In some cases the diagnosis is difficult. The malingerer will at times lose the air of bewilderment and confusion when he is not watched, whereas the Ganserian patient remains in that state all the time. The malingerer is watchful, suspicious, and (although he appears indifferent) ill at ease all of the time, being conscious of the unreality of his symptoms.

The syndrome can also be confused with schizophrenia. The answers of the Ganserian patient are reminiscent of those given by schizophrenics, of those productions Cameron[8] calls metonymic distortions. The answers given by the Ganserian seem even sillier, however, almost as if a voluntary effort had been made to say something ridiculously inappropriate.

A third misdiagnosis easily made is one of mental deficiency or organic conditions. But a mental deficiency of a degree that would explain such absurd answers would have been known prior to the onset of the disorder. Similarly, an organic condition that might lead to these symptoms would have to be at

Downloaded from www.dbraulibrary.org.in

a very advanced stage; again, there would be no difficulty in making the diagnosis.

### INTERPRETATION

Is the Ganser syndrome a psychosis? Ganser himself, Kraepelin,[49] Bumke,[8] Henderson and Gillespie,[47] and MacDonald[59] felt that it is a psychoneurosis, similar to what Wernicke called hysterical pseudo dementia, and should be included in the group of hysterias. The conversion syndrome would consist in the patient acting as if he had lost his rationality. The secondary gain, of course, would be the avoidance of the indictment or of whatever unpleasant situation he has to face.

Other authors felt, instead, that the condition is a psychotic one (Moeli,[65] Weiner and Braiman,[89] Dogliani[30]). We must say that the syndrome indeed presents a psychotic flavor not usually found in psychoneuroses. The psychodynamic mechanism also seems surprisingly simple: it is obvious that the patient wants to avoid the unpleasant situation and the burden of responsibility. Perhaps, as Weiner and Braiman state, he wants to do more than that. By unconsciously selecting symptoms which make him lose his rationality and often forget his personal identity and his past, he wants to reject his whole self, his whole life history—a denial of his total self.

We encounter difficulties when we try to explain the symptoms from a formal point of view. The answers of the patient are related to the questions, although inappropriately, and are reminiscent of the metonymic distortions of the schizophrenic[9] and in particular of the negativistic answers of some catatonics. The similarity is, however, only apparent. The Ganserian seems almost to make an effort to give a silly answer: a catatonic would not say that a horse has six legs.

Many authors have reported that this condition occurs mostly among people who, although not mentally defective, were at least dull adults, of borderline intelligence, or high-level morons. It has never occurred in a person who, prior to the disorder, was of superior intelligence. This fact suggests the possibility that the low mentality of these people had made them aware of one thing: that at times in life it was convenient not to be smart. The mental defect, although not present, was within grasp or could be exaggerated.

## *Capgras's Syndrome*

Capgras's syndrome is a condition that has received considerable attention in the European literature, especially the French and Italian. In the American literature, Davidson,[26] Stern and MacNaughton,[82] and Todd[84] have published articles on the subject.

In 1923, the French psychiatrist Capgras, in collaboration first with Reboul-Lachaux and later with several others, started a series of articles on what he called "*L'illusion des sosies*."[11-13] *Sosie* is a French word meaning "double," a person who looks exactly like another one, just *as an identical* twin would resemble the other twin.*

The phenomenon (or syndrome) described by Capgras is the following: the patient will claim, on meeting someone he knows well, that the person is a double or an impostor who has assumed this person's appearance. For example, the mother of a female patient comes to visit the patient at the hospital. The patient claims that this visitor is not the mother but either a double of her or an impostor who has tried to assume the appearance of the mother in order to deceive the patient. The phenomenon is thus a complicated type of misidentification, much more characteristic and specific than the usual misidentifications occurring in schizophrenia.

Although the first publications reported cases of female patients only, a few cases among males have recently been described.

Is this condition, described by Capgras, a special syndrome, or just a symptom occurring in one of the well-known clinical entities? The problem is controversial. Generally, the French authors tend to give to Capgras's syndrome a special place in psychiatric nosology, whereas the German authors tend to see it as a symptom. From the cases reported in the literature,

* The French word *sosie* (*sosia* in Italian) derives from Plautus's play *Amphytreon*. In this play the god Mercury assumes the aspect of Sosia, servant of Amphytreon.

Downloaded from www.naudb.org

however, it is obvious that, although the patients presented other symptoms, this particular delusion of the double was the center of the symptomatology.

The authors of this chapter have never seen a case as typical as those described in the literature. The senior author, however, has seen a patient, a paranoid with almost completely well-organized delusions, who doubted that her parents were her real parents. She felt that most probably her parents had died a short time ago (that is, at the onset of her illness) and the persons who acted as her parents were either impostors or reincarnations of her parents. The writer considered this delusion part of a paranoid condition (bordering on paranoia).

From an examination of the literature one gets the impression that the patients described could be classified under either paranoid schizophrenia or paranoid states. Capgras's syndrome thus should be more properly called Capgras's symptom. As a matter of fact, similar phenomena are described in the European literature in even rarer syndromes: for instance, the illusion of Fregoli, described by Courbon and Fail.[28] The patient identifies the persecutor successively in several persons—in the doctor, an attendant, a neighbor, a mailman, etc. The persecutor allegedly changes faces, as the famous European actor Fregoli used to do on the stage. Courbon and Tusques[84] have also described the delusion of intermetamorphoses. The patient believes that the persons in his environment change with one another: A becomes B, B becomes C, C becomes A, etc.

But, going back to Capgras's syndrome, several authors report that they have found the syndrome not only in schizophreniclike or paranoid patients, but also in manic-depressives.[82, 84]

Many patients reported recently in the literature have been treated with insulin or electric shock treatments, apparently with good results. Others retained their delusions and illusions or had relapses.

### Interpretation

Even if we deny recognition as a clinical entity to the Capgras phenomenon, it deserves further study from dynamic and formal points of view. The already abundant literature seems to be preoccupied almost exclusively with classificatory controversies.

Cargnello and Della Beffa,[15] reporting an existentialistic analysis of the phenomenon, write that, in the delusional experience of the patient, three persons enter: the patient, the *alter* (the other, the person who was well known to the patient), and the *alius* (the double or the impostor). They conclude that actually it is the *alius* who is lived intensely in the *Erlebnis* of the patient and, although misidentified, is the closest to the ego of the patient.

A few things seem obvious in this syndrome: first, the person whose existence is denied is a very important person in the life of the patient—for instance, the mother. The patient rejects the mother, actually attributes very bad habits to her, but cannot allow herself to become conscious of this rejection because of concomitant guilt feelings or other ambivalent attitudes. What the patient feels about the mother is thus displaced to the double or impostor who allegedly assumes her appearance. Often the idea that the misidentified person is a double or an impostor occurs to the patient as a sudden illumination, or like that "psychotic insight" described in Chapter 23.

Capgras's syndrome thus may be seen as an unusual form of psychotic displacement. All gradations of displacements occur from normal states to neuroses and psychoses. In private practice, we often see how the young wife's resentment toward her own mother is freely displaced and freely expressed to the mother-in-law, for whom she has no ambivalent feelings.

In Capgras's syndrome the real person is spared the hate of the patient—even becomes sanctified, a model of virtue—and the impostor made the target. But the real person, the person whom Cargnello and Della Beffa call the *alter*, becomes a pale, peripheral figure. The patient is really concerned with the *alius*, the impostor.

More difficult than the dynamic is the formal understanding of the Capgras phenomenon. Often, in schizophrenia, the opposite

Downloaded from www.pharmacy.org.in

process takes place: persons and things which, in thinking processes, should only be associated, are identified. In the Capgras phenomenon, not only is there no increased tendency to identify, but a person who should be easily identified is *not*.

The real person is almost divided into two parts (the *alter* or the good part, and the *alius*, the bad part), just as often happens in dreams. In the Capgras phenomenon the persons are different, but the body has the same appearance. There is thus not only a denial of the Aristotelian first law of logic (law of identity)—A is A—but also a denial of Von Domarus's principle (for instance, in spite of characteristics in common, the visitor is not the mother but an impostor [see Chapter 23]). Obviously the mother is identified with the impostor, but this identification remains unconscious.

It is the feeling of the authors that the phenomenon represents one of those difficult paranoid-paranoiac elaborations of thought which have not yet been fully explained.

## *Autoscopic Syndrome*

### CLINICAL PICTURE

Like the Capgras's syndrome, the autoscopic syndrome consists of the delusional experience of a double. In the autoscopic syndrome, however, the double is not a person from the patient's environment but the patient himself. The patient sees a person nearby who looks exactly like himself, talks, dresses, and acts as he does. Quite often this double seems exactly like a mirror image of the patient. Lukianowicz[58] reported an excellent study of this syndrome. Other important reports are those of Lippman,[56] Lhermitte,[52] Pearson and Dewhurst.[67]

The double may appear suddenly and without warning; at other times there are aural warnings. It generally appears in gray, or black and white, like images in dreams. Colors are seldom perceived. The patient occasionally reacts to the discovery of the presence of the double with sadness and amazement, but more often seems indifferent or even happy about it. In a few cases the double is constantly present; in the majority of instances, however, the appearance of the double lasts only a few seconds. Some patients have the experience of the double only once in their life; others repeatedly or constantly after an important event has occurred. Many patients experience the phenomenon only in the evening, at night, or at dawn. Although occasional instances of autoscopic syndrome have been reported in schizophrenia and in depressions, the majority of cases occur in patients suffering from migraine and epilepsy.

### INTERPRETATION

The above described manifestations may be remotely related to, but certainly are not identical with, others which are encountered more often in psychiatric practice, such as eidetic images, hypnagogic hallucinations, or those imaginary companions about whom some patients, especially children, have enduring fantasies.

The term autoscopy was used by Schilder[75, 76] to describe the process by which the individual is capable of doubling his body-image and projecting it into the outside world. As used by Lukianowicz, the term refers to hallucinatory phenomena, predominantly visual. These hallucinatory phenomena have only a remote resemblance to those found in schizophrenia; they have a much stronger resemblance to the phenomena found in organic conditions, especially those involving the parietal and temporal lobes (Critchley,[25] Penfield and Rasmussen,[68] Gerstmann[36]), and in some cases of epilepsy.

The greatest resemblance is to those conditions in which a psychological picture is superimposed on an original organic condition, such as symptomatic epilepsy, cases of phantom limb,[48] duplications of parts of body, and denial of illness.[20]

There seem to be indications, however, that the psychogenic element is important in some cases. For instance, one of the cases reported by Lukianowicz was that of a 56-year-old woman who experienced autoscopic phenomena upon returning from her husband's funeral. These phenomena continued thereafter. Lukianowicz does not attempt a dynamic interpretation of the case, although no organic findings are reported. One could speculate that

Downloaded from www.brainpickings.org

the hidden purpose of the symptom was to make the patient aware that, although the husband was dead, she did not need to feel alone: she could be her own companion.

Undoubtedly, much more research is needed on this interesting condition. At present, Lukianowicz's article is the best contribution on the subject and the reader is referred to it for further study.

## *Cotard's Syndrome (or Chronic Delusional State of Negation)*

In 1880, at the meeting of the Societé Médico-Psychologique in Paris, the French psychiatrist Cotard reported cases of what he called *délire de negation* or delusional state of negation. Since that time controversy has continued as to whether this syndrome deserves a special place in the psychiatric classification or whether it should be included among recognized entities.

In 1892 a Congress of Neurologists, which took place in France, was devoted to this topic, but no definite conclusions were reached. At the present time it is only in France and in Italy that the condition continues to be described as a separate entity. But even in these countries there are many psychiatrists who deny its existence. In the United States the condition would probably be included in the paranoid type of involutional psychosis. This symptomatology is in fact somewhat rare in the United States. A brief description follows:

After an interval of anxiety, the patient, generally a woman in the involutional age, but at times even men and younger or older women, denies any existence to the surrounding reality. Nothing exists; the world has disappeared. After the cosmic reality is denied, the physical reality of the patient himself is denied. At first the patient claims that he has lost all sensation throughout his body; in some cases, he later claims that he does not exist. Everything is denied in this overwhelming delusional state. At times even the possibility of death is denied—the patient considers himself immortal. Other symptoms resemble the picture of involutional psychosis: the patient is depressed, may refuse food, has ideas of having been condemned by God. He may also hallucinate. He retains, however, the capacity to talk freely in spite of the depression and often is given to philosophical contemplations about his own life, life in general, and the world.

For further study the reader is referred to Cotard,[22] Ey,[31] Capgras and Daumezon,[14] Perris,[69] De Martis.[27]

## *Psychose Passionelle of Clérambault (or Pure Erotomania)*

In the French literature and to a lesser degree in the Italian, the so-called *psychose passionelle* or "pure erotomania" is still given a distinct nosologic place by some psychiatrists. It is sometimes called Clérambault's syndrome, from the author who devoted many studies to it.[19]

The condition is not too rare, even in the United States, and the senior author has seen several cases of it. In the United States, however, the condition is generally classified as a paranoid condition, paranoia, or paranoid type of schizophrenia. Chapter 25 has dealt more extensively with this condition, under the heading of erotomania. For the sake of completeness, however, a brief description is reported here of those symptoms, which in some European psychiatric schools are generally considered part of Clérambault's syndrome.

The patient, generally a married woman, claims that another man is very much in love with her. The man, allegedly in love with the patient is generally of a social rank superior to that of the husband—at times, a very wealthy man or a prominent actor, lawyer, physician, etc. The patient would like to reciprocate this love, but the world, especially the husband, does not permit her to do so. This love becomes the purpose of the existence of the patient, and everything else in her life revolves around it. The patient starts to interpret everything as a proof of the love this man has for her, and a delusional system is thus built. For instance, one patient, the wife of a successful storekeeper, considered the business success of her husband as a proof of the other man's love for her: Because of his love, he was directing many customers into the husband's store, so that the husband would make a lot

Digitized by www.libraryofcongress.org

of money. Any gift the husband bought for the patient was interpreted by the patient as an indirect gift from the other man.

For further study the reader is referred to Clérambault[19] and Balduzzi.[4]

## ¶ Collective Psychoses

In old books of psychiatry, one can find reports of collective psychoses or "psychic epidemics" occurring in Europe, from the eleventh to the seventeenth centuries. These reports have to be read with more than a grain of salt, as they lack scientific rigor, although Hecker's volume,[39] published in 1832, is a valuable study.

We believe that many cases dealt not with real psychoses or neuroses, but with collective manifestations of fanaticism in members of particular religious sects. The Flagellants of the plague epidemics in the thirteenth and fourteenth centuries, trying to atone their sins, the Palamites who tried to touch the umbilicus with their head in order to see the glory of the Divinity, the Adamites who walked naked, can hardly be called "psychotic" in a medical sense.

Nevertheless, one gets the impression that actual "collective psychoses" or psychic epidemics occurred at times in the Middle Ages. In our opinion, these were not psychoses, but psychoneuroses of hysterical nature which were induced by the effect the crowd had on the predisposed person. The atmosphere of superstition, ignorance, and intense religiosity predisposed unstable individuals to this form of collective hypnosis. Perhaps a type of society that Riesman[72] has called group-directed is necessary for the occurrence of such epidemics.

Ferrio,[32] from whom most of this information is taken, reports that between the eleventh and the fifteenth centuries a psychic epidemic of St. Vitus's dance occurred, especially in the German and Flemish countries. People affected by the disease gathered together in the vicinity of churches, dancing and singing for several days and nights until they lost consciousness. Many of them had convulsive seizures. In the midst of this excitement some women were made pregnant. In the year 1278, when two hundred of these patients gathered upon a bridge on the Rhine at Utrecht, the bridge collapsed. Many of them perished. According to Ferrio, it seems that the name St. Vitus's dance comes from the fact that some of these patients were kept for treatment in a chapel dedicated to St. Vitus, in Zabern.

A similar epidemic occurred in the south of Italy in the fifteenth century. According to Zilboorg,[84] it was first described scientifically by Baglivi, under the name *tarantism* or *tarantulism*. The name has nothing to do with the name of the Italian city Taranto, as some believe, but with the fact that the patients were thought to have become sick because they had been bitten by a special spider, *Lycosa tarentula*. The patients presented convulsions and general excitement. It was also believed that music would be an effective treatment for it—thus the melody tarantella was created, a popular dance music still played in Italy.

Perhaps, of all the collective psychoses, the most important is *lycanthropy*, some cases of which are said to occur even now in some mountainous villages of Italy. According to Zilboorg, lycanthropy has been described and reported in the medical literature of their times by Marcellus in the third century, by Paré, Pomponazzi, Leloyer, Weyer in the sixteenth century, and by Sennert in the seventeenth century (all quoted by Zilboorg). People affected by this condition considered themselves transformed into animals, especially wolves. They saw themselves as animals and acted as such. Many of them committed crimes while they were in this state. People recognized as affected by this condition were often arrested and executed. According to Ferrio, a French judge named Boguet prided himself on having condemned to death about six hundred people suffering from lycanthropy during an epidemic that occurred in France in the department of Giura.

Although some of these lycanthropous were probably schizophrenics, it seems possible that the majority of them were suffering from some kind of collective hysteria. The conviction that men could be transformed into animals is very ancient; such transformations are often described in the myths and literature of various peoples. Nebuchadnezzar, King of Babylon, thought he was a wolf, and St. Patrick is re-

Downloaded from www.dbpublishing.com

ported to have transformed Veneticus, King of Gallia, into a wolf.

A strong feeling of guilt and unworthiness, experienced so deeply as to make the individual feel that he did not deserve to belong to the human race, found this concrete expression in a suitable cultural atmosphere. In a certain way lycanthropy is a counterpart of other neurotic symptoms, such as phobias, obsessions, etc. In phobias, the patient is apparently afraid of a danger coming from the outside world, in lycanthropy he is afraid of undergoing a metamorphosis. Later the patient must act out the metamorphosis by behaving like an animal. He acts hysterically or impulsively rather than compulsively, but in order to do so he must receive the assent of a group of people who behave as he does. This group replaces his usual social self or super-ego.

Other collective epidemics are said to have occurred in convents, where all the nuns would suddenly become possessed by the illness, abandon the religious discipline, and give vent to hysterical and bizarre actions. Ferrio reports that around the year 1700 the nuns of a convent near Paris started to mew as if they had been transformed into cats.

Today, lycanthropy is a term reserved to describe the delusions appearing in isolated cases of schizophrenia and paranoia of having been transformed into animals.

For further study the reader is referred to Zilboorg and Ferrio.

## ¶ Exotic* Psychiatric Syndromes

### *General Considerations*

All the mental disorders known in the Western world have been found among primitive† people also.[16, 17, 21, 29, 42, 44, 49, 50, 57, 66, 71, 81, 85, 87, 93] What varies is their relative frequency and, to a lesser extent, the manifest content of the symptomatology. It has been said repeatedly that the frequency of emotional disorders increases with the increase of complexity of a culture, but this statement has not been substantiated consistently.[2, 37, 38, 43, 62, 64, 87] Seligman, for example, was unable to find cases of psychoses among the Papuans of New Guinea and concluded that the absence of serious mental disorders is due to the primitivity of the Papuan culture.[77] Van der Hoeven, on the other hand, observed a fair number of psychoses and psychoneuroses among the same Papuans.[42] It is, therefore, evident that general statements about the absence of psychiatric disorders in primitive people cannot be accepted unless carefully evaluated and checked. There are, however, some statistical data available which seem carefully prepared and creditable, for instance, those of Carothers, who estimates that the incidence of psychoses among Negroes in Kenya, East Africa, is one tenth of that found in England and the United States.[16, 17] On the other hand, Lin has observed, in an equally well prepared study, that the rate of psychoses among some tribes in Formosa is equal to that of a German population in Thuringia.[54] Psychiatric disorders among the Ojibwas of Southern Ontario and among the Aiviliks of the Northern Hudson Bay are frequent and severe.[18, 51]

We must furthermore remember that under the category of "primitive cultures" we arbitrarily lump a large group of cultures some of which may, and some may not, have a beneficial effect from the point of view of mental health.

Another important point to consider, when computing the incidence of mental disorders in primitive people, is that many of these people are not prone to report or hospitalize a person whose behavior is not grossly abnormal or intolerable. It must also be kept in mind that hallucinations and delusions, which we consider almost pathognomic of psychoses, are normal and frequent occurrences in many exotic people during their trance states.[6] Hallucinations in these states, however, have a different character and significance from those occurring in a psychosis. They are generally benign and not persecutory in content, last only as long as the trance does, and are most often visual, not auditory. Many tribes choose their shamans and witch doctors among people suffering from mental disorders, since they are

* The word "exotic" is used to mean something foreign to Western cultures.

† "Primitive" in the following pages refers to peoples who have had little or no contact with technology.

Downloaded from www.dbraulibrary.org.in

more apt to achieve the dissociative states of trance and possession which are required in the ceremonies of many primitive people.

It is unfortunate that no detailed personal histories of psychiatric patients of primitive societies have so far been reported. Many authors have stressed the uniformity of the emotional climate in the childhood of exotic people. And yet, from recent anthropological protocols, it can be gleaned that such uniformity is as uncommon for the children of primitive societies as for our children. The same conditions detrimental to mental health may occur. The parents may be domineering, too indulgent, unreliable, indifferent, cruel, hypercritical, etc. There may be a preponderance or absence of one or several of these conditions in different cultures, but no generalization valid for all primitive societies is possible. It is likely that the organization of a culture influences the type of mental disorder prevalent in that culture—for example, the conspicuous rarity of obsessive-compulsive neuroses in many exotic societies may be related to the fact that the many rules and taboos which govern people's lives allow expression of compulsiveness and protect the members of these societies from the anxiety of making decisions.

The belief that the mental health of primitive people has deteriorated whenever they have come in contact with Western cultures has proved untenable. It is true that, in some parts of Africa, Europeans have disrupted old social orders—with detribalization, uprooting from the soil, destructive prejudices, destruction of old beliefs and rituals without adequate substitutes—and that in these areas the incidence of mental illness has increased.[16,17,18,85] But it is also true that in some parts of Polynesia a wise colonial administration has left the native population relatively undisturbed in their tribal systems and customs and, by eradicating cannibalism (for example, on the Fiji Islands), has transformed an extremely suspicious and hostile people into a trusting and friendly one.[53] A more or less temporary impairment of mental health has been observed in people who have been transplanted into different populations—Wedge reports that the incidence of mental disorders among Okinawans who emigrated to the Hawaiian Islands is much greater than among those living on their home island.[88] Since the Okinawan mothers continue their prolonged breast feeding and mothering attitude in Hawaii, Wedge uses this observation as an argument against the importance of the emotional climate in childhood for the development of mental health. One may argue, however, that the mechanical continuation of an attitude is no guarantee that its spirit also continues. The transplantation into a strange and hostile environment may create anxieties in the mothers which are communicated to the children and which may account for the increase of emotional disorders. This increase of mental illness has been reported also among Western people who have emigrated to foreign countries.

When dealing with people living in tropical or subtropical climates, the possibility of an organic etiology for a mental disorder must be kept in mind perhaps even more than it must in our Western practice. The differential diagnosis between a functional and infective psychosis may be very difficult. Positive laboratory findings of an infective agent are not decisive in populations in which those infections are very common. The most important organic conditions to rule out, before diagnosing a functional psychosis in tropical countries, are:

1. Malaria, which, according to Carothers, accounts for 3.4 per cent of first admissions to mental hospitals in Kenya.[16] The pernicious type of malaria, especially, can produce neuropsychiatric symptoms such as confusional states with excitement or stupor, meningeal signs, coma, or epileptic attacks (see also Arieti[3] and Chapter 60).

2. According to Tooth, trypanosomiasis is "the commonest cause of mental derangement throughout large areas of West Africa."[85] The first symptom is usually a change of habits. The patient becomes increasingly irritable, apathetic, morose. A fine tremor may appear in the tongue and lips, extend to one extremity, and finally to the whole body. The speech is low and tremulous. Sleep disturbances occur in 60 to 70 per cent of the cases. Delusions, hallucinations, and manic attacks have been reported. According to Tooth, every symptom of every type of schizophrenia may occur. The

Downloaded from www.brainlibrary.org.in

end stage is that of an euphoric dementia with impulsive behavior.[33, 85]

3. Syphilis. General paresis, which once was believed to be exceptional in primitive people (for instance by Kraepelin), is not uncommon.[49] Carothers has seen a fair number of cases in Kenya.[16] He stresses the remarkably high proportion of expansive cases.

4. Massive infestation with *Ascaris lumbricoides.* One of us (Meth) has observed confusional states, carpopedal spasms, and epileptic attacks in several children in Ecuador.

At this point it should also be mentioned that psychiatric conditions due to nutritional deficiencies, particularly pellagra and kwashiorkor must be considered in the differential diagnosis.[16, 35, 80] Pellagra (see Chapter 62) is not unusual among primitive people. It may be difficult to diagnose in spite of its classical triad (dermatitis, diarrhea, dementia) because the typical skin lesions may be absent or not easily recognized in colored people, and because diarrhea is such a common symptom in warm climates that it is often overlooked. Kwashiorkor is a disease caused by protein deficiency. It is characterized by retarded growth, mental changes, visceral changes, and skin lesions. The high mortality of African children between the ages of one and three years may be due to kwashiorkor. The mental symptoms are apathy and peevishness. The remarkable change in African children from a liveliness equal to that of European children to the frequent apathy after the first year of life has been attributed to protein deficiency. It is not observed in tribes who have an ample supply of animal proteins (milk or fish) or of protein-rich beans.[16]

Psychiatric disorders of the primitive may also be due to toxic causes. Alcoholism is, in most areas, an import of Western civilization. It is not an extensive problem in those parts of Africa where the tribal organization has remained intact; it has become a serious one among detribalized people. Some statistics show that the overwhelming percentage of major crimes has been committed by natives under the influence of alcohol. Meth has made the same observation among Indians of South America, who commit violent crimes almost exclusively when intoxicated.[50, 66, 71, 79]

Drug addictions are common in some countries. Addiction to *Cannabis indica,* or hashish, is frequent in India and in Arabic countries, addiction to *Cannabis sativa,* or marijuana, is prevalent in Central and South America.[29, 50] Hallucinations due to the use of peyotl and dried blossoms of mescal have been reported among the Indians of the Southwest in the United States.*[40]

The Incas and other South American Indians used to snuff the powdered seeds of the tree Piptadenia peregrina, which they called *cohoba,* and as a consequence experienced delusions, hallucinations, and excitement states which made it necessary for the wives to tie up their husbands to prevent them from committing violence. The active principle is *bufotenine,* which is also contained in the skin and salivary glands of the toad *Bufo bufo* and in some mushrooms (*Amanita muscaria,* or fly agaric, and *Amanita pantherina*). In some parts of Siberia the shamans used to eat the mushroom in order to fall into a trance state more easily. The Mexican mushrooms teonanacatl (*Stropharia cubensis*) and *Psilocybe caeruleus var. mazatecorum* produce hallucinations and disorders of visual perception, characterized by changes in the perception of space and colors.[40]

The possibility of infective diseases is wrongly suspected at times in primitive people in whom schizophrenia frequently occurs in acute paroxysms; these may simulate the acute hallucinosis and confusional states of infective deliria. Not uncommonly, the primitive schizophrenic may appear normal after a paroxysm, like the patient who has recovered from an infective hallucinosis. The dementia state of our chronic schizophrenics is uncommon in primitive people. In Africa a Ganserlike syndrome has been described as occurring between psychotic attacks.

The rarity of the simple type of schizophrenia among primitive people may be more apparent than real and is possibly due to the greater tolerance of deviant behavior and the lesser demand for judgment in these societies.

In spite of all these diagnostic difficulties or

* Hofmann's discovery of LSD has revived interest in mescaline and other hallucinogenic substances long known to some exotic peoples (see Chapter 84).

Downloaded from www.dbraum.com

differences, schizophrenia is recognized as the most common psychosis all over the world. Some statistics of mental disorders among primitive people quote its incidence as 60 per cent of all psychoses. Affective disorders and suicides vary in their frequency. They are unusual in most parts of Africa, South America, Australia, and Polynesia. Especially rare are the depressed phase of manic-depressive psychosis and involutional psychoses, whereas the manic type is relatively more common. Among the Papuas of New Guinea and some Eskimo tribes, melancholia and suicides are not infrequent.

## *Functional Psychiatric Syndromes*

### LATAH

Latah is a syndrome first described in Malaya, but recognized later on in many parts of the world. The etymology of the word *latah* is not known. It may derive from the Malayan words for love-making, ticklish, or creeping. In Malaya this syndrome has been known for many centuries and is regarded more as an eccentricity than a disease. It occurs mostly in middle-aged or elderly women. In other parts of the world it is equally frequent in men. Sometimes it has occurred in epidemic form.

Similar syndromes have been described in Siberia under the names of *myriachit* and *tara;* in Hokkaido (Northern Japan) among the Ainu as *imu;* in Siam as *bah-tschi;* in Burma as *yuan;* in the Philippines as *mali-mali;* in Madagascar as *ramenajana;* in Nyasaland as *misala;* in Congo as *banga.* It has also been reported from Somaliland, the southern part of the Sahara, and from Tierra del Fuego without any particular name.[1, 44, 92, 93] Yap[92] feels that the syndrome described by Beard under the name of "Jumping Frenchmen of Maine" or "shakers" or "barkers" or "holy rollers" belongs to the same clinical entity. Contrary to many other authors, he does not include Gilles de la Tourette's disease, also called tic convulsive.

#### Clinical Picture

The patient, generally a middle-aged or elderly woman of dull intelligence and compliant character, becomes increasingly fearful and seclusive. The disorder may start with a sudden fright. Among the Ainu of Northern Japan, the illness often begins when the patient has actually, or imagines having, seen or stepped on a snake. The patient may at first repeat some of his own words or sentences several times; later on, he will repeat the words or sentences of other people, particularly of persons in authority. Still later, the patient, in a pantomime fashion, repeats or imitates gestures and acts of other people, even if this results in harm to himself. At other times he does the exact opposite of what other persons do. The next symptom is coprolalia. At first the patient utters incomprehensible sounds, which later become clearly obscene or curse words which he never used before. The echolalia, echopraxia, and coprolalia are entirely uncontrollable.

Latah patients are often the butt of jokes. Adults and children may tease them, until they tearfully beg to be left in peace or, less frequently, until they become violent.

In other parts of the world the latah syndrome acquires additional characteristics. In Africa the patients may run into the forests; in Tierra del Fuego they may climb dangerous cliffs without regard to their safety. During these fugues, the patients, who are usually males, become violent and present a picture similar to "running amok" (see page 557).

The "Jumping Frenchmen of Maine," who, according to Yap, were suffering from latah, belonged to a sect—The United Society of Believers in the Second Appearing of Christ—which came to this country from Wales in the eighteenth century and settled along the eastern coast. During their rites and at the height of their religious ecstasies, one member started to jump, shake, roll around on the ground, and utter barking sounds, and the others followed suit. For most of them, this behavior ended with the close of the religious ceremonies. Some, however, remained in this state, so that any sharp command or even the pointing of a finger started them jumping, shaking, etc.

It is the opinion of the present writers that the clinical picture of the "Jumping Frenchmen of Maine" is more reminiscent of the

Downloaded from www.ebrary.com

collective psychoses than of the latah syndrome.

Gilles de la Tourette's disease (also called *tic de Guinon, maladie des tics impulsifs,* myospasia impulsiva, multiple tics with coprolalia, or imbacco) starts in children between the ages of five to fifteen years with spasms of the orbicularis oculi. It later spreads to other muscles of the face, then to the neck, upper extremities, and at times to the whole body. Soon all the symptoms of the latah syndrome are added.

The course of the disease is unpredictable. Some patients have become progressively worse, ending with a severe obsessive-compulsive neurosis or even with a psychosis. In other cases, the symptomatology has remained static. The disease may run a paroxysmal course, with the paroxysms lasting for weeks or months.

Again, it is more than doubtful than Gilles de la Tourette's disease is a special form of the latah syndrome. Perhaps it is a combination of the two conditions.[60, 61]

Various interpretations of the latah syndrome have been attempted (see Yap for a good bibliography and discussion). The latah patient is a compliant, self-effacing person who, even before becoming obviously ill, had tried to solve his conflicts by blotting out all expansiveness. Latah may be interpreted as an attempt of the patient to free himself of his anxieties by surrendering himself totally to others. The compulsive utterance of obscene words may indicate that he is not wholly successful in his endeavor. Frightened children often mimic other people. The mimicking may be a primitive anxiety-relieving mechanism, still available to children and primitive people, but not to adult Western man.

### Amok

Amok, or "running amok," is a syndrome first described in Malaya, but found also in other parts of the world—for instance, in the Philippines, in various parts of Africa, and in Tierra del Fuego. The "going berserk" of the old Vikings may be an identical or at least similar syndrome. In Malaya it was frequent until the beginning of this century. According to Van Wilfften Palthe,[86] it occurred often among the patients of Batavia Hospital until 1914, when the old hospital building and old methods were replaced by a modern structure and modern medical care. Since then, running amok has become exceptional. Van Wilfften Palthe has never observed or heard of a case of amok among the many Malayans living in European countries.

In the early days of American occupation of the Philippines, a number of American soldiers became victims of amok Moros. The Moros were a primitive Mohammedan tribe. When their level of education was raised, amok disappeared.[16, 20, 29, 42, 49, 83]

#### Clinical Picture

Amok occurs in males who have a schizoid personality. During a short prodromal period these persons become even more withdrawn than usual. All of a sudden, their brooding is interrupted, they jump up, sometimes with a terrifying yell, grab their dagger, and slash into anyone and anything they encounter on their way. They end up, after having killed several people and animals, either by being killed by the frightened neighbors or by killing themselves. Those few patients who have escaped death, generally because they have made themselves helpless by self-mutilation, either showed complete amnesia for the episode or described a feeling of blackening of eyesight from which they tried to slash their way out.

Kraepelin felt that amok has no uniform etiology and that it may be caused either by an infectious disease, particularly malaria, or by epilepsy and schizophrenia.[49] Perhaps a sociopsychodynamic interpretation of amok is possible. A person who has repressed his rage to the point of appearing apathetic finally bursts out and gives expression to it within the culturally acceptable framework. When this cultural acceptance is withdrawn because of Western influence, running amok becomes rare. Among the Bantu a contributing factor may be the belief that a person destined to die may escape death if someone else is killed in his place.

The multiple violent acts occasionally committed in Western countries by persons with a schizoid personality resemble the clinical picture of running amok and may have similar psychodynamic mechanisms. Such apparently

Downloaded from www.pdfbooksfree.org.in

unmotivated outbursts of violence have been artistically described in the European literature by fiction writers (for instance, Gabriele D'Annunzio and Albert Camus).

Although violent acts committed by paranoid or catatonic schizophrenics may have some resemblance to running amok, the differential diagnosis is generally not difficult. In schizophrenia, there is no amnesia for the violent episode; other symptoms which are present, such as delusions and hallucinations, are absent in amok.

*Pseudo amok* is probably a hysterical syndrome in which the patients are excited and grab their dagger as in real amok, but seem to avoid, skillfully, hurting anybody. When cornered, these patients give themselves up meekly, whereas persons affected by real amok never surrender.

### Koro

Koro is a phobia known among the Buginese and Macassarese in Celebes and West Borneo. The Chinese call it *shook yong*.[88] Kobler reported the occurrence of this condition in Southern China. Van Wilfften Palthe[86] observed it in a Chinese man hospitalized for tuberculosis.

It generally starts suddenly. The patient becomes fearful that his penis will disappear into his abdomen and he will die. To prevent this from happening, he has to grip his penis firmly; when he gets tired, his wife, relatives, and friends help him. The Chinese have a special wooden clasp constructed for this purpose. At times, fellatio practiced immediately by the patient's wife can stop the phobia. This condition can last days and even weeks. The Chinese believe that it is due to the prevalence of what they call "female factor," or *Yin*. Therefore, a medicine belonging to the "male factor," *Yan*, must be administered—for instance, powdered rhinoceros horn. Linton[55] reports a female equivalent of koro in Southeast Asia. Some female patients in Borneo feel that their breasts are shrinking and their labia sucked inward, thus losing female secondary sex characteristics.

This syndrome seems to exemplify how a particular culture introduces specific symbols into psychodynamic processes which are identical to those existing in our civilization. Our patients, however, express castration fear, dependency needs, and inferiority feelings with other symbols.

### Whitico Psychosis

The whitico psychosis is a peculiar syndrome occurring among the Eskimos living around Hudson Bay, particularly the Cree Eskimos (southern Hudson Bay). Among the Ojibwas of southeastern Ontario it is known as windigo.[20, 51]

### Clinical Picture

The patient's first symptoms may be anorexia, nausea, vomiting, diarrhea. At the same time, the patient may fall into a brooding mood, fearing that he has been bewitched. He becomes afraid that he may crave human flesh—that is, that he may become a whitico. A whitico is a supernatural figure, a giant skeleton, made of ice, which devours humans. The patient becomes more and more melancholic, withdrawn, inert, refuses to eat, is sleepless. The frightened family calls on a good shaman to counter the bad shaman's spell. Most often the patient improves after appropriate magic is applied. But, at times, particularly in isolated areas where no "good" shaman is available, the patient may coldly kill one or more members of his household and eat them.

Cannibalism has been a recognized extreme means of survival among Eskimos. Therefore, the use of cannibalism as the content of a phobia in this culture is understandable. Up to this point the syndrome should be called whitico phobia. It becomes a psychosis when the patient actually kills and eats his relatives. This may have the following psychodynamic interpretation: if cannibalism can be life saving in an emergency (extreme famine), then it can also save the life of the patient who is suffering from an emotional emergency.

### Voodoo Death (Thanatomania)

Voodoo death is known among most primitive people.[10, 12, 19] The patient dies without any discernible organic cause when he becomes aware of having transgressed a taboo or when he fears having been bewitched. The following

Downloaded from www.pdfbooksfree.org.in

is a typical case report: A sorcerer in New Guinea had been offended by a young Papuan. In revenge, he told the young, healthy man that a few days ago he (the sorcerer) had put a *bofiet* (an object poisoned by witchcraft) into the young man's path. The young Papuan immediately appeared extremely ill. He did not talk and seemed entirely removed from his environment. Within two days he was dead. The sorcerer was indicted by a Dutch court which, recognizing the bewitchment as cause of death, condemned the man—who, by the way, admitted his guilt freely—to several years of imprisonment.[42]

The interpretation of this condition is difficult. Death from fear is not unknown in the West. We use the phrase "frightened to death," although we generally use it in a metaphorical sense. What has puzzled Western observers of voodoo death is its relative frequency among primitive people and the fact that it seems to occur for unbelievably trifling causes. Of course, these causes are as little trifling for the primitives as those symbols which have become charged with explosive meaning for our patients.

In the Bible (II Sam. 6:6-8) it is reported that Uzzah accidentally touched the ark of God, while it was shaken by the oxen which were carrying it. Nobody was supposed to touch the holy ark, and Uzzah is reported to have died immediately, because of "the anger of the Lord." This account is hardly reconcilable with previous statements in the Bible where great care was made to differentiate voluntary crimes from involuntary ones (Numbers, Chap. 35; Joshua, Chap. 20). It is probable that Uzzah died a voodoo death because of his expectancy of death.

Death resulting from expectancy of death is not uncommon in villages of Western countries. Arieti has heard from reliable witnesses that, in the village of Pomarance in Italy, an elderly man used to say that he would die when the several-centuries-old tower of the village fell down. During a storm the tower was hit by lightning and did fall. Shortly after hearing this news, the man died.

Although we recognize that fear of death, expectancy of death, etc., must be strongly felt in primitives and in people living in extremely religious or superstitious surroundings, it is hard to understand how these emotions can lead to death. It could be that a process of autohypnosis succeeds in altering some vital physiologic mechanisms, presumably through some functional alterations of the autonomic nervous system. It could also be that Selye's[78] reaction to stress fails in some of these cases. The few autopsy reports in these cases have shown only signs of vasomotor paralysis.

## ¶ Psychiatry in a Historical-Geographical Perspective

These accounts of collective and exotic syndromes, although brief, may help to visualize psychiatry in a historical-geographical perspective. We have seen how certain rare diseases or special syndromes appear and disappear in the course of history and how even the incidence of the well-known psychiatric disorders vary in different areas of the world. One could easily yield to the weight of the factor of cultural variability and conclude that culture is by far the most important element in the etiology of mental conditions.[2,5,6,7,17,28,37,38,48,64,72,73,77] If it were so, there could be no universal psychiatry, and a Western psychiatrist of the twentieth century would be unable to recognize mental disorders in members of other civilizations or study psychiatric reports of previous ages. Actually, there is a great uniformity in the psychiatric nosology of people whose cultural norms vary widely. In this chapter, for sake of completeness, we have emphasized what was different. We must remember, however, that the majority of psychiatric cases of all times and all places are similar to ours.

One of the difficulties encountered in the study of psychiatry in different cultures arises from a confusion between the concept of normality versus abnormality and the concept of mental health versus mental illness. Although these two concepts overlap to a considerable extent in what they connote and denote, they are not identical.

Psychiatry has been defined as the science of abnormal behavior, but this definition seems inadequate in a historical-geographical perspective.

Downloaded from www.pbookshop.org.in

In all cultures a concept of normality exists, but what is considered normal differs widely. Here are some examples: In the West, suicide is considered a sign of emotional disorder; in Japan, it is normal for a samurai in certain circumstances. Among the islanders of Dobu (Melanesia), no sane woman leaves her cooking pots unguarded for fear of being poisoned. To us this behavior would indicate paranoia. Among some Eskimo tribes, the mother accepts the killer of her son in her son's stead. Among the Papuans it is traditional for an uncle and nephew (mother's brother and son) to practice homosexuality. In Tibet a group of brothers inherits their father's second wife when he gets old. A Navajo male may marry a widow with a daughter; later he discards the mother and marries the daughter. It is not unusual for an Arapesh to marry simultaneously a mother and her daughter.[5,6,43,61] These are a few behavior patterns which we consider abnormal, but which are entirely normal in other civilizations.

Ruth Benedict defines normality as "primarily a term for the specially elaborated segment of human behavior in any culture and abnormality a term for the segment that that particular civilization does not use . . . normal is that which society has approved."[5,6]

Benedict's definition of normality of behavior seems to have pragmatic value. Perhaps we may paraphrase it and state that normal is behavior that does not deviate from the established norms of the society in which the individual lives and abnormal is behavior that deviates.

Mental illness, however, is not necessarily a deviation from the norm of society and does not necessarily coincide with abnormality—if by mental illness we mean the failure of the adaptive psychological mechanisms of an organism to counteract adequately the stimuli and stresses to which it is subjected.

For instance, the Melanesian woman who fears poisoning is normal from a Melanesian point of view, abnormal from ours. But, although she is abnormal from our point of view, she is not mentally ill. On the other hand, the paranoid patient who is afraid of being poisoned is both abnormal and sick, because his fear is the expression of the failure of his adaptive mechanisms. The disturbance of the psychological function is manifested in some special basic *forms* which are more or less typical of the whole human race. Sets of formal mechanisms, which recur together with a certain regularity, are at the present time considered as constituting the various clinical entities (see Chapter 23).

These remarks should not make one think that the authors give no importance to social, historical, and geographical factors in the engendering of mental illness. The opposite is true.

The culture is important in at least three aspects. First of all, in predisposing to or in preventing a given mental illness. The over-all cultural climate and the specific ways in which children are raised may bring about some psychodynamic mechanisms which lead to one mental disorder more often than to another. For the importance of culture in predisposing to or preventing manic-depressive psychosis, see Chapter 22 (see also Chapters 6 and 86).

Primitive societies in particular offer excellent opportunities to observe and compare differences of child-raising patterns and their psychiatric impacts. There are some islands where tribes exposed to the same racial, geographic, and economic conditions have developed rather different attitudes toward their children and interpersonal behavior. The Arapesh and Iatmul are tribes who live near each other on New Guinea. The Arapesh treat their children with great gentleness. Passive dependency is encouraged from infancy on. Adolescent boys have a warm affectionate relationship with each other. Homosexuality is not recognized; there is no transvestitism in their ceremonies. Among the Iatmul, hostility is aroused from infancy on. Food is not offered, but must be strongly demanded. The mothers are domineering and the relationship between parents and children is cold. Ceremonial transvestitism is frequent and so is homosexuality, although passive homosexuality is tabooed. The Iatmul use members of other tribes as passive homosexual partners.[64] These are interpersonal relationships quite similar to those we observe in the backgrounds of our homosexuals. The assumption of a cause-effect relationship between this particular family constellation and emo-

Downloaded from www.ebrahilibrary.com

tional climate on the one hand and homosexuality on the other has received valuable confirmation by such observations.

The study of exotic cultures may thus be very useful from the point of mental hygiene in helping us find a psychological attitude which allows the freest development of inherent human potentialities. Biology has rediscovered the concept of progress and so, we believe, has psychiatry. We subscribe wholeheartedly to Sapir's exhortation: "Perhaps it is not too much to expect that a number of gifted psychiatrists may take up the serious study of exotic and primitive cultures . . . in order to learn to understand more fully than we can out of the resources of our own cultures, the development of ideas and symbols and their relevance for the problem of personality."[73]

The second respect in which the study of culture is important is in understanding the content and the particular choice of symptoms. It is obvious that some of the manifestations described in this chapter (for instance the fear of becoming a cannibal) may occur only in a certain environment. Until a few generations ago, schizophrenics believed that ghosts and witches were responsible for the subjective experiences which they could not understand. Today they blame radio, television, hidden dictaphones, and radar apparatuses. The third reason culture is important for the field of psychiatry concerns the responsiveness of the culture to mental illness. We have seen, for instance, how such conditions as amok occur because, in a certain way, they are implicitly accepted by the culture. On the other hand, the greater capacity for tolerance of a certain population may make the recognition of the illness more difficult (for instance, simple schizophrenia in certain parts of Africa) and alter statistics and other data about morbidity, hospitalization, and therapy.

CHAPTER 28

# PSYCHOPATHIC STATES

Hervey M. Cleckley

Downloaded from www.dbraulibrary.org.in

SEVERAL DIFFICULTIES prevent the formulation of a precise definition of our subject. The term "psychopathic personality" was for decades, and until recently, the official and technically correct designation for a large group of disorders regarded by many psychiatrists as having too little in common to justify their being grouped in a single category. Here, all classified together, were patients with schizoid traits and with cyclothymic or paranoid tendencies, sexual deviates of all types, as well as those with antisocial behavior disorders, gross inadequacies of character, and numerous other difficulties. Despite its official status, the term was seldom used among psychiatrists to designate this motley group. Along with its less formal equivalent, psychopath, it has continued to appear in regular discourse among physicians as a means of indicating not the heterogeneous group but one, and one only, of the types of disorders listed therein.

Several years ago the term "psychopathic personality" was discarded in a revision of the nomenclature, and "personality disorders" was chosen as an appellation for approximately the same group as that mentioned above. In the new and currently approved terminology we find this category:

*Personality Disorders*[7]

- Personality pattern disturbance
  - Inadequate personality
  - Schizoid personality
  - Cyclothymic personality
  - Paranoid personality
- Personality trait disturbance
  - Emotionally unstable personality
  - Passive-aggressive personality
  - Compulsive personality
  - Personality trait disturbance, other
- Sociopathic personality disturbance
  - Antisocial reaction
  - Dyssocial reaction
  - Sexual deviation; specify supplementary term
  - Addiction
    - Alcoholism
    - Drug addiction
- Special symptom reaction
  - Learning disturbance
  - Speech disturbance
  - Enuresis
  - Somnambulism
  - Other

Despite these changes, the terms "psychopathy," "psychopath," "constitutional psychopathic inferiority," "psychopathic personality," and "psychopathic states" remain in use among psychiatrists. These terms, unless carefully qualified, do not, in ordinary discussion, refer to primary sexual deviation. I have never heard them employed to designate a schizoid personality, a cyclothymic personality, or someone troubled with somnambulism, speech disturbance, or enuresis. Most of the conditions under this general heading of "personality disorders" are regarded by many observers as chronic and deeply ingrained in what some might call the character or essence of the person. This much they have in common. Thus, also, they contrast with the ordinary psychoneurosis or psychosis which is generally regarded as a pathologic process that may arise in a heretofore well-adjusted man or woman. Some who do not assume that these so-called personality disorders are hereditary or necessarily congenital feel that they are constitutional in the sense that they are basically rooted in the subject's identity. Often these conditions are regarded as borderline states, as falling in an area between psychoneurosis and psychosis or, perhaps, between ordinary conduct and criminal behavior. In the long list of items in "personality disorders," we find that sociopathic personality disturbance, antisocial reaction is defined as follows:

> This term refers to chronically antisocial individuals who are always in trouble, profiting neither from experience nor punishment, and maintaining no real loyalties to any person, group, or code. They are frequently callous and hedonistic, showing marked emotional immaturity, with lack of sense of responsibility, lack of judgment, and an ability to rationalize their behavior so that it appears warranted, reasonable, and justified.
>
> The term includes cases previously classified as "constitutional psychopathic state" and "psychopathic personality." As defined here the term is more limited, as well as more specific in its application.[7]

Some feel that it is unnecessarily confusing to place such a disorder as this, which is, of course, the psychopathy so long familiar to clinicians, in the same general category as such minor and usually unrelated problems as somnambulism, enuresis, and speech disturbance. Perhaps in unspoken recognition of the inadequacies of our official schemes of classification, psychiatrists in practice continue to use the discarded term and to understand the specific disorder that each means to designate by it. At a meeting of the American Psychiatric Association, or at a staff conference at a state hospital, if a physician expresses an opinion to one of his colleagues about a psychopath, it is clearly, and at once, understood that he is not speaking of a cyclothymic or schizoid personality or of ordinary homosexuality but of the grave character and behavior disorder so familiar to most psychiatrists as a distinct and easily recognized entity. What can be correctly said about a psychopath in this sense has little or no relevance to most of the other conditions lumped willy-nilly together under the general category "personality disorders."

Let us then confine our chief attention to this entity, to what is now officially listed as the "sociopathic personality disturbance, antisocial reaction," but what, for brevity and convenience, I shall continue to call the disorder of the psychopath. In their recent and interesting study, McCord and McCord[20] gave this definition: "The psychopath is an asocial, aggressive, highly impulsive person, who feels little or no guilt and is unable to form lasting bonds of affection with other human beings." Few who are familiar with the subject would disagree with this accurate statement. Some might, nevertheless, say that these words could be used for other types of maladjustment—that to depict the astonishing entity of the real psychopath more details must be given. But no matter how much we may add, it is difficult, if not impossible, to convey in language the paradoxical, complex, and subtle elements of the psychopath's behavior to one not thoroughly familiar with it directly by experience.

Let us note here a few features, not with confidence that they will give a firm definition but in the hope that they may suggest some aspects of a serious and baffling disorder. The psychopath does not give the impression, even

Downloaded from www.dbraulibrary.org.in

on careful psychiatric examination, of being ill mentally, or handicapped, or disturbed emotionally. Nor does he, typically, show any attitude or outlook that would indicate he lacked conscience or chose rebellious or antisocial aims. His reasoning is excellent. What he tells of his fealties, his aims, and his understandings indicates that he is normal, reliable, and utterly sincere. Despite this, his past conduct and what will follow is very likely to bear out the truth of Lindner's statement that here we encounter "the most expensive and most destructive of all known forms of aberrant behavior."[27]

## ¶ Historical Background

Some students of the psychopath's disorder trace his appearance in the literature back to Pinel's observations of *manie sans délire* well over a century ago. Pinel was apparently confounded to discover, in patients who showed no disturbance of their reasoning abilities, behavior as maladapted to ordinary human goals as that exhibited by many who were psychotic in the ordinary sense. As quoted in Maughs's[31] excellent historical review, Pinel thus expressed himself: "I thought that madness was inseparable from delirium or delusion, and I was surprised to find many maniacs who at no period gave evidence of any lesion of the understanding."

It is probable that Pinel included in the group he designated as "mania without delirium" other types beside the psychopath we encounter today. Many paranoid patients and perhaps some with major hysteria or psychomotor epilepsy might also have exhibited highly logical reasoning abilities despite their aberrant manifestations. Long afterward, another observer, Trélat, expressed something similar about the psychopath in his paradoxical descriptive phrase, *la folie lucide*. Benjamin Rush's observations also strongly suggest that he observed with surprise patients who, without the influence of delusion or the handicap of irrational processes of thought, carried out inappropriate, unrewarding, and self-damaging acts. He assumed that the explanation must lie in a disorder of the "will."

J. C. Prichard,[40] who is generally credited with the formulation, in 1835, of the concept "moral insanity," encountered patients who, despite freedom from intellectual disorder, behaved in such a way as to force him to the conclusion that in them,

> . . . the moral and active principles of the mind are strongly perverted or depraved; the power of self-government is lost or greatly impaired and the individual is found to be incapable not of talking or reasoning upon any subject proposed to him, but of conducting himself with decency and propriety in the business of life.[31]

Few definitions arrived at today can better convey some important aspects of the psychopath.

The concept of "moral insanity" or "moral imbecility" was extremely influential throughout the latter part of the nineteenth century. Henderson[18] points out with regret that a state of "moral defectiveness" is still legally recognized in Great Britain. During the decades when phrenology was ascendant, faculty psychology was popularly regarded as having been well established by scientific methods. Various disorders were logically but unrealistically described as attacking "the will," the "moral affection," "the emotions," the "sense of deity," and numerous other faculties that were regarded by many scientists of the times as discrete and compartmentalized functions which could, in isolation, become diseased or destroyed. Among the clergy, and elsewhere, voices were raised against these new concepts. An American physician insisted that they were designed "to break down all the safeguards of our Christian civilization, by destroying if possible, all ground for human responsibility." A professor of medical jurisprudence, Dr. Ordronaux, in 1873 concisely summarized the argument of those who denied the existence of "moral insanity" in the following statement: "Our moral nature is, like the mind, a special endowment. It feels, it is conscious. . . . Moral nature knows no alterations in rhythm, craves no rest, never sleeps voluntarily. The only disease to which moral nature is subject is sin."[31]

The concept received support from many outstanding psychiatrists, however, among them,

Downloaded from www.pdfbooksfree.pk

Maudsley, who believed that the emotional balance of a person could be so disordered by illness that he lost the capacity to appreciate moral issues and to conduct himself in a socially acceptable manner, despite his retention of normal cognitive functions. Mercier also came to the conclusion that: "There are persons who indulge in vice with such persistence, at a cost of punishment so heavy, so certain, and so prompt, who incur their punishment for the sake of pleasure so trifling and so transient, that they are by common consent considered insane although they exhibit no other indication of insanity."[18]

Despite the fact that faculty psychology has been discarded long ago, some of the issues that arose out of the concept of "moral insanity" have a substantial resemblance to some of the problems still unsolved today by those who support the M'Naghten rules, or by those who argue that these are obsolete and believe criminal responsibility can be better determined by the rule followed in the recent Durham case. It is of interest that the early psychiatrists who noted that serious personality disorder could exist without a "lesion of the intellect," seemed to regard it as a genuine illness or disability and to distinguish it from ordinary tendencies to depravity, folly, or crime.

Late in the nineteenth century Koch offered the term "psychopathic inferiority" as a designation for patients with severe behavior disorder. This term in its various forms, "psychopathic personality," "psychopathic state," and "psychopath," through the years developed some curious and ironic implications. Though the term "psychopathic" literally conveys the idea of a sick mind, of mental illness, those so diagnosed have been officially regarded as mentally competent and legally responsible, in contrast with the psychotic. In fact, the practice has been followed in some state and federal institutions of classifying patients under the two diagnostic terms: (1) no nervous or mental disease, and (2) psychopathic personality. The purpose of such an apparently paradoxical conclusion is to stress the point that such a person is not eligible for compensation because of a genuine disability, and that he is also to be held legally responsible for antisocial conduct.

We have noted that even in the time of Pinel other, and often unrelated, types of personality disorder were classified along with what we now regard as the psychopath or sociopath. This tendency has served to promote confusion. Until approximately the last decade, the chief efforts devoted to psychopathic personality seemed to consist of gathering more and more essentially dissimiliar entities under a single and vaguely defined label and then, with great academic labor, subdividing the heterogeneous mass into meticulously differentiated types and subtypes. In these serious efforts to make fine differentiations in minute parts of what was not actually a homogeneous entity, Kraepelin[25] listed seven types of psychopath and Schneider[43] ten.

Some of the subclassifications in these categories, such as *The Liars and Swindlers* and *The Antisocial*, seem to apply to all psychopaths, while others, such as *The Depressive, The Insecure*, and *The Asthenic*, seem not to apply to any type of psychopath but to people with profoundly different emotional difficulties. Kahn,[20] whose textbook *Psychopathic Personalities* was for more than a decade regarded as the chief exposition of the subject, lists sixteen types. Actually the disorders described include all the familiar psychoneurotic reactions and a rich variety of human eccentricities and frailties. Only a very determined reader will be able to find anything in this classic study about the psychopath himself. This is no reflection on the excellence of Kahn's work but rather a commentary on the confusion that can arise when psychiatric usage demands that diverse things be designated by the same term.

Adolf Meyer[32] played an important part in separating behavior disorders from the well-known psychoneurotic reactions. Partridge, approximately three decades ago, carefully distinguished the true psychopath and did much to focus attention on his disorder as an entity.[36, 37, 38, 39] Henderson's study, presented in the Salmon Lectures of 1938,[18] stimulated wide discussion and gave a long-needed emphasis. Karpman, over a period of many years, has discussed the psychopath's peculiar in-

Downloaded from www.PsychiatryOnline.org

ability to develop a major and lasting emotional attachment to another person and his persistent failure to grasp in any practical sense the meaning of responsibility.[21, 22, 23]

## Characteristic Clinical Features

The typical psychopath is a person who appears to have at least average, and often unusual, ability and who seems to be clearly aware of the amenities and to affirm the moral code. Frequently he demonstrates superior intelligence and other assets and succeeds brilliantly for a while in work, in studies, and in all his human relations. But inevitably, and repeatedly, he fails, losing his job, alienating his friends, perhaps losing his wife and his children. It is difficult to account for these failures. Seldom can one find adequate motivation to explain why such a person has, in the midst of success, grossly shirked his immediate responsibilities, perhaps abandoned his work at the behest of impulses that seem to the observer no more compelling than a trivial whim. However effective he may show himself to be over a limited period, when given sufficient time he proves himself inadequate. His failures deprive him of what he tells us are his chief objectives, and also bring hardship, shame, or disaster to his wife, his children, his parents, and to all those closely concerned with him.

In addition to such relatively passive types of failure, most fully developed psychopaths also commit aggressive antisocial acts. They forge checks, steal repeatedly, lightly indulge in bigamy, swindle, and show little or no compunction about their sexual behavior, no matter what the consequences may be. Some who have attracted wide public attention have committed murder or other shocking felonies, usually with little or no provocation, often without comprehensible motivation. The majority, despite many conflicts with the law, appear to avoid crimes sufficently grave to result in their being removed from society for long prison terms.

It is difficult to illustrate briefly this striking pattern of repeated failure and willful antisocial conduct. Let us, however, consider one case.

A man in his twenties, who has been arrested seventy or eighty times, as a child was often truant from school. Occasionally, he stole from his parents some object such as a watch or a piece of table silver. These acts never seemed prompted by a keen desire or ordinary temptation. He often sold for a pittance the object he had stolen. When truant from school, he did not engage in anything that the ordinary boy might regard as high adventure. He wandered about, engaging, apparently without enthusiasm, in petty mischief such as setting fire to a privy at the edge of town or shooting at chickens with an air gun. Often he hung idly about a drugstore and, vaguely bored, read comic books. During his teens he bought many articles for which he had no particular use and, without asking permission, charged them to his father. Neither punishment nor reasoning influenced his conduct.

Always this young man seemed to understand that he had done wrong, and he solemnly agreed never to repeat the errors that were causing his family so much sorrow. His appearance of sincerity at such times was impressive. After being apprehended, he freely discussed the gravity of his misdeeds and the importance of avoiding anything similar in the future. His stated resolutions did not seem perfunctory or sullen but rather reflected good judgment, insight, and the utmost candor. Despite this, his maladjustment continued. In the late teens he several times drove off in the automobile of some neighbor or in one he found parked downtown. His father, who had considerable financial means and who was influential in the community, faithfully made restitution for his thefts and other damaging acts. His schoolteachers and the minister joined his parents in efforts to influence him.

Those who dealt with him came, in time, to feel that such a continual pattern of misbehavior must differ profoundly from ordinarily motivated rebellion. After he became old enough to obtain a driver's license, his father, thinking that he might have some strong and specific desire to possess an automobile, bought one for him in the hope that it would influence him favorably. Not long afterward, while out driving, he parked the new car, crossed the street, and took possession

www.freedlibrary.org

of a battered and inferior vehicle which he later abandoned in the country after a minor accident. Subsequently, after driving another stolen car across a state line, he fell into the hands of the federal authorities.

After months of imprisonment he was granted parole. He appeared to have gained real maturity and expressed the most appropriate intentions about his future. For a while he seemed industrious, confident, and happy in work that he had obtained. Then, without warning to his parents (with whom he was living), he disappeared. Approximately a week later his father received a telephone call from a city on the other side of the state, informing him that his son was in jail. Numerous forgeries and swindlings now came to light, as well as an episode of disorderly conduct in a low dance hall. Our subject had there provoked a quarrel and, after a deplorably unpleasant scene in public, had inflicted a minor injury on one of the waitresses who was trying to restore order.

This habit of casually leaving his parents' home at the behest of any whim persisted over the years. He expressed strong natural affection for both father and mother and was most convincing when he spoke of being willing to do anything to avoid causing them sorrow or distress. Nevertheless, after saying he was going down to the drugstore or perhaps to a moving picture, he would sometimes not return that night or be heard from for many days.

Once a friend of the family, who was thought to be very influential with younger people, set out to counsel him about his problems. The older man was astonished, and also gratified at what appeared to be the frankness and courage with which the younger man faced every issue. So impressed was he with the attitude of our subject that he could not restrain admiration. As plans for the future were discussed, the counselor found himself increasingly influenced by the other's expressed aims and his wise analysis of life and its potential values. In fact, he found himself beginning to give thought to his own status and to possible changes that might enable him to live more meaningfully. After this heartening interview the older man drove the younger to his parent's home. Full of confidence, he departed as his new disciple walked in the front gate. The latter did not, however, enter the house. Strolling casually around it, he went out of the back gate and sent no word to his parents until he was again in the hands of the authorities.

The persistence of this young man's inconsiderate, callous, and antisocial conduct is remarkable. Though his parents have many times paid fines for him and otherwise made restitution, they have not been able to prevent him from repeatedly receiving punishment that would be likely to cause an ordinary person to mend his ways. He appears to learn nothing important from experience. Like many psychopaths he is quite familiar with the correct ethical criteria. He claims allegiance to such criteria and can in words formulate excellent rules and plans for himself to follow. One could scarcely imagine that, in the full sense of the word, he is sincere in all this. Yet, like many other psychopaths, he does not seem to be simply lying, or at any rate to be quite aware that he is lying, or even to grasp emotionally the essence of what is falsehood. Perhaps such people mean for the moment to do what they promise so convincingly, but the resolution passes almost as the words are spoken. Perhaps, like other psychopaths, he can foresee and accurately describe the disastrous consequences of the serious misbehavior that he nevertheless repeats time after time.

This young man illustrates several other features that I believe are typical and highly characteristic of the psychopath. He expresses normal reactions (love, loyalty, gratitude, etc.) with a most impressive appearance of sincerity and depth, but the emotional ties and the attitudes he claims fail to deter him from deeds that continually contradict his verbal profession. There appears to be in him a strange lack of insight, or perhaps a total lack of one of the dimensions that make up insight, for after innumerable lies he still speaks of giving his word of honor. He speaks of this in such a way as to indicate that he expects such a pledge to be taken very seriously, despite the fact that he is addressing a group of psychiatrists to whom he has repeatedly demonstrated his untrustworthiness.

Like many other psychopaths he has demonstrated, sometimes over considerable periods, adequate general abilities and occasionally has

Downloaded from www.dbpublishing.com

shown indications of extraordinary talent. But he always throws away what he has gained, what he insists are his chief objectives. No adequate motivation can be demonstrated, or even readily imagined, to account for such conduct. Often the conceivable temptations that appear to underlie his failures and socially self-damaging deeds are extremely trivial, scarcely sufficient to prompt more than a whim if any positive impulse at all. Yet they evoke actions that cause the loss of fortune and the respect of friends, the destruction of marriage, and repeatedly bring about the necessity of his confinement in jails and psychiatric institutions.

The callousness with which this young man ignores the anxiety and distress of his parents suggests an almost total immunity to remorse or feelings of guilt. In situations where one would think his own personal pride is involved he seems similarly immune to shame. Once, while idly seeking an evening's bawdy amusement with several other men, he is said to have legally married a well-known prostitute whose professional services he and his companions had often shared. Neither in anticipation of this step nor afterward did this incident appear to cause him real embarrassment.

## Distinctions Between Psychopathy and Other Psychiatric Conditions

Perhaps a comparison of the psychopath's maladjustment with that observed in other psychiatric disorders may help to etch more clearly the strange and puzzling pattern of his conduct.

### *The Psychotic*

No matter how poorly adapted to handle his affairs competently, and no matter how much the psychopath's irresponsible behavior may endanger the lives or property of his fellows, he is technically regarded as sane and cannot be controlled or protected by the legal measures that are utilized to deal with patients suffering from ordinary psychotic disorders. Unlike the psychopath, most psychotic patients show evidence of irrational thinking that can be demonstrated in court. Many are influenced by delusional ideas or by hallucinations that make their aberrant behavior more understandable and, in an important sense, more rational. If a schizophrenic patient hears a voice that he genuinely believes to be God's voice telling him to kill or to commit some other grave offense, and if his delusional ideas furthermore afford him reason to do so, his proceeding to carry out such a regrettable act is not logically incomprehensible. On the other hand, we see the psychopath repeatedly carry out acts as self-damaging, disastrous, and inappropriate as many that are considered characteristic of schizophrenia, without the delusional or hallucinatory prompting. In contrast with the psychotic patient, the psychopath shows no disorder of cognition at verbal or theoretical levels. Nor does he show the profound depression or the overmastering elation that helps us understand much of the irrational behavior of the melancholic or manic disorders. It is, in fact, remarkable how little capacity the psychopath seems to have for normal feelings of depression even under circumstances where one might deem such a reaction natural and inevitable.

### *The Psychoneurotic*

The patients in this category, though they may suffer severely from unreasonable anxiety, have phobic dreads, disturbing obsessive thoughts, and other unpleasant subjective symptoms, behave rationally in their relations with others and often succeed in achieving consistent success in their work. They are no more likely to carry out antisocial activities than is the average law-abiding citizen. Perhaps there is no symptom so common in this group of reactions as anxiety. Here we have a sharp and profound contrast with the psychopath, one of whose most basic characteristics is relative freedom from anxiety and apprehension. This feature of the psychopath appears to be related to his incapacity for genuine remorse and an inability to avoid repeating actions that would ordinarily produce remorse.

Downloaded from www.dbraulibrary.org.in

### *The Ordinary Opportunist, Lawbreaker, or Criminal*

Most habitual criminals probably show some features of the psychopath. On the other hand, most of them work more consistently toward obtaining their ends and seem to keep in view some definite goal, however socially undesirable it may be. The ordinary lawbreaker seems also to utilize his gains (for example, the money from a robbery) more understandably than does the psychopath, who often makes little or no use of what he attains as the result of deeds that eventually bring him to disaster. Most antisocial activity, however wrong, is purposive in comparison with that of the psychopath. Many criminal acts, such as, for instance, obtaining a million dollars from the bank by embezzlement, are readily comprehensible in terms of strong motivation. The psychopath, on the other hand, often steals small sums or forges little checks while he is affluent and despite the fact that he can, if he stops to consider the situation, clearly foresee that it will cause him to lose an excellent job and disgrace him among his fellows. Even a fleeting whim, a gesture by which to pass an idle moment, may lead the psychopath to squander the only funds available for his family's livelihood during the next month, to commit bigamy, or to attempt the seduction of his best friend's wife.

The ordinary criminal is usually more consistent than the psychopath in avoiding the consequences of his antisocial acts. The psychopath is often ingenious, and his lack of anxiety or feelings of guilt, as well as his appearance of absolute candor, often enable him to avoid detection. He is likely, however, after many cleverly arranged thefts or swindles, to lose interest in safeguarding himself and to carry out another act under circumstances where his detection is inevitable.

Many criminals show loyalty to other members of their group, and some appear to have a firmly held creed of defiance to law and society. In contrast, the typical psychopath shows no loyalty to anything or anybody. He seldom has a formulated and sincerely held attitude of rebellion but usually claims full allegiance to the principles of law and morality.

### *Schizoid, Paranoid, and Cyclothymic Personalities*

These conditions, as we have noted, are grouped together with the psychopath (or sociopath) as if all were types of a basic disorder and deserved the same generic label. Technically, the schizoid personality is someone who manifests, in a milder degree, tendencies and traits characteristic of schizophrenia, but who is not sufficiently abnormal to be called psychotic. The paranoid and cyclothymic personalities are regarded as standing in a similar relation to paranoia and manic-depressive psychosis. Some would also say that the schizoid features in schizoid personality are static, whereas the disorder in schizophrenia is a process of pathology that is likely to progress or perhaps to remit. Cases diagnosed as schizoid personality sometimes prove to be what has been called ambulatory pseudoneurotic schizophrenia.[19]

Though free of hallucinations and distinct delusions, and able to carry on work in the community, some persons of this sort are profoundly disordered within, despite their deceptive surface of rationality and conformity. I have seen a considerable number of these masked schizophrenics who were more dangerous and, in an important sense, more psychotic, than some of the most obviously ill patients in an ordinary state hospital. The schizoid personality, like the psychopath, has a rational surface and is free from the classic evidences of psychosis. Nevertheless, schizoid people show oddness and peculiarity. They often become fanatically concerned with a cause or even a hobby, and may persevere in it indefinitely. In contrast, the typical psychopath outwardly shows nothing at all that suggests oddness or anything that seems to be a clue to any disability. He is, typically, affable, confident, in every way impressive. Though both schizoid personality and psychopathy may be thought of as masked disorders, the mask of the psychopath is far more deceptive. It is infinitely less suggestive of what lies behind it.

In his interesting novel, *Compulsion*, Meyer

Downloaded from www.cbtaditya.org.in

Levin[28] presents Artie Straus (the character based on Loeb) as behaving and apparently feeling as a real psychopath does. On the other hand, Judd Steiner (the representative of Leopold) appears, at least to this writer, as a person who was afflicted with masked schizoid disorder.

### *Specific Sexual Deviation*

No one familiar with the psychopath will deny that his sexual attitudes and activities are far from normal. While it is true that some homosexuals and many sadists may also show features of the psychopath, it seems to me misleading to try to identify the two groups. My own experience has led me to conclude that most psychopaths have a heterosexual orientation but that, as in all major activities, their relations with the other sex are extremely superficial, impersonal, and, in comparison with those of the ordinary human being, virtually meaningless. Here, as with parents or with children, they seem incapable of loyalty or of deep need. None of the emotional attachments they claim are genuine or lasting. Typically, they give the impression of sincerely devoted lovers and often evoke the loyalty of mates who suffer repeated outrages and betrayals at their hands.

Some psychopaths indulge occasionally in deviated sexual acts with real homosexuals, probably less through a specific tendency in this direction than through lack of restraint and compunction toward acts generally regarded as distasteful or dishonorable. A few psychopaths I have known sometimes resorted to homosexuals in order to obtain easy money at times when it was not readily available elsewhere. When the suffering and humiliation every psychopath brings upon his mate are contemplated, one might be tempted to say that all of them are truly sadistic. It is my impression, however, that the usual psychopath does not derive specific erotic pleasure either from physically hurting a sexual partner or from causing his wife to suffer through his neglect, his criminal or disgraceful acts, or his gross infidelity.

If true sadistic tendencies are combined with the psychopath's lack of compunction, a formidable menace to others results. According to evidence brought out at the trial of Neville G. C. Heath, this man followed an extremely irresponsible career for many years.[5] On several occasions he was court-martialed and discharged from the military service. Forgeries, thefts, housebreaking, impersonation of an officer, fraud, and many elaborate episodes of swindling brought him repeatedly to the attention of the police. The history available about this handsome, attractive delinquent prior to his two sadistic murders strongly indicates the typical psychopath.

These murders were acts of memorable brutality and horror. Each of the two young women tortured and killed by Heath within a period of three weeks was cruelly butchered. The sexually sadistic quality of Heath's behavior on these two occasions is made plain by the nature of the mutilations. A nipple was bitten entirely from one girl's breast. With the other girl, this had almost been accomplished. At the autopsy both showed that some instrument, perhaps a poker, had been thrust with violence into the vagina, rupturing it and damaging the abdominal viscera. One body had been lashed severely. The abdomen of the other had been ripped open. Heath is described as being extremely calm and poised after these deeds, and entirely free of remorse. After the first murder he spoke with great interest about accounts of it in the newspapers, expressed opinions about how the gruesome wounds might have been inflicted, and even communicated with the police, offering to help them discover the murderer.

It is my opinion that only a small proportion of typical psychopaths commit murders. Those who have this propensity are probably the most dangerous and the most ruthless of all criminals. They are also the most likely to repeat their crimes, no matter what reformation they claim to have achieved. They are unmatched in giving the impression of profound sincerity, in swearing a convincing allegiance to all that is good and lawful.

### *The Mental Defective*

Ordinary mental defect, the simple lack of sufficient intelligence to foresee accurately the

Downloaded from www.cbtlibrary.com

consequences of one's acts in all the complications of this life, readily accounts for repeated failure in some people, and also for some crime, misdemeanor, and folly. If the deficiency is severe, it may render the person incompetent to carry out the ordinary affairs of life. The results of such a handicap as this are easily comprehensible. In contrast with the psychopath, mental defectives show poor judgment and reasoning power that can be demonstrated in theoretical situations. They cannot construct, in words, brilliant plans for the future or discuss their affairs in such a way as to give a convincing impression of wisdom.

The typical psychopath, in contrast, shows no evidence of a cognitive defect that might account for the failures and follies of his career. Not only on psychometric tests but also by his actual accomplishment during periods when he is putting his abilities consistently to use in constructive projects, he may demonstrate superior intelligence. His disorder cannot be detected except through study of the full conduct of his life, the goals he actually seeks, what distracts him from ordinary aims, his affective relations with family and friends, and his detailed interaction with society.

## *Other Character and Behavior Disorders*

Though delinquency is not primarily a medical term, it is useful to designate milder, less persistent, and more circumscribed disorders of behavior and frictions with the social group. The word suggests a maladjustment not expressed in felonies or other major transgressions but in a repetitious series of annoying improprieties, failures, misdemeanors, or derelictions of duty. As with the psychopath, adequate motivation is not often obvious for the pursuit of these milder patterns of delinquent behavior. Close study may, however, reveal conflicts, frustrations, and dissatisfactions that are prompting such conduct as a revolt or protest against an unpleasant situation. Healy long ago was impressed by the purposive nature of delinquency and pointed out that under similar conditions of rejection or insecurity one child withdraws and develops anxiety, while another, apparently in response to the same stimulus, becomes defiant and engages in various types of mischief.[16,17] It is quite possible that the true psychopath's grossly self-defeating and antisocial way of life may also represent some graver and more persistent revolt of this sort. Convincing evidence for this is, in my experience, much more difficult to find in the psychopath.

Probably most people, in the process of growing up, engage in destructive pranks and other socially unacceptable acts. In a good many who later become well-adjusted and law-abiding members of the community, such behavior during adolescence may include some truly regrettable deeds and may extend over a long period of time. Some adults show persistent delinquency about paying bills but do not show the psychopath's generalized irresponsibility. Others conduct themselves promiscuously and deceitfully in sexual matters but remain reliable in financial affairs. The milder and more circumscribed behavior disorders, particularly those manifested in the teens, should not be precipitately identified with psychopathy.

## *The Alcoholic*

Psychopaths, when drinking, often indulge in outlandish or outrageous behavior. Some of them, of course, become alcoholics. On the other hand, though the alcoholic often neglects his responsibilities and fails in his goals because of the disabling effects of excessive drinking, he does not usually show the incapacity of deep affection and the callousness that careful scrutiny reveals in the psychopath. Many alcoholics drink too much because of anxieties and emotional stresses to which the psychopath is immune. The impulse in the alcoholic to evade his problems by the influence of drink often leads to a vicious circle whereby his lack of sobriety makes additional problems for him or makes worse his old ones. Often, serious patterns of self-defeat develop. When the psychopath drinks excessively he is seldom, if ever, driven by distress and conflict but seems to use alcohol to catalyze his unengaging and socially unacceptable antics.

## ¶ Medicolegal Status

The psychopath, by whatever term he might be labeled, has been almost universally judged sane by the courts and regarded as free from psychosis by physicians. In the determination of both legal competency and legal responsibility, it is, traditionally, the subject's reasoning abilities that are investigated and evaluated. Though competency and responsibility are often thought of as approximately equivalent, there are some important legal differences that the physician should consider.

Urgent questions of competency sometimes arise when it is thought by a patient's family that he is in need of treatment in a hospital. If he denies this need and refuses to go, as indeed many psychotic patients do, before it is possible to send him to a hospital for treatment against his will he must be pronounced incompetent by the court. If such a patient shows a gross derangement in his reasoning, expresses delusional ideas, and reports hallucinations, there is little chance that the court will fail to commit him to an institution. Few will question the incompetency of a man who expresses himself thus: "Gentlemen will you come to . . . and idenafy none ministrative body that receives the life generated by fourth patented generator below sound. . . . Until you gentlemen decide further What my occupation is you may as well announce me as comforting 35 Whirlpools below sound."[3]

The man who, in clear, well-formulated language, claims that the Masons or the Knights of Columbus are persecuting him because of the uranium in his blood will also be considered insane. Though such derangements of reasoning usually play the chief part in technically establishing incompetency, there are often other factors that may exert considerable influence on the lunacy commission. Prominent among these are such questions as: Is this man a serious menace to himself and others? Is he incapable of sustaining his life if left to his own devices?

As all psychiatrists realize, many patients who maintain bizarre delusions and continue for years to experience hallucinations do no harm to themselves or to others. These manifestations, it is true, indicate that they are psychotic. But some psychotic people are able to adjust themselves as unrestricted members of the community, to avoid harmful or annoying conduct, and even to support themselves. Among numerous examples known to me is a woman who has been hearing a voice for many years. She believes it comes from her stomach. Often she heeds its advice, which, on the whole, has been fairly sensible. If this woman developed tendencies that threatened her own safety, such as refusing to eat, or meditating half the night in the privacy of her own back yard clad only in a nightgown during a blizzard, the fact that she has auditory hallucinations would ensure and expedite her commitment.

The psychopath whose competency is questioned will show no defect in his reasoning in so far as this can be demonstrated in court. He remains free of delusions and hallucinations, and everything he says is likely to give the impression that he has excellent judgment and the best of intentions. If he opposes efforts to send him to a hospital, it is impossible to show technically valid grounds for commitment, even though he has demonstrated for years a far greater maladjustment in the community than has the average patient who is sent to a state hospital. Since there may be good reason to believe that he will seriously injure or even kill his wife, and a virtual certainty that he will continue in fraud, larceny, and forgeries, impoverish his family, seriously disturb the normal development of his children, and otherwise gravely and persistently damage society, the need to bring him under some sort of control often far exceeds such a need in patients belonging to any other diagnostic group.

It is true that the wife whose life is threatened may take out a court order in an effort to protect herself. A true psychopath is not likely, however, to be deterred by such a measure if his fancy really prompts him to kill her. Those who are unfamiliar personally with the psychopath are likely to think that his forgeries, thefts, assaults, and other repeated conflicts

Downloaded from www.dbraylibrary.org.in

with the law will keep him sufficiently controlled through imprisonment. This does not usually occur. Only those who have followed the career of many psychopaths over the years can appreciate the magic skill by which they evade lasting confinement and return again and again to their old damaging pursuits.

The psychopath characteristically makes an excellent impression in court when he wishes to avoid commitment. He makes a similar impression before parole boards. When on trial for a legal offense, if it serves his purpose to appear afflicted with disorder, many psychopaths are able to point out that they have been in mental hospitals a half-dozen or a dozen times. Some very cleverly simulate the manifestations of ordinary psychosis. A good lawyer, reviewing the formidable record of purposeless folly and self-defeat, seldom finds it difficult to persuade the jury that the defendant is not normal, that mentally or emotionally he is unbalanced and should receive treatment, not punishment. Time after time, decisions are made to send these people to a psychiatric institution instead of to jail. There they are diagnosed as sociopathic personalities and promptly released. The families of many psychopaths, still clinging to the hope that they will change, repeatedly pay fines and make restitution to those who have been damaged. Such kindness and hope result in the psychopath's remaining free to do additional mischief. If the wife and parents of such a man finally decide to let him take the consequences of his actions, there are usually several women at hand whom he has somehow charmed into the belief that he is at heart a most honorable gentleman, who is misunderstood and now in need of their support. They use every influence available to help him evade legal consequences and have "another chance."

I do not maintain that real psychopaths never serve terms in prison. Those convicted of felonies undoubtedly are segregated from society, sometimes for long periods. It remains, however, a remarkable fact that so many psychopaths repeatedly evade penalty and restriction and remain free to continue their damaging conduct. During recent years, in some courts with which I am familiar, extremely disordered psychopaths have occasionally been pronounced incompetent and sent to psychiatric institutions against their will. In such instances concrete evidence in their behavior was carefully weighed and apparently regarded as of more pertinence to the question than the intact verbal reasoning demonstrated by the psychopath.

In decisions about competency and commitment, a person is ordinarily examined by a lunacy commission appointed by the court and consisting of two physicians and a lawyer. When the psychopath is on trial for breaking the law, he is ordinarily tried before a jury. As we have noted, under these circumstances he often succeeds in using the impressive accumulation of outlandish misconduct in his past to evade or partially evade punishment. When the psychopath commits a maximally grave felony, such as murder, the question not of competency but of responsibility emerges as a crucial issue. This is a question to be decided not by a commission of experts but by a jury of laymen. In the past, typical psychopaths have nearly always been adjudged as having full legal responsibility and thus as being subject to the ordinary penalties for their crimes.

In most of the United States and elsewhere in the English-speaking world, the jury determines responsibility by the well-known M'Naghten rules. According to Hall, the core of these rules lies in these words:

> . . . to establish a defence on the ground of insanity, it must be clearly proved that, at the time of committing the act, the party accused was laboring from such a defect of reason, from disease of the mind, as not to know the nature and quality of the act he was doing; or, if he did know it, that he did not know he was doing what was wrong.[14]

Interpreted literally or narrowly, these rules seem to confine attention to pure cognitive processes which, in the psychopath, certainly show no demonstrable disorder. Thus interpreted, the rules would also establish legal responsibility in many schizophrenic patients. Surely every psychiatrist has seen delusional and hallucinating patients who could clearly

downloaded from www.pdfchm.com

express their knowledge that it is wrong to kill and also to steal. Such patients, unlike the psychopath, may also apply this knowledge to their conduct and refrain from malfeasances small and great.

The rules have, in rare instances, been interpreted so narrowly that a psychotic person driven to murder by his delusions has been adjudged as legally responsible. Guttmacher[12] cites the case of a schizophrenic man who was heard to say that he knew it was wrong to kill but that he must (for delusional reasons) nevertheless kill a man he held responsible for his wife's death. Voices kept telling him that it was imperative for him to carry out this deed in order for her spirit to obtain peace. Because of this man's having said he knew it was wrong to kill, the court held that he was a responsible agent.

Generally, the M'Naghten rules are not so narrowly interpreted. If the defendant is influenced by delusions, or hallucinations, most jurors today are likely to concede that his appreciation of the nature of the act he committed was probably distorted. Evidence of so grave a mental disorder would be considered by many as necessarily interfering with adequate evaluation of his conduct.

In a relatively small number of states the concept of "irresistible impulse" may also be brought forward as grounds for establishing the legal irresponsibility of a defendant. Though such a concept may be thought of as a step to avoid confining the judgment to a theoretically disparate faculty of cognition, in the opinion of many, it leaves the door open for dubious and sometimes specious arguments that can extend all the way into the philosophical areas of free will and determination. When the presence of an irresistible impulse is claimed, the thoroughgoing determinist may find it difficult logically to maintain that any defendant under any circumstances is legally responsible.

True folly can arise when one attempts to examine a "will power" verbally isolated from the integrate of human functioning and to localize illness in such a hypothetical faculty. The question of whether a criminal impulse is pathologically strong or whether what attempts to resist it is pathologically weak can lead readily to debates of great impracticality and irrelevance. Jerome Hall makes an excellent point when he emphasizes the fact that a widespread use of the concept of irresistible impulse to confer irresponsibility for crime would have the effect of making "irresistible an impulse which now is resistible and resisted because of penal laws."[14]

Many psychiatrists and others concerned have condemned the M'Naghten rules as unrealistic, worthless, and misleading. It has often been said that they are based on long obsolete concepts of human personality function, that they completely ignore important scientific discoveries of psychiatry, which, if utilized, would now enable us to determine responsibility with far more accuracy. Some opponents of these rules are sweeping in their rejection. Zilboorg[47] expresses himself thus:

> When they . . . ask me whether the defendant in the dock is in my opinion insane, I must candidly state, if I am to remain true to my professional knowledge and faithful to my oath, first that I do not understand the question and, second, that since I don't understand the question I do not know whether the defendant is insane or not. I admit the situation is embarrassing and puzzling to all concerned, but it is beyond my knowledge, and power to remedy or alleviate it.

Opponents of the M'Naghten rules have hailed as a major step forward in medicolegal matters the decision of Judge Bazelon in the Durham case.[15,29] In coming to this decision, the court formulated a new test of criminal responsibility which has been enthusiastically acclaimed as a means of allowing scientific facts to be applied to this problem. Judge Bazelon expressed the opinion that "in attempting to define insanity in terms of a symptom (i.e. irresistible impulse or moral knowledge), the courts have assumed an impossible role, not merely one for which they have no special competence." The essence of the new test is contained in these words, "An accused is not criminally responsible if his unlawful act was the product of mental disease or mental defect."[8]

Downloaded from www.dbraulibrary.org.in

This test apparently broadens the field of inquiry and gives the psychiatrist-witness all the freedom he has been demanding to apply his modern scientific knowledge of the human mind and its disorders. Some psychiatrists, however, are less confident than others that today we possess sound knowledge that regularly affords us the final answer to such a question. Despite the optimism with which many psychiatric writers, who condemn the M'Naghten rules, speak of the scientific facts that modern psychiatry can bring to bear in efforts to determine responsibility, there are others who would grant that the outstanding neurologist Walshe is not entirely in error in the words that follow:

It is important to realize that there is no generally accepted body of psychiatric doctrine or practice, but that there are, on the contrary, many conflicting and incompatible schools of both, while the psychiatric body is rent with fierce intestine feuds on matters both of theory and practice. There is no science of psychological medicine in the sense in which the term "science" is used by natural scientists. Psychiatry and psychological medicine is, in fact, not a branch of natural science, and, if it has any scientific affiliation at all, it is with historical science. . . . Thus we see psychiatry swinging perpetually between allegory and machinery in its theory and practice, from the attempted exegesis of dreams to what in a barbarous neologism is called psycho-surgery.[5]

Jerome Hall[14] maintains that the M'Naghten rules, if used sensibly and in the light of concepts generally agreed upon in psychiatry today, constitute a valuable instrument which should not be discarded. Psychiatrists today do not think of personality function in terms of abstract and isolated faculties. It is difficult to conceive of a person "thinking" without also "feeling." One is not likely to experience volition entirely free of emotion. What has been observed of human function strongly indicates that it is integrated, that it cannot be broken down in actuality into the fragments such words as those above indicate. With this in view, Hall makes some excellent points in support of these rules:

This view of the participation of the rational functions, including evaluation, does not imply any depreciation of the role of the instincts in normal conduct. For consistently with this theory, one asserts the fusion of various aspects of the self. This means that moral judgment ("knowledge of right and wrong") is not reified as an outside, icy spectator of a moving self; on the contrary, the corollary is that value judgments are permeated with the color and warmth of emotion, as is evidenced by the usual attitudes of approval that coalesce with right decisions. Indeed all action, especially that relevant to the penal law, involves a unified operation of the personality. . . . The M'Naghten rules provide an analytical device for dissecting this action.[14]

In my opinion the questions of responsibility and competency, as far as the psychopath is concerned, should be considered separately. I strongly believe that any patient's demonstrated incapacity to handle his responsibilities and to avoid bringing serious trouble to himself and others should be given weight in decisions about competency and commitment. In this I am in agreement with McDougall[30] who wrote that the true criterion for all such decisions should be: "Can the patient be trusted to look after his affairs without undue risk to himself and others?" He then adds, "And there is no other criterion." I do not think it will ever be possible to bring the psychopath under sufficient control to make practical efforts toward the solution of the grave problem he poses until this criterion is regularly given due consideration in questions of commitment.

If one follows the new rule devised by Judge Bazelon, the question of responsibility in the psychopath would depend chiefly on whether one found it correct to define his abnormality as a "mental disease or mental defect." It has long been customary in psychiatry and law to distinguish sharply between this abnormality and all the conditions to which the terms "mental disease" or "mental defect" are applied. Few psychiatrists could doubt that crimes committed by a psychopath are the product of his aberration. The psychiatrist-witness's opinion would, inevitably it seems, depend on whether or not he classified this aberration as mental. This decision, it seems to me, would in turn substantially depend on whether or not this term is limited

Downloaded from www.dbraulibrary.org.in

in its meaning to an assumed disparate faculty of cognition. Thus, as far as the psychopath is concerned, it would appear that the psychiatrist in court is faced with essentially the same decision, whether he testifies under the M'Naghten rules or the Durham test. Either may be interpreted narrowly and confined to mere cognition or more broadly, as Jerome Hall[14] suggests that the M'Naghten rules be interpreted. Despite some very important achievements in the last half century, psychiatry does not today, in my opinion, possess newly discovered and well-established facts which afford a scientific answer to the ultimate questions that arise in determining responsibility.

## Diagnostic Criteria

Perhaps it may be useful to list the major points that I have found particularly characteristic of the typical psychopath whose life pattern might be taken as the core of a general concept of this disorder.

### *Unexplained Failure*

There is no cognitive deficiency in the ordinary sense but usually at least average and often distinctly superior intelligence, as determined in psychometric examination or by the easy achievement of temporary success in studies or business for as long as his abilities are consistently employed. Despite this, he inevitably fails in every constructive activity he undertakes.

### *Undisturbed Technical Intelligence*

The good reasoning abilities with which he is endowed are not disrupted or disorganized, as in psychosis, nor are they distorted by the influence of delusions or hallucinations. Nothing is demonstrable in his thinking at a theoretical level that accounts for the irrationality of his conduct in life.

### *Absence of Neurotic Anxiety*

He is not handicapped by anxiety, phobias, obsessions, hypochondriacal preoccupations, or other manifestations commonly regarded as psychoneurotic. He is often poised and at ease in many situations where the average person would be tense and apprehensive.

### *Persistent and Inadequately Motivated Antisocial Behavior*

Nevertheless, he persistently follows a pattern of antisocial behavior that is usually also self-defeating and frustrating to all the aims he claims to pursue. No adequate motivation can be found for such behavior, and often the stimuli that provoke it seem scarcely comprehensible.

### *Irresponsibility*

Despite the strong impression he gives of being a steadfast and reliable person, he will, eventually, ignore even the gravest of responsibilities and often for the most trivial of reasons. Such failures do not, of course, occur immediately or uniformly. Not all his checks bounce. He is not arrested daily. But, after gaining security for himself and the confidence of others, he will invariably shrug off his major obligations and throw away all that he has gained.

### *Peculiar Inability to Distinguish Between Truth and Falsehood*

His disregard for truth is remarkable. Usually, he seems confident and at ease when making a solemn promise he will never keep, or when attempting to exculpate himself from charges of misconduct. Whether there is a good chance that he will get away with a lie or whether detection is almost certain, he shows no sign of perturbation and coolly maintains his position. While committing the most serious of perjuries, it is easy for him to look anyone calmly in the eye.

Often the solemn falsehoods he perpetrates are entirely unnecessary. For example, a psychopathic husband, already divorced by his wife, wrote in the footnote of a letter to her matter-of-fact instructions about the insurance policies he was sending under separate cover to provide for her and their children. There

Downloaded from www.dhara-library.org.in

were no insurance policies and he had never seriously considered providing for his family in this way or in any other. He was well aware that he would soon be found in falsehood about this, and he had nothing to gain materially by such a lie.

### *Inability to Accept Blame*

Though he brings disaster repeatedly upon himself and others, he never accepts responsibility for it. As long as possible, he denies any part in what has occurred. When the facts are too plain for this, his expressions of regret may be eloquent and convincing, his plans for restitution admirable. His actions, however, indicate that no appreciable remorse has been experienced. It is doubtful if he is capable of feeling sufficient guilt or shame to influence him beyond the moment.

### *Failure to Learn by Experience*

Despite the unimpaired reasoning ability that he demonstrates in theoretical situations and the foresight with which he describes his plans for the future, he shows extremely defective judgment when he becomes an actual participant in the affairs of life. No matter how many times he comes to frustration or disaster, he does not learn by such experience to avoid the type of conduct responsible for his failures.

### *Incapacity for Love*

Though often cordial and apparently affectionate, the psychopath's behavior strongly indicates that he is incapable of genuine love, that he cannot form enduring personal attachments. This is not to say that he does not react with minor and ephemeral affect of this sort. He is also often eloquent and convincing in speaking of his devotion and his personal commitments. Psychopaths of both sexes, through this appearance of warmth and sincerity, often win the loyal love of a mate who endures repeated outrages in the relation. Though the psychopath may show transient generosity in many small matters, in crisis and in the continuing pattern of his conduct a formidable egocentricity emerges. Despite a ready and sparkling display of shallow feelings, particularly in trivial relations, in all his major affective relations there emerges evidence of astonishing callousness.

### *Inappropriate or Fantastic Reactions to Alcohol*

It has been noted that the ordinary alcoholic should not be identified with the psychopath. Though some psychopaths do not drink at all, many indulge in sprees during which alcohol seems to catalyze their tendency toward uninviting, buffoonish, or destructive behavior. Often a small amount of drink will bring out in psychopaths what would never emerge from a normal person, even in extreme intoxication. One psychopath, after two highballs, began spitting on the floor of his host's living room. Another, after more liberal use of stimulating potations, climbed a tree in the residential section and, in broad daylight, undressed himself, while hurling imprecations at a policeman below.

### *Lack of Insight*

Though many observers regard the psychopath as having insight because of what he can express in words about himself and his situation, his actions repeatedly demonstrate that his grasp or realization of what he has expressed is insubstantial. Often, it seems little more than an empty verbalism, not really insight but a clever mimicry of insight. He is remarkably lacking in the capacity to see himself as he appears to others and to view his conduct as others see it, to evaluate the sorrow he brings and the damage he does to others. The nature of this limitation has been several times illustrated for me by brilliant psychopaths, who knew me to be painfully familiar with their astonishing records of dishonesty and irresponsibility, but who nevertheless submitted my name as one to recommend them for positions demanding trustworthiness and stability.

Downloaded from www.dbraulibrary.org.in

### *Shallow and Impersonal Responses to Sexual Life*

The sexual life, in both male and female, is almost inevitably promiscuous. Some have concluded from this that the psychopath is driven by extraordinarily powerful sexual urges. I believe that this is unlikely. Even the feeblest of urges would have no difficulty in gaining expression against what forces of compunction or shame might, in the psychopath, be mobilized against it. Usually, psychopaths seem no more strongly motivated in their sexual irregularities than in petty thievery, the passing of a bad check, or the numerous other disloyal, shameful, and dishonorable acts they commit of a nonsexual nature. The sexual experiences of these people are probably impersonal, emotionally trivial, and poorly integrated with their alleged goals.

### *Suicide Rarely Carried Out*

A few decades ago, most psychiatric textbooks described the psychopath as often having strong suicidal tendencies. The percentage of suicides among the group classified as psychopathic personality reported by some observers was indeed impressive. I am inclined to believe that such statistics reflect not a tendency to suicide in a psychopath but in others included, as I have noted above, under the same general category. The psychopath, or sociopath, in the sense to which I am restricting the term, often threatens suicide or even carries out sham efforts, sometimes with high drama, to give the impression he has tried to end his life. As a group, these patients have impressed me as lacking the capacity for remorse, true depression, or the deep realization of failure that forces patients with other disorders to suicide.

The position in which a psychopath sometimes finds himself, after a succession of self-imposed failures, acts of deep disloyalty, public episodes of disgraceful behavior, or serious crimes, is often one that would cause limitless despair in a normal person, that would make strong impulses toward suicide readily understandable. Having thrown away all that man ordinarily desires, with his family in disaster and himself in confinement, the psychopath, though he detests the restriction of prison or hospital that he has brought upon himself, appears almost immune to the sort of anguish and despair that would be inevitable in another. It is my belief that the rarity of suicide among true psychopaths is an important characteristic.

### *Persistent Pattern of Self-Defeat*

Many psychopaths, it has been noted, succeed for a while, sometimes brilliantly, in various worth-while pursuits. In surveying the long and impressive record of failures, disorderly activities, and arrests that accumulate behind a psychopath, these temporary periods of industry and effectiveness are sometimes overlooked. One of the truly remarkable features of this life pattern is that a person who shows so concretely the ability to succeed will throw away all he has gained, and apparently what he desires, for no reason comprehensible to others. Sometimes these people, after periods of excellent adjustment and apparent contentment, seem deliberately to go out of their way to bring disaster upon themselves. The intricate pattern of gratuitous folly, nonsensical failure, and unprovoked social aggression repeated over and over may indeed impress one as an expression of madness. The careful observer may be forced to ask himself: If this is sanity, can it be more than sanity in name only?

## ¶ Etiologic Factors and Attempts at Interpretation

For many decades it was generally assumed that the psychopath's abnormality must be the result of hereditary defect. Numerous statistical studies seemed, indeed, to furnish convincing evidence for this assumption. Almost all the early investigations of this sort were made on heterogeneous groups. Many included patients with gross physical defects and other signs thought to be indicative of neuropathic taint. Even in more recent studies,

Downloaded from www.chiranjivi.org.in

it seems likely that other patterns of delinquency as well as schizoid, paranoid, cyclothymic personalities, and other conditions listed under the general category "personality disorder" may be included with the primarily sociopathic reaction. Many of the reports during the last few decades on investigations to determine the influence of hereditary factors have been contradictory. Nevertheless, the very recent work of Newkirk,[31] indicating that hereditary factors are probably important, deserves careful consideration. Thompson[46] also has presented evidence to support the contention that organic neurologic disorder underlies psychopathic behavior.

Some electroencephalographic studies[10, 44] suggest that a significant proportion of psychopaths show abnormal tracings. These findings certainly imply an organic basis for the disorder. Other reports, however, indicate that no higher incidence of abnormality appears in the electroencephalographic records of this group than among normal people.[45] It is difficult, at present, to maintain that the electroencephalographic investigations have established generally accepted evidence for or against a neurologic basis for psychopathy.

During recent decades increasing emphasis has been placed on the influence of environmental or psychogenic factors. Some observers appear to be convinced that these play the major part in causing the psychopath's disorder. Positive statistical evidence to support this explanation, as far as I know, is also lacking. Numerous dynamic explanations of the psychopathic pattern of behavior have been brought forward, and through analytic methods some investigators have found what they regard as the primary causal influences in early childhood or infantile experience. Of such efforts the work of Franz Alexander[2] has probably been most influential. Through psychoanalytic investigation he came to the conclusion that severe unconscious conflicts are within the typical socially destructive patient, that these give rise to impulses that are acted out in behavior rather than, as in ordinary psychoneurosis, experienced as anxiety. Alexander used the term "neurotic character" to designate such a disorder, and many psychiatrists have regarded this as a synonym for the psychopath. Others make a distinction.

Lindner[28] reported investigations by hypnoanalysis through which he believed he discovered the origin of a psychopath's disorder in an incident that occurred when the patient was between six and eight months of age. Lindner felt that he obtained evidence under hypnosis, through preverbal memory, that the patient was at this tender age terrified by the sight of his father's penis (during intercourse between the parents), and that castration fear was a major factor in his adopting a psychopathic mode of life. Karpman,[22] though he believes that some patients regarded as psychopaths are constitutionally abnormal, maintains that the behavior of most represents a reaction to unconscious neurotic conflict. Some physicians have regarded the psychopath as a product of extreme parental spoiling. Others have concluded that convincing evidence shows early parental rejection often to be a crucial factor.

My own experience with psychopaths certainly does not suggest that they appear only in families of inferior moral or intellectual levels. A good many of the most seriously disordered psychopaths I ever encountered had successful and sometimes very distinguished antecedents. I have not regularly encountered any specific type of error in parent-child relation in the early history of my cases. This, of course, does not afford proof that such specific errors may not play the regular and important role in causation assumed by some observers. I am increasingly impressed with the difficulty in obtaining objective and reliable evidence of what was felt twenty or thirty years ago between a child of one year (or of three) and his parents. Assumptions about infantile, and even intrauterine, experience are sometimes made solely on the basis of analogy and symbolism. These methods can be used with such elasticity that it is not difficult to "discover" in the unconscious virtually anything the investigator chooses to seek.[4] I do not believe that convincing evidence of the causal factors and developmental pattern of psychopathy has yet been established.

Aside from its possible causes, the nature of the psychopath's disorder brings up puzzling

Downloaded from www.jhnlibrary.org

questions. Why should a person who demonstrates all the adaptive facilities needed for a successful life regularly come to such egregious failures? In his outer aspect he appears to be functionally perfect. Yet his behavior suggests that a deep disorder, involving the basic sources of emotion and judgment, must prevent him from utilizing correctly the intact outer mechanisms of personality that he so clearly possesses. This concept may be clarified by a comparison with semantic aphasia.

In this deep, and one might say concealed, speech disorder, the patient can often speak words and sentences correctly or even fluently. Yet such a patient does not understand what he has put into language. Though his peripheral mechanisms of speech function and produce the words as sounds, they do not really express their apparent meaning. In fact, it is probably accurate to say that speech in this disorder, however well formulated, has no meaning and is not language at all. In the sense in which the term is used to designate this type of speech disorder, one might conceive of the psychopath as being disabled by a *semantic* personality disorder. The true abnormality is thoroughly masked by the surface, by the unimpaired mechanical operation of all functions that can be perceived by the observer. But, lacking the connections with, and the correct motivation from, a normal inner core, these peripheral facilities are not sanely employed. They produce, instead, only a mimicry or illusion of true sanity.[3]

## ¶ Treatment

The successful treatment by Freudian psychoanalysis of patients regarded as psychopaths has occasionally been reported.[42] Lindner,[28] using hypnoanalysis, also reported remarkably good results with several cases in relatively brief periods of therapy. Karpman[22] has expressed optimism about the beneficial effects of prolonged psychotherapy on the majority of those classed as psychopaths, who, he maintains, are actually neurotic. A minority, whom he designates anethopaths, are regarded by him as being emotionally abnormal at the core of the personality and thus unamenable to treatment. A very few workers have reported worthwhile results with electric shock treatment and with lobotomy operations. Rarely, one encounters statements that improvement was obtained by the use of drugs, by counseling, and by various other methods of psychotherapy.[29] It is generally agreed that punitive measures such as imprisonment are not likely to produce favorable changes in the real psychopath.

The work of Aichhorn,[1] Redl,[41] and others with milieu therapy, particularly in dealing with youthful delinquents whose behavior suggests that of the adult psychopath, has attracted a great deal of attention. Some who have used these or similar methods are more optimistic than most psychiatrists who have dealt extensively with adult psychopaths. The McCords,[29] in their recent book *Psychopathy and Delinquency*, attempt to evaluate the curative effects of milieu therapy on very young boys (average age eleven years) at the Wiltwyck School in New York where in "a warm permissive environment . . . individual and group therapy combine their techniques." After a painstaking study, including the application of psychological tests designed by the authors specifically to measure psychopathic tendencies, the McCords conclude that, "the Wiltwyck environment, 'a new situation' causes radical alterations in personality." They add: "When the children return to their homes (generally in slum neighborhoods) the 'situation' again changes, and their attitudes and actions may change with it. Yet the extent of change in the boys' characters offers substantial hope that the effects of treatment are permanent."

Though, as noted above, a few have been encouraged about psychoanalytic treatment for psychopaths, other analysts are far from optimistic. Phyllis Greenacre[11] points out that favorable changes are often illusory and quickly vanish, leaving "the fundamentally unsound organization of the personality of the psychopath . . . not . . . much influenced or even touched." On the basis of my own experience with patients of this type who have been treated by competent analysts, I find myself today in agreement with O'Malley who in

Downloaded from www.dbeilibrary.com.cn

1924, after reviewing the results of analytic treatment in psychopathic personality, had to conclude that it "has proven a failure."[35] All other methods available today have been similarly disappointing in well-defined adult cases of this disorder with which I am directly acquainted.

It seems to me, nevertheless, that important steps can be taken toward arriving at a better solution for the many problems posed by the psychopath than any existing today. First of all there is needed a more general recognition of his disorder as a genuine illness or psychiatric abnormality, a specific pattern of malfunctioning that, in severe cases, causes maximal disability and makes it impossible to maintain his role as a responsible member of the community. If the laity could become more familiar with the ever-accumulating sorrow, damage, despair, confusion, farce, and disaster that each psychopath leaves in his path, organized efforts might be aroused to devise adequate medicolegal means of restraining him in his now virtually unhindered career of destruction. At present, most psychopaths elude restriction. Neither penal institutions nor psychiatric hospitals possess the means of holding them long enough to afford the community protection or to give an adequate trial to the various therapeutic measures that are attempted. Though the record of their extreme incompetency may facilitate obtaining exoneration or leniency in the courts when faced with imprisonment, it does not, as matters now stand, enable society, through commitment, to keep them under psychiatric supervision.

Let us here put aside the questions that arise concerning criminal responsibility in murder and separately consider what legal means can be obtained to bring psychopaths, who are obviously and grossly disabled, under better control. In order to do this, it will be necessary for the facts of their conduct to receive adequate attention in estimating their status. In attempts to determine his competency, or incompetency, the examination must not be confined to the psychopath's abstract powers of reason—to his judgment as an outsider in theoretical situations. Full consideration should be given to what he does as well as to what he says. This type of disorder, like schizoid, cyclothymic, and paranoid disorders, occurs in varying degrees of severity. The courts do not commit relatively well-adjusted people with distinctly schizoid or cyclothymic abnormality. So, too, no sensible person would argue that people showing evidence of mild behavior disorders and delinquencies should be identified with the maximally disabled psychopath and pronounced incompetent.

If a means became available of obtaining adequate control over psychopaths who plainly show themselves not fitted for unrestricted freedom in the social group, it would be possible to set up facilities specifically designed to deal with their problems. Our large state and federal psychiatric institutions, organized for the treatment of patients psychotic in the traditional sense, are not well adapted to handle the psychopath. The numerous private hospitals primarily designed for the needs of psychoneurotic patients lack the means of restraining him and are unable to deal adequately with the problems he creates. The establishment of institutions primarily for psychopaths would not be advisable until legal means of controlling them are available. The expense of building and operating specialized institutions of this sort would be large. There is good reason to believe, however, that it would be far less than what the psychopath is costing the public today.

Even if no really curative treatment should be discovered, despite organized efforts over the years in institutions specifically adapted to the problems of the psychopath, a great deal might be accomplished through careful supervision and control of destructive activities that today seem to run virtually unchecked. Pinel, Esquirol, and other early psychiatrists are honored today for the profound changes they brought about in the care of psychotic patients. Let us remember that these men did not discover any specific treatment for the psychoses. They introduced sensible and humane ways of handling patients and discarded inappropriate and futile measures that had been causing great and unnecessary suffering. Systems of parole and probation specifically set up for the

Downloaded from www.dbraulibrary.org.in

psychopath, carefully designed in the light of his needs and his proclivities, could give each patient as much freedom from restraint as he showed himself capable of utilizing safely. In a properly controlled situation, it might be possible for many psychopaths to use their excellent abilities constructively and achieve a much better adjustment than is possible for them today.

CHAPTER 29

# SEXUAL DEVIATIONS

Paul Friedman

Downloaded from www.dbraulibrary.org.in

BROADLY SPEAKING, we designate as sexual deviations or perversions any patterns of sexual behavior which differ from normal coitus and serve as major sources of sexual gratification rather than as foreplay to coital activity. Union of the genitals is either absent or subordinate. There may be an "anatomical transgression" whereby other body parts assume the dominant role, or an excessive lingering on foreplay activities, or any combination of the two.[78]

In defining perversion, however, a distinction must be made between perverse acts and perversion as a psychopathological condition. A person whose primary mode of gratification is one of normal coitus might, nevertheless, derive some additional gratifications from acts that in themselves would be classified as perverse. As long as genital gratification in coitus is dominant, such a person would not be defined as a pervert.

## Historical Remarks

Attitudes toward perversions have always varied widely from culture to culture. Among the ancient Greeks, who tended to look on women as inferior beings without souls, erotic relationships between adult men and young boys (pederasty) were culturally sanctioned and were praised in poetry and philosophical writings. In these relationships the older man typically played the masculine, the younger the feminine role. They were regarded as aesthetically superior to the relationships between men and women, which were seen as serving merely the reproductive function.

Moreover, the Greek institution of pederasty must be viewed within the context of Greek culture, which permitted a relatively free expression of sexual impulses. As Freud[78] stated:

> The most striking distinction between the erotic life of antiquity and our own no doubt lies in the fact that the ancients laid the stress upon the instinct itself, whereas we emphasize its object. The ancients glorified the instinct and were prepared on its account to honour even an inferior object; while we despise the instinctual activity in itself, and find excuses for it only in the merits of the object.

In contrast to the Greek conception, the Judeo-Christian tradition maintains that pro-

creation is the only legitimate aim of sexual activity, and hence tends to condemn all forms of sexual activity not directed toward this aim. Mosaic law is explicit in its prohibition of homosexuality and of intercourse with animals, prescribing the death penalty for these offenses (Leviticus, 20:15–16, 23; Exodus, 22:19).

The strongest religious sanction against these two sexual practices has been derived from the story of Sodom and Gomorrah, as given in the Book of Genesis, in the assumption that such were the sins for which their inhabitants were punished; hence the term "sodomy," which to this day is used to denote both. This assumption, however, differs distinctly from the traditional Jewish interpretation that the sin of Sodom and Gomorrah was primarily one of hostility to strangers, and it has also been questioned by some Protestant and Catholic theologians. But whatever the author or authors of the original story might have intended to convey as to the nature of the sin, the fact is that, upon the basis of its interpretation in terms of anal or animal intercourse, the medieval church as well as secular powers inflicted extremely severe punishments—including death by burning or by being buried alive—upon persons convicted of sodomy. Hence the charge of sodomy was often raised against heretics, without basis in fact, as a convenient way to discredit heresy.[10, 50, 181] *

Nevertheless, it seems that homosexuality, already rather widespread among the Teutonic tribes in the pre-Christian era, continued to be practiced extensively in Germany during the period of Church domination; and, indeed, it is said to have been quite frequent in the religious-military Order of the Knights Templars. In a manner somewhat reminiscent of the Greek notion, it later found expression in certain nineteenth-century German poetry written in praise of young boys.

Although forbidden by the Koran, homosexuality is reported to have been widely practiced also in some Moslem countries, but there the pattern appears to have taken rather a bisexual form, adult males having been attracted both to young boys and to girls.

Perverse practices seem to be widespread among various primitive tribes. Not rarely, such acts—for example, intercourse with animals—form part of their religious ceremonies. Anal intercourse, in particular, plays an essential role in the initiation rites of certain tribes.[152, 184] *

Not until the second half of the nineteenth century did the phenomena of perversion begin to receive serious psychiatric attention. The pioneering step was taken in 1870 by Westphal,[182] who published a case study of a homosexual patient in his newly founded *Archiv für Psychiatrie* and suggested the term "contrary sexual feeling" (*Konträre Sexualempfindung*) to describe attraction to persons of the same sex.

Krafft-Ebing,[127] Kraepelin,[126] and other leading psychiatrists of the late nineteenth and early twentieth centuries considered sexual perversion to be essentially a form of "degeneracy" caused by a hereditary "taint" and often associated with physical stigmata of degeneracy. In his later writings, Krafft-Ebing modified his views by placing greater emphasis —as did Binet[26] and Bloch[27]—upon accidental causes. Kraepelin's discussion in *Clinical Psychiatry*[126] does not deal with "perversions" as such, but only with "inversion." Essentially, however, his approach is similar to that found in Krafft-Ebing's earlier formulations.†

* A major step in the direction of more humane treatment of homosexuals was taken in France, at the beginning of the nineteenth century, when the Napoleonic Code abolished all penalties for homosexual acts occurring between adults in private and without violence. Similar laws were subsequently enacted in several European and South American countries, and a proposal along such lines is currently under consideration in Great Britain.

* More detailed data on perverse practices in various cultures can be found in the writings of Ellis,[50] Chevalier,[35] Bloch,[27] Westermarck,[179, 180, 181] Devereux,[40] and Ford and Beach.[59] The works by Ellis and by Bloch served as the principal sources for the above account.

† Also similar in its implications, though less directly concerned with sexual perversions, was the theory of Lombroso,[145] who maintained that the "congenital criminal" was either an atavistic or a degenerate type, and that such atavistic or degenerate characteristics could be detected by means of physical stigmata. Like Krafft-Ebing, Lombroso, in his later writings, modified his views in the direction of a more environmentalist approach.

Downloaded from www.dbraulibrary.org.in

The view that sexual perversions are a result of "degeneracy"—either in the constitutional or in the sociological sense—was vigorously challenged by Bloch.[27] Although he agreed with Krafft-Ebing that perversions often are combined with pathological states, such as epilepsy or syphilis, Bloch pointed out that they can be found also in the absence of organic or mental pathology. He likewise argued against the notion that sexual perversion is a result of civilization, maintaining not only that perverse practices are, if anything, more frequent among some primitive tribes, but also that there are no differences in their frequency among the various social classes.

Bloch agreed that genuine homosexuality (as distinguished from pseudohomosexuality, of which he recognized several types) might be due to congenital predisposition, but he insisted that such predisposition can and often does occur in individuals who are physically and mentally healthy. He suggested—in this respect anticipating, as did Freud, results of much more recent endocrinological research—that the organic factor predisposing to homosexuality is essentially a chemical factor connected with the production of sexual tension rather than with the functioning of the reproductive organs. Genuine homosexuality, he stated, makes its appearance very early in life. (As an illustration of its supposed independence of environmental influences, he added that it has been known to develop in males brought up in a feminine environment!)

The ultimate cause of sexual perversion, according to Bloch, is the need for variety in sexual relationships which is characteristic of the human species. Taking a view similar to the one already formulated by Binet,[26] he attributed particular importance for the development of perversions to accidental occurrences in childhood. Among factors which strengthen the perversion, he mentioned repetition, suggestion, and imitation, the latter applying particularly where perversions have become a national custom.

A theory, advanced by Hirschfeld[103,104,105] and adopted later also by Krafft-Ebing,[127] conceived homosexuality to be an intermediate category between the two sexes. This hypothesis was attacked by Bloch, who pointed out that it failed to account for all cases, for example, those of male homosexuals with strongly masculine characteristics.

Hirschfeld,[104] in a paper he contributed to the *Encyclopaedia Sexualis* shortly before his death in 1935, vigorously defended the view that homosexuality is based on hereditary predisposition. One of his many arguments was that homosexual feelings develop spontaneously, "despite the powerful suggestion of the environment in the opposite direction." He also considered that, if homosexuality were caused by external factors, "it would be possible not only for the heterosexual individual to become homosexual, but also for a homosexual to become heterosexual," an assumption he deemed to be "at variance with the results of abundant experience."

Space does not permit a discussion of the work of all those who have contributed to the human and scientific understanding of sexual deviation—or sexual perversion, a term expressing essentially moral condemnation and social disapproval—but brief mention, at least, should here be made of the important role played by Moll,[150,151] Mantegazza,[147,148] Rohleder,[162,163] Chevalier,[35] Hamilton,[96,97] Davis,[37] and, in more recent years, by Kinsey and his coworkers[123,124] in weakening the barriers of the taboos on open discussion of these sexual phenomena.

## ¶ Psychodynamics: General Remarks

The publication, in 1905, of Freud's *Three Contributions to the Theory of Sex*[78] marked a milestone in the scientific investigation of sexuality. In this fundamental work Freud formulated, for the first time, his concepts of infantile sexuality. This formulation was in sharp contrast to the traditional views which equated sexuality with genitality and with the reproductive function, and according to which sexuality first makes its appearance at puberty. Freud found that the sexual development begins at birth. "Sexual" is a quality, and the whole body is able to provide the infant with

Downloaded from www.libtool.com.cn

sexual sensations. Freud designated the energy attached to the sexual instinct as "libido."

Describing the various steps or phases of libidinal development, Freud could show that originally the child's sexuality is not centered on the genital organs but on other parts of the body. The development of the libido starts with an "oral" phase in which interest is centered around the mouth. This is followed by a period when the main interest is focused around the anus, thus ushering in the "anal" phase. In the third, the "phallic" phase, it has shifted to the phallic organ which is the penis or the clitoris. But other parts of the body, such as the eyes, skin, etc., also have their sexual charge and become particularly sensitive to certain stimulations to which they respond with sexual sensations. Their ability to generate such sensations was Freud's reason for referring to all these organs as "erogenous zones."

The nongenital sexual impulses, which exist side by side in a loose connection and are not yet integrated into a unified instinct, are referred to as "partial" or "component" drives. The infantile sexuality is at first auto-erotic, that is, it is directed toward the child's own body. It is a relatively undifferentiated state; excitement can be aroused by any of a wide variety of stimuli, and there is no sharp distinction as yet between excitement and gratification. The sexual impulses at this stage find expression in various activities, such as looking, exhibiting, and a preoccupation with anal functions. The sum total of all undifferentiated, pregenital drives is characterized by Freud as "polymorphous perverse." One of the characteristics of the polymorphous phase is that the performance of physiological functions, such as sucking or defecation, provides gratification of the component drives. Even though interest in the genital organ develops quite early, it is only gradually that the genitals assume a more specialized function, by serving as means of discharge of excitation which has been aroused through other erogenous zones.

Looking at the process of psychosexual development from the standpoint of object-relation, one can likewise say that the child remains for a long time in a polymorphous perverse state. When his initially auto-erotic sexual impulses become directed toward other persons, they continue at first to be polymorphous perverse in character. This means that the earliest impulses directed toward others are not yet genital impulses but impulses relating to the component drives. This can be seen, for example, in the young child's interest in the feces of other persons.

Sexual maturity is reached only when all the component drives have become integrated and subjected to genital primacy. Although they continue to play a role in adult sexuality, normally their function is one of foreplay (kissing, looking, exhibiting, etc.) leading to coitus. However, if one of the component drives becomes the predominant source of sexual gratification, we speak of perversion. The nature of such a dominant component drive is usually reflected in the content of the perverse act. Thus, a predominance of the anal component may give rise to anal intercourse or to coprophilia; the impulses to look and to exhibit may lead to voyeurism and to exhibitionism; etc.

A perversion may come about either through arrest or fixation at a pregenital stage of the libidinal development, or through later regression to such a stage. But, whereas the child's sexuality is unorganized and polymorphous perverse, the sexual life of the pervert is organized and under the dominance of a partial instinct. Moreover, unlike the child, the pervert is capable of achieving genital orgasm.

Freud's theories on perversion found further crystallization in his later writings. *Leonardo da Vinci: A Psychosexual Study of an Infantile Reminiscence*[73] and "A Child is Being Beaten"[66]—published in 1910 and 1919, respectively—are here mentioned as most important in the development of his ideas. That the "impulse of cruelty" plays a significant role in the psychosexual development of the child, he had stated already in the *Three Contributions*, but the study of aggression and of its vicissitudes, as related to the Oedipus complex, showed the perversions to have a defensive function as well.* Freud's original view that

* The reader is particularly referred, in this connection, to the excellent studies by Sachs[164] and Gillespie.[84]

Downloaded from www.dbraulibrary.org.in

neurosis was the negative of perversion underwent considerable modification. It became clear that the latter represented only a narrow, conscious part of a much larger, unconscious system. In perversion, only one particular part of the pregenital sphere is consciously retained; the others are repressed, as in neurosis.

In perversion as in neurosis, the factor that disturbs genital primacy is castration anxiety.[52] Under its influence a regression takes place, whereby a specific infantile drive component becomes predominant. Unlike the neurotic symptom, the perversion provides a means of genital discharge, albeit one which fails to equal the gratification attainable by the normal person.

The important role of final gratification in many perverse acts was recently emphasized by Balint,[15] who describes them as "deceptive measures" intended to deflect attention from the genital pleasure and thus to protect the pervert against castration anxiety. In many instances, masturbation subsequent to the perverse act is needed for the attainment of orgasm.

An essential difference between neurosis and perversion is found in the attitude of the ego. As we know, the neurotic looks upon his symptom as a hindrance or a painful affliction and consciously defends himself against it, whereas the pervert accepts his sexual deviation as a source of gratification. According to Nunberg,[156] in perversion "the mental representative of the object is repressed, but the instinct is not only conscious but also capable of action"; he contrasts this particularly with the phobias, where the object is repressed and the instinct is disguised by displacement. Thus, both in perversion and in neurosis, there is repression with respect to the oedipal object of the sexual strivings.

Eidelberg[48] showed, on the basis of case studies, that the perverse act "is not identical with the component instinct" but, like the neurotic symptom, "represents a compromise and contains elements both of instinctual gratification and of frustration" and also "satisfies the demands of the superego." The real content of the instinctual gratification remains unconscious in the perversion, just as it does in the neurotic symptom.

In contrast to the nondynamic theories, particularly to those regarding the perversions as constitutional inferiorities, the psychoanalytic concept emphasizes the universality of the elements from which perversions may develop. Freud wrote:

> If it is correct that real obstacles to sexual satisfaction, or privation in regard to it, bring to the surface perverse tendencies in people who would otherwise have shown none, we must conclude that something in these people is ready to embrace the perversions; or, if you prefer it, that the tendencies must have been present in them in a latent form.[72]

This, in very brief outline, is the substance of psychoanalytic thinking on perversion in general. As we shall see, defense against castration anxiety is the main function in every perverse syndrome.

Downloaded from www.dbraulibrary.org.in

## Special Pathology

The psychoanalytic classification distinguishes between deviations with respect to the sexual object and deviations with respect to the sexual aim. But this differentiation has more theoretical than practical value; there is actually no sharp demarcation between the two aspects. Hence we shall find it more useful to deal in greater detail with the most frequent forms of perversion and to make but brief mention of some encountered less commonly.

Among the major sexual perversions we include overt homosexuality, pedophilia, fetishism, transvestitism, exhibitionism, voyeurism, sadomasochism, zoophilia, coprophilia, and necrophilia. Masturbation, even though it plays a part in some perverse acts, is not itself considered a perversion unless it constitutes the preferred mode of sexual gratification.

### *Overt Homosexuality*

The term "homosexuality" (literally, "same sex") refers to the choice of a love-object of the same sex.

Not all individuals who at one time or another engage in homosexual activity are homosexuals in the full sense of the term.* Persons capable of sexual intercourse with partners of either sex are described as bisexual. Overt homosexuality denotes a predominance of homosexual activity as a source of sexual gratification. The occurrence of homosexual acts in the history of an individual does not, in itself, constitute this condition. Conversely, the existence of latent homosexuality does not necessarily result in overt homosexual behavior but may lead, for instance, to paranoid delusions arising from projection of homosexual tensions.[65]

In discussing the causation of homosexuality, let us first consider the problem of constitutional predisposition. As already noted, some sexologists, particularly Hirschfeld,[104] regarded homosexuality as largely due to constitutional and hereditary factors. Others, for example Ellis,[50] insist that, in addition to a type of acquired homosexuality, there also exists a type which is due primarily to constitutional factors.

In the *Three Contributions*[78] Freud summarized his view as follows:

> The nature of inversion is explained neither by the hypothesis that it is innate nor by the alternative hypothesis that it is acquired. In the former case we must ask in what respect it is innate, unless we are to accept the crude explanation that everyone is born with his sexual instinct attached to a particular sexual object. In the latter case it may be questioned whether the various accidental influences would be sufficient to explain the acquisition of inversion without the co-operation of something in the subject himself.

The biological experiments of Steinach[174, 175]† supported Freud's theory of bisexuality. Coming back to this problem in his paper "The Psychogenesis of a Case of Homosexuality in a Woman,"[77] Freud stated:

> It is not for psycho-analysis to solve the problem of homosexuality. It must rest content with disclosing the psychical mechanisms that resulted in determination of the object-choice, and with tracing the paths leading from them to the instinctual basis of the disposition. There its work ends, and it leaves the rest to biological research. . . . Psychoanalysis has a common basis with biology, in that it presupposes an original bisexuality in human beings (as in animals). But psycho-analysis cannot elucidate the intrinsic nature of what in conventional or in biological phraseology is termed "masculine" and "feminine": it simply takes over the two concepts and makes them the foundation of its work.

While thus recognizing that constitutional factors may to some extent be responsible for the degree of susceptibility to psychogenic influences, psychoanalytic theory holds that the latter are essential in the development of homosexuality. In the following paragraphs the psychoanalytic theory of the psychogenesis of homosexuality will be briefly outlined.

In the psychoanalytic conception, one of the main causes of male homosexuality is castration anxiety. The awareness that the woman has no penis implies a threat of castration. Moreover, the female genital may be

Downloaded from www.dbraulibrary.org.in

* According to Kinsey *et al.*[123] approximately one third of American males go through one or more overt homosexual experiences at some time in their lives. (Some earlier estimates of the number of homosexuals in the United States are summarized in the Kinsey report.) Even though this estimate is subject to a wide margin of error owing to inadequacies in Kinsey's methods of sampling and analyzing data,[17, 88] undoubtedly the actual figure is very substantial.

† In these classical experiments Steinach showed that, by grafting the puberty glands of the opposite sex on castrated animals, it was possible to produce an inversion. More specifically, after the graft the animals tended to manifest behavior which would be more characteristic of the opposite sex, and also to direct their sexual activity to animals of their own sex. Further evidence that the individual organism usually combines some masculine and some feminine characteristics was found by Goldschmidt[87] in his studies of the gypsy moth. Varying proportions of masculine and feminine characteristics could be produced by crossbreeding of several varieties of the insect. Goldschmidt explains this finding by assuming that the chemical factors in the chromosomes, which determine sexual differentiation, are of different strengths in the different varieties of the insect. Thus, in the light of Goldschmidt's experiments, sexual differentiation becomes a relative matter dependent on chemical reactions. It may be of interest here to mention Fessler's[58] report on the case of a male transvestite whose manifest symptoms developed after removal of testicles. Fessler was able to show that in this case a psychological readiness, so to speak, had antedated the traumatic loss of testicles; the trauma acted as a trigger which mobilized the patient's deeply repressed feminine identification.

perceived in oral-sadistic terms as a castrating instrument.[52, 110] While the fetishist and the transvestite (as we shall see later) deny that the female lacks a penis, the homosexual accepts this fact but feels threatened by it. Hence the majority of male homosexuals are attracted by women, yet reject them as sexual (genital) partners. This attraction often is reflected in the choice of boys with feminine traits, as in Greek pederasty, or of male partners showing some characteristics of the subject's mother or sister.

In some instances identification with the mother leads to the choice of adolescent boys who represent the subject himself at a comparable age; he re-enacts toward them the maternal role, with the tenderness he had wished to receive from his own mother. This type of object-choice is narcissistic in the sense that such individuals bestow their love on themselves.

In other cases the identification with the mother, which follows the oedipal disappointment, takes the form of a wish to obtain sexual gratification in the same way as the mother. The anus here serves as a substitute for the maternal vagina, and the father becomes the object of passive-receptive strivings. In cases of this type, the manifest behavior pattern is of the "feminine" and tender kind, but there may be considerable latent hostility toward the father, with unconscious ideas of castrating him through homosexual intercourse.[52, 155] Traces of archaic oral identification with the father may likewise be present in the idea of submitting to him through anal intercourse. The passive-receptive love for the father also may develop as a reaction to the oedipal castration fear. It may, in its turn, give rise to castration anxiety.*

Nunberg[155] describes a type of male homosexuality in which aggression against the male (the father) "is not warded off, but . . . makes up an integral part of the subject's homosexual love." This is illustrated by the case of a patient who, since childhood, had suffered from ideas of physical weakness and had practiced gymnastics to overcome this weakness. He felt attracted primarily by strong men, with the idea that through homosexual contact he would gain some of their strength. In the homosexual act one not only appropriates to himself the strength of the partner (representing the father) but also symbolically "makes a woman out of him and subsequently feels himself sufficiently masculine to take possession of his mother." Nunberg suggests that this type of homosexuality is closer to paranoia than are the others "and possibly represents something intermediate between neurosis and psychosis." According to him, aggressive impulses are characteristic of many types of homosexuality.

Identification with the strong male was conspicuous in many of my homosexual patients. One of these was a young man who, since early adolescence, was attracted by strong men on whom he desired to perform fellatio so as to absorb their strength. As a child he had been physically weak and fearful, shying away from athletic activity and any kind of competition. His mother had died when he was two and a half, and he had slept in the same bed with his father until the age of thirteen. The father then married a girl only slightly older than the boy, and about whom the latter had entertained sexual fantasies. The patient's overt homosexual behavior dated from the father's marriage. The analysis showed that his homosexual striving corresponded to the type described by Nunberg; namely, that it represented the wish both to be and to castrate the father.

In female homosexuality one of the causal factors is likewise the castration complex, which results in anxiety at the sight of the genital of the opposite sex.[52] However, there is an important difference. Since the infant's earliest attachment is to the mother, the first love-object of the little girl is a homosexual one. Thus, in the woman, a homosexual attachment represents a regression to this early stage.[40, 52, 132] Hence female homosexuality carries more archaic traces than does male homosexuality, and "brings back the behavior patterns, aims, pleasures, but also the fears and

* Ferenczi,[54] who used the term "homo-erotism" instead of "homosexuality," distinguished sharply between two types: "subject homo-erotics," who act and behave like women, and "object homo-erotics," who are conspicuously masculine and merely exchange a female for a male object in their sexual choice.

Downloaded from www.dbraulibrary.org.in

conflicts of the earliest years of life."[52] This probably explains the fact that oral eroticism predominates in female homosexuality.[52]

As in male homosexuality, a distinction can be made between the narcissistic type and the one determined by the negative Oedipus complex.

The types here described, or some combinations of them, constitute the vast majority of overt homosexuals.

A phenomenological differentiation of passive and active is as relative for male homosexuals as is the distinction of masculine and feminine with respect to female homosexuals. That no sharp demarcation exists between activity and passivity is shown by the reversal of roles between the same partners on different occasions.[149] The common notion that homosexuals are recognizable by their physical appearance is certainly fallacious. Those who are ostentatious about their sexual leanings, and who can easily be identified by their clothing or manner of walking, represent merely a very small minority. Such ostentation or exhibitionism may be an expression of opposition to the prevailing code, an opposition based upon resentment of society's attitude toward homosexuality. To some degree this resentment is actually present in all homosexuals. Indeed, notwithstanding the intense object attachments characteristic of many homosexual relationships, their alliances often seem to be motivated more by spite and aggression than by libidinal strivings.

The feelings of resentment might be less virulent if the penalties against voluntary homosexual contact between adults were abolished.* In our culture the disapproval of female homosexuality tends to be less severe. Affectionate manifestations, such as kissing, are socially permissible among women but arouse offense in the case of men. In this connection it is also important to remember that male homosexuals tend to be more promiscuous than homosexual women. There are some cases on record of male homosexuals who had overt contacts with hundreds of partners.[127] This promiscuity and the insatiable need to seek repeated orgastic experiences bring to mind Freud's[72] compassionate statement when speaking of the difficult life of the pervert: "In reality, perverts are more likely to be poor devils who have to pay most bitterly for the satisfactions they manage to procure with such difficulty."

To conclude this cursory outline, brief mention at least must be made of the alleged correlation between homosexuality and specific sublimations. Ellis[50] and others have amassed impressive data of illustrious men, throughout history, known to have been homosexuals. The problem of a possible affinity between this perversion and particular talents or sublimatory pursuits has engaged a great deal of interest in recent years.* It has become the subject of promising psychoanalytic investigations whose results, however, still must be awaited.

## *Pedophilia*

Pedophilia (literally, "love of children") is the term applied to sexual activity involving a sexually immature object. A pedophile may be homosexual, heterosexual, or both in his choice of objects, and, theoretically, his activity can take almost any of the forms characteristic of heterosexual or homosexual activity with an adult partner.

In actual fact, however, a large proportion of male pedophiles are either partly or totally impotent, so that their pedophilic activity does not usually include intercourse but is more likely to involve masturbatory-exhibitionistic practices. This is especially true of those whose objects are very young children. Occasionally, the child may suffer major physical injury, as in a case reported by Krafft-Ebing[127] where

* Homosexuals tend to compensate their feelings of guilt and inferiority by projecting them onto others; hence their belief that the world is full of homosexuals. In the course of analytic treatment, it very often transpires that the patient ascribes homosexual leanings particularly to his own father.

* Of interest in this connection may be Alexander's[4] assumption as to the relationship between sublimation and perversion in general; namely, that the specific partial instinct dominant in a perversion cannot find more sublimated forms of expression. Thus the sexual sadist, for instance, would lack self-assertion in social relationships; the voyeur would not develop an interest in exploration or scientific research; etc.

Downloaded from www.dbraibrary.org.in

the attempt at anal intercourse with a one-and-a-half-year-old child caused an injury to the baby's anus. But since the pedophilic activities are often confined to fondling, exhibitionism, and masturbation, such instances are comparatively rare.

The typical pedophile's impotence and lack of interest in intercourse support the assumption that pedophilia reflects a feeling of genital inadequacy and a resulting fear of dealing with adult love-objects. This fear is strikingly illustrated in the case of a male patient, described by Karpman,[114] where, at the age of seven, a subsequently repressed seduction by a woman led to a fear of intercourse with women who had pubic hair and, as a result, to the preference for young girls still devoid of it.

Apart from the fear of dealing with an adult object, pedophilia has still other determinants, such as narcissistic identification with the immature object. These factors have been noted by Fenichel[52] and other authors.

## *Fetishism*

In this perversion the object of the sexual drive is either a part of the human body (*pars pro toto*), such as hair or a foot, or an article of apparel, most typically a shoe, associated with a person of the opposite sex. Fetishism occurs much more often in men than in women, and it is the feminine foot or the feminine shoe that may be described as a typical fetishistic love object.* Discussing the (unconscious) symbolic thought connections which may determine the replacement of a human object by a fetish, Freud[78] remarked: "The foot, for instance, is an age-old symbol which occurs even in mythology" (adding in a footnote, "The shoe or slipper is a corresponding symbol of the *female* genitals.") and "no doubt the part played by fur as a fetish owes its origin to an asssociation with the hair of the *mons Veneris*."

In a sense, fetishism may be described as an exaggeration of a phenomenon which is present to some extent in normal love relationships —the lover's affective overvaluation of some feature or body part, or of some article associated with the love-object. Normally, such special attachments are subordinate to one's interest in the actual person, but in fetishism the situation is reversed; attachment to the fetish assumes the primary role, and the presence of the fetishistic object is indispensable for the occurrence of orgasm.

In the case of some fetishists, to look at the fetish or to touch it is sufficient to produce orgasm, without supplementary overt stimulation; others resort to coitus or masturbation in the presence of the fetish in order to bring about an ejaculation.

Binet's[26] theory concerning the role of "accidental" circumstances in childhood in the genesis of the fetishistic perversion has already been mentioned. Another early theory was that of Krafft-Ebing,[127] who maintained that foot fetishism is really a variety of masochism, since the lover lowers his own status in relation to the love-object by focusing his attention on her foot. Ellis,[50] taking issue with this view, cites cases of foot fetishists whose attitudes toward women gave no other evidence of self-abasement, but he agrees that foot fetishism may sometimes be a sadomasochistic manifestation.

From the psychoanalytic point of view, choice of the fetish is determined on a symbolic basis. Thus the foot, having a phallic significance, serves as symbolic reassurance of the existence of a female phallus.[1,70] The pregenital, especially coprophilic, significance of the fetishistic object was stressed by Freud[70] and later by many other authors. Strong olfactory sensations emanating from the foot, which are largely repressed, probably account for its frequent choice as a fetish. In recent years, increasing emphasis has been placed upon the aggressive element underlying fetishism and most of the perversions in general.[14] The mag-

* Probably the earliest recorded case of foot-and-shoe fetishism is that of the French writer Restif de la Bretonne (1734–1806). According to Ellis,[50] de la Bretonne was the first to give a detailed phenomenological description of the development of his fetishistic tendencies, both in his first literary success, *Le Pied de Fanchette*, and in his autobiography, *Monsieur Nicolas*. In his case the preoccupation with the fetishistic object was not a full-fledged perversion, since a desire for normal intercourse continued to be present. (His fetishism apparently reached its highest point as a result of desire for a woman who was inaccessible as a genital object.)

Downloaded from www.dbraun.org.nz

ical significance inherent in some fetishistic manifestations, especially in those which involve mere looking, is self-evident. In her paper on "Respiratory Incorporation and the Phallic Phase," Greenacre points up the fetishistic attachment of a patient to certain objects and the magical value they represented in early life (*see* Ref. 92, pp. 259–292).

Since both fetishism and male homosexuality can be viewed as means of dealing with castration anxiety, it might be instructive to compare the two perversions in this respect. Lorand, examining these relationships in his paper "Fetishism in Statu Nascendi,"* has aptly remarked that "fetishism saves the individual from becoming homosexual, but saves him at the same time from becoming normal which would bring the danger of castration" (*see* Ref. 146, pp. 11–24).

## *Transvestitism*

The term "transvestitism" (literally, "cross-dressing") was coined by Magnus Hirschfeld. It refers to a sexual perversion in which sexual gratification is obtained by wearing the clothing of the opposite sex and by genital contact with such clothing. There is often a certain tendency to feel and act like members of the opposite sex. This was well expressed by a boy of twelve who had developed a habit of putting on his mother's silk nightgown over his naked body. Referring to this habit once by way of free association, he said that it felt "as silky and velvety as mother's skin."

Some authors classified male transvestites as homosexuals, a view which derived some support from the observation that transvestites showed effeminate traits. But Hirschfeld[108] challenged this view. According to him, transvestitism is a completely distinct perversion, since most transvestites tend to be attracted to persons of the opposite rather than of the same sex. While this phenomenological approach seems correct as far as it goes, it is also true that in many case histories of homosexuals we find episodes of transvestitic manifestations dating back to childhood or adolescence.

The psychoanalytic view of transvestitism,[28, 53] may be summarized as follows. Here too, as in many other perversions, there is an attempt at reassurance against castration anxiety. This arises from the infantile belief that the woman has lost her penis as a result of castration; hence the subject, too, might become a victim of castration. By donning female clothing and by continuing to receive sensations from the penis, the transvestite unconsciously identifies with a phallic woman whose penis is hidden by her clothing. But his identification with the phallic woman does not extend to imitating her object-choice; as already mentioned, most often his choice is directed toward persons of the opposite sex. The phallic woman, besides being his identification figure, represents also the transvestite's love-object. Seen in relation to the Oedipus complex, whence the castration anxiety of the transvestite is derived, there are two different aspects in this representation. On one level the love-object represents the mother, but on a deeper level it represents also the father, and is thus homosexual in nature.

The feminine identification of the male transvestite is typically accompanied by masochistic features which usually manifest themselves through fantasy content. In some cases, however, they may involve self-infliction of severe pain on the part of individuals who not only put on female clothes but also tie themselves with ropes. There are known cases of such transvestitic acts (in adolescents) resulting in death.[166] Schechter[166] suggests that the transvestitic suicidal act in adolescent boys symbolically represents "the first submission to the all-powerful father figure." One of my homosexual patients used to tie himself to a chair or to a bedpost while wearing his mother's or sister's clothes, and always attained orgasm by struggling to get out of both clothes and ties.

The foregoing comments evidently require

* This study of fetishism in a child is important also from another point of view. Since domination of the sexual organization by a partial instinct is one of the characteristics of perversion, and since in this respect the pervert shows a similarity to the child, the question arises whether it is indeed appropriate to speak of "perversion" in childhood. Undoubtedly, this concept in its application to children has a valid meaning, although perhaps not one entirely equivalent to its meaning as applied to adults.

Downloaded from www.pbookshop.com

some modification in the case of the female transvestite. Since masculine attire cannot provide a woman with the illusion of having a penis, female transvestitism has more of a "make-believe" character. As already noted, some homosexual women wearing masculine clothing do it probably rather out of bravado and defiance than from a genuine transvestitic impulse.

There is a definite point of similarity, at least on the descriptive level, between transvestitism and fetishism. The fact that both utilize articles of clothing of the opposite sex has already been stated, but a corollary of this observation still remains to be pointed out. In a recent paper, Balint[14] emphasized that a fetish, in contrast to a living sexual partner, has no demands of its own, that no effort is required to "win" or "hold" the fetishistic object. The same holds true for transvestitism, which similarly employs an inanimate object as a means of sexual stimulation.

But this point of similarity between the two perversions should not be overdrawn, since the inanimate object plays a different role in each. In the case of fetishism, the inanimate object acquires importance in itself as a result of symbolic displacement; in the case of transvestitism, it acquires significance primarily when brought into direct contact with the subject's body. Unlike the fetishist, the transvestite is not "in love" with a specific article, as such, but utilizes articles of apparel of the opposite sex as a means of attaining orgasm and of facilitating identification with the other sex.

## *Exhibitionism*

This perversion involves exhibition of the genital organs for the purpose of obtaining sexual gratification.

Exhibitionism was introduced into psychiatry as a clinical entity in 1877 by the French neurologist Lasègue.[133] As its striking characteristics, he described that the act was "instantaneous and compulsive"; the subject was spellbound, unable to control his impulses to exhibit his genitalia, finding himself always in a state of heightened anxiety. Garnier,[83] in 1900, completed the symptomatological outline by emphasizing that the compulsion refers not only to the exhibitionistic act itself but also to the time and place of its performance.

In its pure form, exhibitionism is rarely found in women. Descriptively, one may say that the male genital exhibitionist very frequently suffers from potency disturbances and has little interest in normal sexual relations. He performs the exhibitionistic act only in the presence of strangers, and often his own family is quite unaware of his abnormality. In fact, it sometimes happens that there are several male exhibitionists in one family and that they do not know of each other's perversion.

While the exhibitionistic act often has an aggressive aspect, in the sense that the woman is shown the penis against her will, in other cases—for example, of pedophiles—it may take place without such an aggressive connotation. Exhibitionism also plays a role in male homosexual relationships.

Exhibitionism as a clinical syndrome differs from the exhibitionism that forms a part of the normal developmental process in young children. This normal exhibitionism of childhood is practiced by mutual consent; often, as in the "doctor" game, it is closely tied up with voyeuristic elements. The adult exhibitionist's susceptibility to visual stimulation, however, usually is weak; thus he is typically not stimulated by the sight of the female breast.

Viewed from the dynamic aspect, the defensive function of the exhibitionistic act is almost self-evident, inasmuch as the exhibitionist demonstrates to the woman and simultaneously to himself that he is still in possession of a penis. Christoffel,[36]* who made a thorough study of the problem, aptly observed that male genital exhibitionism has some characteristics of an unconscious phobia—more specifically, of a claustrophobia. The exhibitionist's behavior is characterized by anxiety, and the claustrophobic quality of this anxiety is evidenced by his feeling of insecurity in his own home and his own bed. The typical exhibitionist does not exhibit in his home, and only

* Christoffel's paper includes interesting historical and cultural material on male genital exhibitionism.

Downloaded from www.pbaunigov.in

very rarely will he display his genitalia from his window.

The compulsion of the exhibitionist to return to the scene of his crime is the manifest symptom of his deep sense of guilt and need to be punished. Also significant is the tendency, noted by Christoffel, to report other exhibitionists to the police or (more often) at least to frighten them.

The magical thinking inherent in exhibitionism is as prominent as in its counterpart, voyeurism. The exhibitionistic act implies the magical wish for the woman to exhibit her own phallus: "I wish you would do the same."

An impressive amount of material on the subject of the magical overvaluation of the penis, as it is encountered universally in folklore and myth, was collected by Ellis.[50] It is of interest to remember that in medieval times the exhibition of the phallus or phallic symbols was used in order to frighten or to delude demons.

## *Voyeurism*

In this perversion the primary means of sexual gratification consists in looking at the sexual organs or sexual activities of others. Voyeuristic practices range all the way from "peeping," which is carried out without the cooperation of the person being observed, to spectatorship at elaborate performances, for example, in houses of prostitution. The sex acts staged on these occasions are usually a combination of various forms of perversion, preponderantly sadistic in nature and often including intercourse with animals.

Underlying voyeurism we find similar infantile fixations, relating to primal scenes, as in exhibitionism; and, like almost every perversion, voyeurism can be interpreted as an attempt at reassurance against castration anxiety. But because such reassurance cannot be obtained, the voyeuristic tendencies usually become insatiable, sadistic, and displaced to areas other than the genitals.[52]

In voyeurism the original sadistic impulse to destroy is transformed into a milder one, to look: "I didn't do it, I only watched the other fellow do it." According to Fenichel,[52] this tendency to replace sadistic action by the more ego-syntonic form of looking or watching can be studied particularly in women: "Curiosity in women sometimes is more or less openly aimed at witnessing catastrophes, accidents, war scenes, operations, hospital scenes, and the like; such curiosity represents active sadistic castration tendencies, reduced from action to observation."

To examine the universal validity of this statement would lead too far afield, but I should like to remind the reader of a fascinating illustration of precisely this type of camouflaged sadistic voyeurism in a work of literary art, Ibsen's famous play *The Master Builder*. I refer, of course, to the dramatic scene where Hilde Wangel, the heroine, witnesses the builder's fall from the top of his last creation, to which he has mounted at her instigation. It is a powerful example of the great naturalistic dramatist's acute—one can almost say, clinical—observation of human behavior. For, as Reik[161] rightly remarks, the sexual symbolism of this climbing and falling, which seems so obvious to us today, certainly was quite unknown to Ibsen, the puritanical Norwegian, in 1891.

That the act of seeing, which in voyeurism and some other deviant sexual tendencies is the tool of perversion, plays a focal part as well in our normal sexual and cultural development, no one will deny. As Freud[78] put it:

> Visual impressions remain the most frequent pathway along which libidinal excitation is aroused; indeed, natural selection counts upon the accessibility of this pathway—if such a teleological form of statement is permissible—when it encourages the development of beauty in the sexual object. The progressive concealment of the body which goes along with civilization keeps sexual curiosity awake. This curiosity seeks to complete the sexual object by revealing its hidden parts. It can, however, be diverted ("sublimated") in the direction of art, if its interest can be shifted away from the genitals on to the shape of the body as a whole.

## *Obscenity, Pornography, and Coprophilia*

These are all closely related to the exhibitionistic and scopophilic perversions.

That the verbalization of obscenity has a

Downloaded from www.freeuniversity.org.in

special, unconscious significance was first discerned by Freud[81] and further described by Ferenczi,[55] Bergler,[19] Jones,[112] and others. Words are often the tools of

mild exhibitionists and voyeurs, who instead of actual exposure content themselves with an act that has been weakened into the form of speech, and who in doing so select those words that (through their being forbidden, as through their motor and plastic attributes) are especially calculated to evoke the reaction of shame. This perversion might be called "coprophemia."[55]

Ferenczi[55] differentiated between "coprophemia" and "coprolalia," defining the latter as "the involuntary obsessive expelling of obscene words, as may happen, for instance, in severe cases of *tic convulsif*."

But some individuals, usually males, use obscene words and also pornographic or erotic literature as a means of stimulation to the point of orgasm. Typically, but not invariably, this is done in conjunction with masturbation. In some cases, men who are relatively isolated from opportunities for heterosexual contact utilize such material to achieve sexual arousal. Women appear to be less responsive than men to this type of stimulation.

As Fenichel[52] points out, in one respect the use of pornographic literature in conjunction with masturbation is nearer to normal sexuality than is masturbation by itself, "the book being a medium between sexual fantasy and sexual reality." But whether the use of erotic literature actually comes closer to normal sexuality depends, of course, on the type of material involved.

In coprophilia, excretory functions (defecation) serve as the primary means of obtaining orgasm. This perversion sometimes takes on a voyeuristic character, for example, when a man derives gratification from watching women defecate.

Coprophilia, too, can be described as a defense against castration anxiety. By emphasizing the anal zone as a source of sexual pleasure, the difference between the sexes is circumvented, and hence the conflict about castration is removed. The symbolic equation feces = penis is thus confirmed. In some cases a fetishistic fixation was detected as a factor in this perversion.[52]

Fenichel[52] stresses the combination of coprophilic, exhibitionistic, and sadistic elements involved in coprolalia, "in the joy of uttering obscenities."

## *Sadomasochism**

In sadomasochistic perversion the infliction of pain is a prerequisite for sexual gratification. The sadist is the one who inflicts the pain upon the sexual object; the masochist endures it in a passive way.

Detailed descriptions of sadomasochistic practices are contained in the older literature on sex, particularly in the works of Krafft-Ebing,[127] Ellis,[50] Bloch,[27] Moll,[150] etc.

Freud[78] considered sadomasochism to be the most significant of all perversions, inasmuch as "the history of human civilization shows beyond any doubt that there is an intimate connection between cruelty and the sexual instinct." "Sadism and masochism," he wrote, "occupy a special position among the perversions, since the contrast between activity and passivity which lies behind them is among the universal characteristics of sexual life." Schilder,[167] emphasizing the close relationship between sadism and masochism and the integral part they play in sexual life, believed that they represent only an accentuation of a general human tendency to distribute the roles of activity and passivity, aggression and submission.

According to Freud's early formulation in the *Three Contributions*,[78] the

connotation of sadism oscillates between, on the one hand, cases merely characterized by an active or violent attitude to the sexual object, and, on

* The term, a modern contraction of "sadism" and "masochism," illustrates the inextricable alliance of the two concepts. "Sadism" is derived from the name of Donatien Alphonse François de Sade (1740–1814), more generally known as the Marquis de Sade, a French writer whose novels depict many incidents involving torture and cruelty. The term "masochism" is similarly derived from the name of an Austrian novelist, Leopold von Sacher-Masoch (1836–1895), who often dealt in his books with the theme of subjugation of men by women, and who in his own life displayed masochistic traits, for example, a desire that his wife should be unfaithful to him.

Schrenck-Notzing[170] preferred the term "algolagnia," which means "pleasure in pain," designating sadism as "active algolagnia" and masochism as "passive algolagnia."

Downloaded from www.pdfbooksfree.org.in

the other hand, cases in which satisfaction is entirely conditional on the humiliation and maltreatment of the object. Strictly speaking, it is only this last extreme instance which deserves to be described as a perversion. Similarly, the term masochism comprises any passive attitude towards sexual life and the sexual object, the extreme instance of which appears to be that in which satisfaction is conditional upon suffering or mental pain at the hands of the sexual object. Masochism, in the form of a perversion, seems to be further removed from the normal sexual aim than its counterpart; it may be doubted at first whether it can ever occur as a primary phenomenon or whether, on the contrary, it may not invariably arise from a transformation of sadism.

There is no sharp demarcation line dividing the roles in a sadomasochistic relationship. Neither of these roles is specifically tied to one of the sexes. In some sadomasochistic pairs the sadistic role is taken by the man, in others by the woman. Sadomasochistic relationships likewise occur among homosexuals. Case histories of sadists and of masochists constantly reveal "traces of both groups of phenomena in the same individuals" and that the two are so closely related that they can be regarded as representing the same perversion.[59]* (In the *Three Contributions* Freud made reference to these findings.)

A patient with strong homosexual tendencies,† whose masturbatory activities were invariably accompanied by masochistic fantasies, frequently dreamed of witnessing sadistic acts inflicted upon others. These dreams would usually cause nocturnal emissions. A typical, recurrent dream is the following:

He is in a sort of stone cell, the type of cell one would find in a medieval castle. A man in brightly colored pajamas is chained by the wrists, facing the wall. A woman dressed in a rather loose, flowing robe is beating him. The man struggles and finally breaks loose. Somewhere the man has found an ice pick. He throws it at the woman, and the pick sticks in her face. He pulls it out, throws it again. This, as the woman slowly backs away, is repeated three or four times.

It is not possible in the frame of this chapter to attempt a detailed account of Freud's ideas on sadomasochism and the sequence of their development. The problem of masochism presented greater difficulties than that of sadism, owing to its apparent contradiction of the pleasure principle. According to his original conception, the component instincts of sadism and of masochism formed a complementary pair (very much in the same sense as those of exhibitionism and scopophilia). We have seen that in his earlier work[78] he assumed that masochism, which involves the turning of aggression upon the self, is derived from sadism (that is, from aggression against the object). Later on, Freud[64, 66, 67] elaborated a different view; namely, that both sadism and masochism are derived from the death-instinct. In this new formulation, masochism was the primary and sadism the secondary phenomenon. However, Freud proceeded from it to the further assumption that masochism, which thus had turned into sadism, could once more be turned back against the self, and this form he termed "secondary masochism." In a footnote added in 1924 to the *Three Contributions*,[78] Freud summarized his new conception thus succinctly:

> I have been led to distinguish a primary or erotogenic masochism, out of which two later forms, feminine and moral masochism, have developed. Sadism which cannot find employment in actual life is turned around upon the subject's own self and so produces a secondary masochism which is superadded to the primary kind.

Moral masochism can be defined as a form of masochism which has "loosened its connection with what we recognize to be sexuality," and in which "it is the suffering itself that matters."[67] The moral masochism is expressed in unconscious feelings of guilt derived from the Oedipus complex.

Freud's ideas on masochism, especially the conception relating it to the death-instinct as well as his concepts of feminine and of moral masochism, have aroused considerable con-

* In this connection Ellis also argued that de Sade himself could really be considered a masochist rather than a sadist.

† This is the same patient I mentioned in my illustration of certain transvestite practices (see page 598).

Downloaded from www.pbookshop.com

troversy.* On the other hand, there is considerable agreement on the view that a turning of originally object-directed sadism upon the self plays a role in the masochistic perversion.

To summarize, we may say that, in the psychoanalytic conception, sadism and masochism represent means of defense against castration anxiety. By performing symbolic castration on others, the sadist gains the reassurance that he is the castrator and not the one castrated; especially where the symbolic castration is mild in character, it means that the effect on the victim is not so serious. (Of course, this does not hold true for extreme sadistic acts, such as lust murder.) As for the masochist, his guilt feelings stemming from the oedipal conflict are allayed by the pain and suffering which become the "price" for genital orgasm. Thus, by submitting to symbolic castration, he obtains the proof that his organ still is intact.

## *Zoophilia*

Zoophilia erotica, a term coined by Krafft-Ebing,[127] denotes a love for animals. Zoophilic perversion may take any one (or a combination) of at least three possible forms: (1) sexual arousal through observation of sexual activities of animals (voyeurism); (2) a form of fetishism whereby animal objects, such as furs, acquire special sexual significance; and (3) actual intercourse with animals (zooerasty). This is an excellent example illustrating how many different aspects a perversion can present.

Observation of sexual activities of animals is a frequent occurrence in young children, but there are some cases on record of adult persons, male as well as female, deriving gratification from the observation of horses being bred.

Sexual intercourse with animals has in some periods and cultures had religious sanction, but in others has been severely condemned. Mosaic law prescribes the death penalty for the offending person as well as the animal. In medieval Europe the punishments inflicted for such contact included death by burning for both.

Zoocrasty appears to have been most frequent among peasants living in close contact with animals and among persons of low educational level. The animals most commonly used for this purpose include the goat, the dog, and the sow, but even geese are known to have been used occasionally. Animal intercourse is said to be particularly frequent among shepherds, and approximately 9 per cent of the males from farm areas sampled by Kinsey *et al.*[123] had experienced it at some time in their early teens. In my clinical practice I have found that most persons who had sexual contact with animals were either psychotic or of extremely low intelligence.

According to Ellis,[50] there are some cases on record of women attempting coitus with large dogs and suffering major genital injury as a result. He states that while actual coitus between a woman and a dog seems to be quite rare, apparently dogs are used by women much more frequently for purposes of cunnilingus and are able to perform it without special training.

A case of a man who had practiced animal intercourse was psychoanalytically studied by Lorand.[146]

## *Lust Murder*

This is the most extremely sadistic perversion. It involves killing and the mutilation of corpses for the purpose of sexual gratification. According to Krafft-Ebing,[127] the lust murderer does not attempt coitus with his victim, because it is the act of murder itself that provides him with genital gratification; he thus differs from the rape murderer, who resorts to killing in order to prevent discovery. Lorand,[146] on the other hand, maintains that the lust murderer's sexual aim is to have intercourse with the corpse, since he cannot face the possibility of rejection by a living woman. The same view was held by Ferenczi (as mentioned by Lorand without citing source). This inter-

* Of the numerous psychoanalytic contributions to the problem of masochism, unfortunately but a few can be cited. The reader is especially referred to (besides Freud's own writings) the works by Reik,[160] Nunberg,[158] Deutsch,[40] W. Reich,[159] Fenichel,[52] Horney,[110] Lampl-de Groot,[131] Eidelberg,[45] Bergler,[17] Berliner,[22, 23, 24] Nacht,[153] and Loewenstein,[144] whose recent paper contains an extensive bibliography on the subject.

Downloaded from www.pdfbooksfree.pk

pretation would make lust murder closely akin to necrophilia.

Intermediate in character between lust murder and the sadomasochistic perversion are those perverse practices which involve injury to the victim or the sight of the victim's blood as a condition of genital discharge. Thus, Krafft-Ebing[127] reported the case of a man who periodically visited a prostitute in order to see her kill an animal in his presence, a sight which apparently provided him with genital gratification.

## *Necrophilia*

Necrophilia (literally, "love of corpses") is a very rare perversion and one that involves a very deep-lying disturbance. It consists in having intercourse with corpses, followed, in some instances, by mutilation of the latter. Some of the individuals known to have practiced this perversion had no interest in normal coitus.

As was already noted by Bloch,[27] necrophilic fantasies are more frequent than actual necrophilic acts. Such fantasies have been reported in the psychoanalytic literature; among others, in the case of a patient with an actual history of animal intercourse.[146]

A motivating factor in necrophilia—and even more strongly marked here than it is in pedophilia—seems to be the need to eliminate the risk of rejection by choosing an object that can offer no resistance or opposition of any kind. Indeed, this is the explanation suggested by Krafft-Ebing,[127] who reported cases of necrophilic perversion in some detail. However, even though it may be partly correct, his interpretation cannot fully account for the facts in these cases. It fails to account for the mutilation of the corpses, for the considerable risk taken by the necrophiles in removing the bodies from graves, or for the fact that some of them showed no interest at all in intercourse with living women.

## *Group Perversion*

This term is applied to any sort of sexual activity involving the participation of more than two persons.* One type of group perversion is the orgy.[50] Originally, the orgy had a religious function, permitting sexual excesses on special ritual occasions, somewhat analogous to the totemic feast as described by Freud in *Totem and Taboo*.[79] As Ellis[50] points out, some of the medieval church festivals (for example, All Fools' Day) were characterized by permitted relaxation from certain customary constraints. The medieval flagellation orgies, though different in their manifest intent, sometimes had the character of a group activity leading to sexual excitement.

Other activities that come under the heading of group perversions include group rape (a group of men raping one woman) as well as voyeuristic practices in which sexual excitement is reached by one individual or a group of individuals while watching sexual activity of others. (However, such activities are classified as group perversion only if three or more of the participants are involved in its perverse aspects. If a voyeur watches normal coitus between a man and a woman who do not know that they are being observed, we do not speak of a group perversion, even though three persons are involved and voyeuristic activity is perverse.)

As Sperling[173] has suggested, in a group perversion there is usually a leader who is a genuine pervert; the "followers," according to this view, participate in the perversion under conditions which are ego-alien to them, but the fact that they do so indicates the presence of a super-ego that permits substitution by a leader.† Sperling refers to this condition as "induced" perversion.‡

* In a certain sense, the triangular sex situation (*ménage à trois*) resembles a group perversion. Almost without exception, a strong homosexual element is present under the guise of heterosexual interest. The perverse aspect of such relationships becomes more clearly apparent when exhibitionistic and voyeuristic manifestations are involved as well.

† Sperling further suggests that culturally sanctioned perversions in primitive societies have the same character, that is, were introduced by a genuine pervert.

‡ That there is always a biological compliance and a readiness for sexual seduction seems beyond doubt. "He only can be seduced who is capable of being seduced."[150]

## Community Attitudes and Preventive Aspects

In our society the attitude of the community to sexual deviations is still one of contempt and moral condemnation, strongly determined by unconscious as well as conscious fears.

Not surprisingly, there is a particular virulence in the public's reaction of fear and indignation to criminal acts involving rape, pedophilia, lust murder, etc. Not only do such cases of "sex fiends" arouse severe panic in the neighborhood where the act was committed; they tend to receive such intense and wide publicity that they may remain a source of horrifying fascination for a long time. (The tale of "Jack the Ripper" continues to agitate the imagination of anxious mothers to this very day.) This peculiar fascination, perennially exploited by the popular press, is indicative of a specific ambivalence in relation to sex and cruelty. Such accounts, like the "penny dreadfuls," exert an insidious appeal to unconscious sadomasochistic strivings in the reader; hence the objection of many community leaders to the sensational reporting of "sex crimes," on the ground that such newspaper stories might stimulate potential criminals to commit similar offenses. The actual extent of this danger is difficult to assay, especially in view of the enormous amount of comparably arousing material disseminated by other mass media.

With regard to homosexuality, the community reactions are much more variable. Although a great deal of opprobrium still attaches to it, some of the opposition takes the form of ridicule rather than of violent indignation, and, at least in some segments of society, an increasing tolerance for the homosexual can be observed.

No doubt the community must protect itself against certain dangers inherent in some forms of sexual perversion. From this standpoint, as well as from the medicolegal aspect, it is necessary to distinguish two different categories of perversions: (1) extreme and violent forms of sadism which actually present a danger to society, and (2) pervert practices constituting rather a nuisance, such as exhibitionism and "indecent assault."

Exhibitionistic acts, it is true, can occasionally have traumatic consequences if the victim is young and impressionable, but such a case would not necessarily be typical. In this connection it should be pointed out that there is sufficient evidence to indicate that the choice of a victim by the sexual pervert is not always an accidental matter.[101] In pedophilia, for instance, the juvenile object is sometimes a fully willing participant in the sexual activity, although, in terms of the law, the responsibility for the acts rests on the adult partner. In some perversions (for example, nonviolent homosexuality) the roles of the participants are more or less voluntary, so that no clear demarcation exists between offender and victim. The effect on the victim may vary a great deal, depending on the person's psychological make-up. This likewise applies to the victim of "indecent assault."*

The fact that sexual perversions are punishable by law is meeting with increasing opposition based upon the view that sexual morality is a private matter and should be subject to public regulation only if (1) the acts are carried out in public places, (2) one of the partners is a minor, or (3) violence or coercion is involved. Particularly the opinion that homosexual practices should not be subject to legal sanction receives support from contemporary psychiatry.† From the psychodynamic standpoint, homosexuality is a manifestation of an underlying disturbance which is primarily a psychological problem.

As far as really dangerous perverts are concerned, it appears necessary to isolate them for the protection of society, but the fact that imprisonment has no deterrent effect is amply

* This is a legal rather than a psychiatric term, used differentially from "rape" to denote sexual attacks involving no attempt at genital intercourse. The attack usually serves as a means of providing sexual gratification, and its form may range from exhibitionism to attempted contact with genital zones. An attempt to coerce the victim is usually an essential feature of indecent assault.

† The reader is referred to the Wolfenden Report[187] for extensive clarification of this question.

Downloaded from www.chaurasiaonline.com

evidenced by the number of individuals repeatedly apprehended and convicted of the same offense; this is especially striking in the case of exhibitionists, for example.

Under the present system, whether an offender is sent to prison or to a mental hospital depends upon the judge's application of the M'Naghten rule in deciding whether the defendant is legally insane. This formula, which dates back to 1843, is completely at variance with current psychiatric opinion.

At any event, the mere isolation of sexual offenders by society cannot suffice for the prevention of dangerous perverse acts. As we know, sexual deviations have their origin in childhood and may be fostered by unconscious or conscious parental attitudes and influences. Either by prohibiting genital sexuality or by directly encouraging tendencies to pregenital manipulations, the parents may actually foster the development of perverse sexual strivings, thus giving them super-ego sanction. Sometimes the very manner in which the child is admonished for a perverse act is designed to encourage the perversion. Concurrent therapies of parents and children indicate that similar perverse tendencies are often present in both. Public enlightenment thus may contribute eventually to the prevention of sexual offenses.

## *Therapy*

In discussing methods used in the treatment of sexual inversion, Ellis[50] noted the ineffectiveness of castration or vasectomy. Hypnosis, as used by Krafft-Ebing,[127] Schrenck-Notzing,[171] and others, achieved only very limited and short-lived success. The association technique developed by Moll[151] consisted essentially in attempts to shift or recondition the patient's inclination from homosexual to heterosexual object-choice by utilizing similarities between the two, for example, using an attraction to boys as a basis for developing an attraction to boyish-looking girls.

In contrast to these various methods, which aimed at a cure of the inversion as such, Hirschfeld's[104, 105] "adaptation therapy" sought primarily to adjust the patient to his inversion; it was advocated and employed particularly by those who stressed the congenital character of inversion. Some authors, notably Ellis,[50] expressed the view that treatment of the congenital invert should aim at what today would be called sublimation of the inverted impulse. Adaptation in this sense undoubtedly represents a legitimate therapeutic objective in a large number of cases.

One of the central difficulties in the treatment of perversion lies in the fact that the pervert, unlike the neurotic, derives conscious gratification from his symptoms. Hence very few perverts seek treatment on account of their perversion, unless they are forced to do so because of external pressures. More frequently, they consult the psychiatrist on account of concurrent neurotic symptoms.

However, even when a patient initially has no desire to be cured of his perversion, some progress can often be made by showing him some of its genetic sources. Such insight opens the path to further analytic work. Where guilt feelings (as distinguished from mere social fears) can be made conscious to the patient, the therapeutic outlook is more favorable.[124] In the treatment of perversion, as in the treatment of phobias, direct intervention is often necessary. A completely neutral attitude in the therapist is apt to be interpreted by the patient as parental sanction. Thus in many instances it is advisable to impose the rule of abstinence as soon as the transference situation provides a suitable basis for the successful use of such intervention.

There is no doubt that, in those cases which are amenable to treatment at all, psychoanalysis is the method of choice, but there are many instances in which it is difficult to obtain a cure. Even when the removal of a person's perverse symptom proves impossible, psychotherapy still can help him to reach a better social adjustment.

In 1935 Freud[111] wrote to an American woman who appealed to him for advice about her homosexual son:

Dear Mrs. . . .

I gather from your letter that your son is a homosexual. I am most impressed by the fact that you do not mention this term yourself in your information about him. May I question you, why

Downloaded from www.obgyn.ir

you avoid it? Homosexuality is assuredly no advantage, but it is nothing to be ashamed of, no vice, no degradation, it cannot be classified as an illness; we consider it to be a variation of the sexual function produced by a certain arrest of sexual development. Many highly respectable individuals of ancient and modern times have been homosexuals, several of the greatest men among them (Plato, Michelangelo, Leonardo da Vinci, etc.). It is a great injustice to persecute homosexuality as a crime, and cruelty too. If you do not believe me, read the books of Havelock Ellis.

By asking me if I can help, you mean, I suppose, if I can abolish homosexuality and make normal heterosexuality take its place. The answer is, in a general way, we cannot promise to achieve it. In a certain number of cases we succeed in developing the blighted germs of heterosexual tendencies which are present in every homosexual, in the majority of cases it is no more possible. It is a question of the quality and the age of the individual. The result of treatment cannot be predicted.

What analysis can do for your son runs in a different line. If he is unhappy, neurotic, torn by conflicts, inhibited in his social life, analysis may bring him harmony, peace of mind, full efficiency whether he remains a homosexual or gets changed. If you make up your mind he should have analysis with me!! I don't expect you will!!! he has to come over to Vienna. I have no intention of leaving here. However, don't neglect to give me your answer.

Sincerely yours with kind wishes,
Freud.

CHAPTER 30

# DRUG ADDICTIONS

Marie Nyswander

Downloaded from www.dbraulibrary.org.in

As viewed by the medical practitioner, drug addiction today has three distinct aspects—psychological, pharmacological, and sociological. Of these, only the pharmacological aspects appear to remain constant. Regardless of time and place, pharmacological manifestations of the use of narcotics and the predictability of their effects have not changed.

## ¶ History of Narcotic Drugs

We find that man has used opium (from the opium poppy, *Papaver somniferum*) as far back as we have recorded data. Findings indicate that the Europeans have been cultivating opium for at least four thousand years, and the earlier records of the Sumerian civilization indicate that not only was the drug in use then but was given a name which it still holds today, "the plant of joy." Ancient writings show that opium was used throughout the rise and fall of the Babylonian, Egyptian, Grecian, and Roman empires. Homer refers to the poppy and its properties of "lethal slumber."

Hemp (*Cannabis indica, Cannabis americana*) has an equally long history of use as a narcotic and medicine, dating before 500 B.C. In India this drug was used orally in connection with certain religious rites. Its use did not remain restricted to India but, along with opium, was well known to the Europeans.

Records of the use of the leaves from the erythroxylon coca tree date it as a later discovery of man, occurring in the eleventh century in South America. This tree was utilized by the Incas in their religious rites. It seems entirely probable that the chewing of coca leaves has been a custom there as long as men have inhabited the region. Its introduction to Europe, however, was not until the middle of the eighteenth century and is credited to Joseph de Jussieu, a botanist.

Prior to 1903 opium and cocaine were used in their crude forms. Opium was smoked or the tincture, known as laudanum, was taken orally. At the beginning of the nineteenth century, Sertürner[15] isolated an active constituent from opium, which is known as morphine. Within the following thirty years, codeine, narcotine, papaverine, and other alkaloids derived from opium were discovered.

The invention of the hypodermic needle by Woods of Edinburgh in 1853 was to play an

important role in the story of modern addiction. At the time of the hypodermic's discovery, the claim was made that addiction was not possible if hypodermic administrations were used. The explanation for this claim was that if the narcotics did not reach the stomach, the person would not develop a "hunger" for them.

In 1898 heroin was isolated from opium and was widely heralded as a nonaddicting substitute for morphine. Its use became widespread, and fully fifteen years elapsed before physicians acknowledged its great addicting propensities.[16] Since that time, chemists have created a number of analgesics, hoping for one with the effect of morphine but without its addicting qualities.

Narcotics consist of two groups: (1) opium and its derivatives, and (2) their synthetic equivalents.

Opium is available for medical use in its pure powdered form. When opium is mixed with ipecac, its proprietary name is Dover's powder. Laudanum is a tincture of opium, and when this tincture is camphorated it is known as paregoric. Pantapon is a refined opium which is available for oral as well as hypodermic use.

The derivatives of opium include morphine, heroin (not manufactured in the United States), Dionin, Dilaudid, Metopon, Dromoran, and codeine. Codeine, too, has derivatives, namely eucodal and Dicodid (Hycodan). The two last-mentioned drugs are used more frequently in Europe than in the United States. The synthetic equivalents of the opiates consist of Demerol (meperidine, Dolantin) and methadon (Amidon, Dolophine, and Adanon).

Each of these drugs was originally felt to be nonaddicting, but in a short time after they became available, primary addictions to them were occurring.[19] The addictive potentiality of these drugs has been graded from the greatest to the least, in the following order: morphine, heroin, Dilaudid, Metopon, Demerol, methadon, and, lastly codeine.

Since 1915 the addict's drug of choice in the United States has been heroin. This has undoubtedly been due to the fact that it has a greater potency than the other narcotics and is also more easily obtained. Juvenile addicts use it almost exclusively. Its presence here is, of course, illegal. It is made from opium or morphine, probably in this country. Second in preference to heroin is morphine. However, addicts will use any narcotic if their drug of choice is not available.

Cocaine addiction is comparatively rare owing in part to its scarcity and to the fact that its effects of visual and auditory hallucinations are feared by most addicts. There is no evidence that tolerance is built up by repeated use of cocaine, nor that withdrawal symptoms occur at its cessation.

There has been a marked rise in the use of marijuana (Indian hemp) in both the American and European continents. In India it is either chewed or mixed with liquid drinks, but here it is smoked in the form of cigarettes. Its use is primarily confined to juveniles and jazz musicians. Its chief harm may be that it brings the user in contact with dispensers of heroin. There is no evidence that marijuana inflicts serious harm on the smoker. Although transient psychoses have been reported, these are few. Like cocaine, there is no tolerance developed, and there is no evidence of withdrawal symptoms upon its discontinuance. Marijuana creates for the smoker a euphoric state in which time passes seemingly very slowly. The pharmacological actions are not known but are probably cerebral in origin. Intellectual and muscular performance are impaired, and electroencephalograms show an increase in the muscular activity of the scalp.[20]

## ¶ Incidence of Drug Addiction

The nineteenth century marked the advent in this country of large-scale addiction. In 1885 addiction in the United States was estimated at from 1 to 4 per cent of the population. The exact incidence is still unknown, but a decrease in addiction occurred with the passage of revenue acts throughout the world, thus bringing drugs under government supervision (Harrison Narcotic Act, 1914, United States, and The Dangerous Drug Act, 1916, England).

Estimates of the incidence of addiction currently range from 60,000[2] to triple that number. England estimates only 400 addicts!

Downloaded from www.uramericanlibrary.in

Since 1914 the United States laws governing addict, peddler, and the physician-addict relationship have been the most stringent in the world, but it cannot yet be said that these measures have succeeded.

Addiction is common to the large cities and occurs most in New York, Chicago, San Francisco, etc. In the southern part of the United States, addicts are to be found primarily in the smaller towns.

The sexual ratio of addicts has reversed itself with the advent of the Harrison Narcotic Act. Prior to its passage, there were approximately 3 females to 1 male addict. At present, the ratio is 4 males to 1 female.

Except for physicians and nurses who comprise the largest single professional group, addicts are, on the whole, unskilled workers. This fact is explained by their early association with drugs, which interrupts all schooling.[17]

Studies of the religious background of addicts fail to reveal any predominant sect. Although recent surveys point to a rise in the incidence of addiction among Jews and Catholics, the evidence is not as yet conclusive.

It is, of course, an arduous task to estimate the family background of an addict. However, preliminary studies showed that 54 per cent came from homes that were intact and relatively normal.[11] More recent studies reveal varying psychological disturbances taking very specific directions.[1] In almost half the families investigated, the father of a juvenile addict either worked out of town, lived apart from the family, or was indifferent if not hostile to the addict. The mother appeared to dominate the household. Furthermore, these families were shown to have an undemanding attitude toward the addict. They did not encourage him to follow a vocation or schooling. As an example of this, one mother said to me, "Steve was never very good in school, but neither was I, so I didn't worry. I just wanted him to get by and be happy." This boy had an I.Q. of 124.

## ¶ Addiction Defined

British physicians have a simple operational definition of the addict—a person who feels normal on drugs.

In the United States Wikler defines addiction as the compulsive use of chemical agents which are harmful to the individual, to society, or to both.[21]

### *Tolerance*

Inherent in the definition of addiction are the phenomena of tolerance, dependence, and relapse.

Tolerance is the condition in which a diminution in the effectiveness of a drug occurs with repeated use. It is illustrated in addicts in whom tolerance reach has been built to as high as 75 gr. of morphine a day with no untoward effect.

Tremendous tolerance can be built up in a matter of months. Experimentally, it has been demonstrated that a tolerance of 1,200 mg. a day can be established in four months' time.[23]

With the development of tolerance to narcotics, some of the effects of a single dose of the drug cease. Thus, in the case of morphine addiction, there is no longer a depressant effect on respiration. With the growth of tolerance, the characteristic constipation may leave or may turn to diarrhea. The characteristic constriction of the pupils often disappears.

The physical reasons why addicts can tolerate such high doses of the drug are not yet understood. Tolerance is known to develop most easily under the regular administration of the drug. Recent reports indicate that a high degree of tolerance may occur with as few as eight doses of morphine administered in a two-day period.[22]

At present there is some indication that the early theories concerning the metabolic rate at which an addict destroys morphine in the body have some basis in fact. Another explanation was offered by the cellular-tolerance theory which postulated that the cells of the central nervous system become hyperirritable with repeated use of morphine and hence require more and more of the drug to reduce them to a state of equilibrium.

### *Dependency and the Abstinence Syndrome*

Physical dependency on the drugs is dramatically demonstrated when, after addiction

Downloaded from www.pdfbooksfree.org.in

is present, the drugs are withheld. The abstinence syndrome, thus provoked, consists of dilation of the pupils, twitching of the muscles, goose flesh, lacrimation, rhinorrhea, yawning, and sneezing. If allowed to continue, the symptoms may become alarmingly severe, with profuse sweating, elevation of temperature and blood pressure, vomiting, and dehydration. Although few deaths occur under even abrupt withdrawal, it is generally considered to be inhuman to give such treatment.

Withdrawal symptoms are physiologically determined and have been produced in dogs, cats, and monkeys, as well as in spinal and decerebrate preparations.[24]

Through the use of drugs, a new biological dependency such as thirst or hunger has been created.

A chemically induced abstinence syndrome may be effected with administration of the drug Nalline (n-allyl-normophine) to a person who is addicted. Nalline is antagonistic to the effects of morphine, despite the fact that it is also an opium derivative. Discovered in 1912,[18] it is in chief use by obstetricians who employ it to rid the newborn of possible lethargic effects from the narcotics given previously to the mother.

It is interesting to note that when Nalline is given in combination with morphine, it does not diminish that drug's analgesic effect.

### *Relapse*

Relapse is generally considered to be psychological and social in origin. However, there may be a pharmacogenic factor in relapse. It is quite common to observe addicts, during a long prison confinement, undergoing withdrawal signs. They subjectively report a deep craving for drugs and simultaneously experience mild lacrimation, sweating, etc. Whether they are psychologically reproducing the signs of physical dependency or whether there is a chemical stimulus involving the central nervous system has not been clearly determined as yet.

## ¶ Clinical Course of Addiction

Despite popular belief, addiction does not seriously impair either the mind or body, as do barbiturates and alcohol. There is no evidence of mental deterioration caused by drugs even after an addiction as long as fifty years.[12] Although addicts neglect their bodies and, as a result, may appear emaciated or have rotting teeth, they are a surprisingly healthy lot.

The course of addiction varies with the laws of the country as well as with the economic status of the addict. In England there is little association of criminality with addiction. In the United States those addicts who have been medically addicted and continue to receive drugs from physicians retain their economic status, working and living normally with their neighbors. The wealthy addict is rarely hailed into the courts.

The larger majority of addicts in this country, are, however, forced into social deterioration. Because of the exorbitant cost of illegal narcotics, addicts must rob, steal, prostitute, pimp, or peddle drugs. Social, not pharmacological, factors produce this type of criminality.

The years spent as a social outcast take their toll. For the ordinary addict, any dream of living within the law must be discarded. A marked diminution in libido may lead to marital difficulties. Gradually, the addict's main goal of existence becomes the satisfaction of his need for drugs.

## ¶ Psychodynamics of Addiction

Personality theories of the addict advanced twenty to thirty years ago have generally been discarded with the accumulation of data from institutions such as the United States Public Health Hospital at Lexington, Kentucky. In addition, these years have also seen a change in the type of addict himself.

Whereas dynamics of addiction formerly grouped narcotic addiction with alcoholism, pharmacological and psychological data now available warrant a clear line of demarcation between the two.

Drug addiction cannot be said to follow one specific neurotic pattern. Studies show that psychotic disturbances do not occur any more frequently among addicts than are found elsewhere.[12] Using our current nosology, addicts would fall into three main categories of personality disturbances: (1) inadequate person-

Downloaded from www.pharmpharm.org.uk

alities, (2) character disorders, and (3) all varieties of neuroses.

Psychiatric diagnoses have not appeared to be helpful in predicting the course of treatment for an addict. Borderline psychotics often surmount addiction and remain drug-free, and mild character disorders often remain in transient addictives. We must conclude that addiction may exist in individuals with almost any psychic organization, and that they may overcome the illness without necessarily undergoing any obvious change in the personality.

There is undoubtedly a psychological factor which determines an individual's reaction to drugs and, more specifically, why he chooses the drug he does. Work with placebos indicates that the person who will get consistent relief of pain from placebos is also apt to favor opiates over other drugs.[3]

Work by Chein[4] on the premorbid personality shows specific psychiatric disturbances which predispose such a person to addiction. Gerard[4] holds that all juvenile addicts are very disturbed individuals and would probably have required help in meeting their life problems whether or not they took to drugs.

Omnipotence, grandiosity, and magical thinking are revealed by conscious daydreams. Mistrust bordering on paranoid projections is frequently encountered. An inability to relate other than in a narcissistic fashion is best illustrated by the addict's frequent belief that he is so uniquely interesting that he should be paid by the treating psychiatrist.

Characteristic of the addict's psychology is his ambivalence regarding drugs. This is reflected in his statements and in his jargon, in which he refers to drugs as "junk" or "crap."

One observes a flattened effect in some addicts. This state is desired by the addict and is given the word "cool." In his innermost self, his idealized image is to be a person who is quiet, untroubled, and contemplative. Narcotics facilitate just such a state by virtue of their action on reducing aggression. So strong is the action of narcotics on aggression that vicious criminal tendencies have been known to have been reduced or eliminated after addiction.[6]

The continued use of drugs solidifies behavior, which includes a passive withdrawal from the main stream of life. His symptom becomes like a religion to the addict, and he moves in a circle inhabited by other devotees. They not only accept, in each other, the antisocial behavior into which they are forced but develop their own language for interchange. Although they, in part, feel rejected by the nonaddict world, they, in turn, exclude nonaddicts. Though these concomitants to addiction may prove decisive in the treatment of addicts, they are not necessarily representative of the basic dynamics behind addiction.

## *Wikler Theory*

I think it can be readily seen that a discussion of the psychodynamics of addiction in terms solely of unconscious impulses and psychic organization is to avoid the specific role which the continued use of drugs plays on an individual's reality and unconscious.

The theoretical formulations of Wikler are based on animal and human subjects and are the most comprehensive and inclusive that we have to date.[23] His postulated psychodynamics take into account the specific actions of narcotics.

Wikler has demonstrated that the specific actions of narcotics are based on the primary needs of man: hunger, sexual urges, aggression, and removal of anxiety and pain. Thus when the addict says he feels "normal" on drugs, he does. He feels sexually satisfied, full of food, and free from anxiety and pain; nor is he beset with aggressive strivings. (This is in marked contrast to the alcoholic who chooses a drug which releases inhibitions and becomes belligerent, exhibitionistic, grandiose, etc.)

Wikler concludes that "regardless of conventional personality classifications which may be applied to them, addicts are individuals in whom the chief sources of anxiety are related to pain, sexuality and the expression of aggression."

In summary, then, we may say that the complicated psychodynamic picture of the addict must include: (1) a possible premorbid personality problem, (2) normal strivings on

Downloaded from www.pdfaithy.org.in

a sexual and aggressive level, (3) overwhelming anxiety when it comes to satisfying these strivings by life's ordinary methods, (4) the knowledge of a drug which is pharmacologically specific for satisfying these strivings, (5) the creation in him of a new need by the use of narcotics, and (6) the all-important secondary reactions and gains from the continued use of them.

## ¶ Diagnosis

The diagnosis of drug addiction may be made quite simple for the physician by the manner in which the patient states his problem. The addict who is seeking drugs rather than treatment will probably attempt to simulate painful illnesses. He may put blood in his urine and complain of kidney stones. He may clutch his abdomen, heart, or back and complain of ulcers or a heart or gallbladder attack. Needless to say, the mention of a complete work-up before any medication is prescribed will generally speed his departure.

In cases involving former addicts who are attempting to reinstate themselves with a licensing bureau or an employer, Nalline has proved an effective gauge. Administration of 5 mg. of this drug to an actively addicted person will produce withdrawal symptoms within twenty minutes. Some patients offer to take such a test monthly, in order to reassure their families or employers. A cautionary note: Before Nalline is given, the patient should be forewarned that if he is on drugs, the injection may precipitate serious withdrawal effects which will be refractory to morphine for a period of about two hours.

## ¶ Treatment

### *Psychiatric Treatment*

Perhaps in no other field of medicine have so many strongly held beliefs been held by so few and developed on the basis of so little experience. The present recommended official treatment procedures stem from, and are limited by, recommendations made by the American Medical Association in 1924, which resulted in the Treasury Department issuing regulations which prevent physicians from administering opiates for the maintenance of addiction. This action seems to have been based on the widely held assumptions that addiction was evil, caused physical deterioration, and forced people into vicious crimes, and that physicians would be forced into criminal collusion if allowed to prescribe narcotics for them.

Although professional groups and individuals, surveying the current treatment status, suggest some modification of these early regulations, the basic premise for most treatment still is based on a moral attitude toward addiction. It follows, then, that acceptable treatment at the present time includes (1) enforced institutional treatment for approximately four months, (2) regulations against ambulatory treatment until the subject is drug-free, and (3) prohibition of self-administration of drugs even if regulated by a physician.

Estimates of cures based upon thirty-five years of these procedures range from 1 to 15 per cent.[13] It would appear that the old saw is true of the drug addict: "He who is forced against his will is of his own opinion still." Modern psychiatric knowledge insists that we take into account the motivation of a patient. It would therefore appear that supportive, reeducative, and rehabilitative methods are of little use to the addict when they are forced on him or when he has not expressed any wish for such help.

Successful treatment of addicts who wish help can be effected and is being effected despite limitations placed upon the physician. It is impossible to ascertain how large a group these addicts comprise. There are several papers available describing the successful psychoanalytic treatment of addicts on an ambulatory basis.[10, 14]

Psychiatric treatment of addicts does not differ from the treatment of any disorder which has symptoms of a behavioral nature. The presence of addiction may be treated as may any other symptom. A recent study[10] showed that, during the course of ambulatory psychiatric treatment, all the patients who con-

Downloaded from www.dbraulibrary.org.in

tinued therapy requested help for withdrawal, on their own initiative, within three months. Withdrawal, under conditions where the patient requests it, becomes a relatively minor procedure and may be accomplished at home or in a local hospital. One such patient, addicted for ten years to 4 oz. of paregoric daily, conducted her practice of law during withdrawal. She was gradually withdrawn (administering drugs to herself) and finally hospitalized over a week end to complete total discontinuance.

### *Withdrawal Treatment*

Withdrawal treatment of all narcotics (except primary addictions to codeine and Demerol) consists of giving the addict either morphine or methadon and slowly reducing the dosage until he is entirely off drugs. The maximum initial dose for any addict is either ¼ gr. morphine or 10 mg. methadon four times daily. In morphine withdrawal, dosages are reduced to ⅛ gr. morphine, and then 1 gr. codeine is substituted. This amount is eventually reduced to the vanishing point. In methadon withdrawal, the patient is kept on 5 to 10 mg. of methadon four times daily for several days. The shots are progressively reduced during the next few days and then stopped altogether. The major difference between withdrawal results of the two drugs is that morphine produces severe withdrawal symptoms within twenty-four to seventy-two hours, whereas methadon produces milder symptoms which occur from four to seven days after the drug has been discontinued entirely. A description of the detailed management of the patient during withdrawal can be found in the paper of Nyswander.[9]

To sum up, it can be said, in general, that addicts who consult the physician in order to be withdrawn from drugs, or for psychiatric treatment, can be helped, and that, as far as the majority of addicts are concerned, the physician can do nothing until they—for reasons of their own—seek such help.

## ¶ Barbiturate Addiction

Although hospital records show admissions for barbiturate addiction which date back twenty-five years or more, it was first reported in the medical literature in 1949 by Isbell.[5] It is still not uncommon to meet or to receive letters from physicians who vehemently deny that such an addiction can occur.

Barbiturate addiction is indeed very common and frequently goes unrecognized. The patient who is taking two, three, or four sleeping pills a night is more than likely addicted. He not only will not stop, he cannot stop. And if he does stop abruptly, he may experience such discomforting symptoms that he will beg to return to the pills or will obtain them without the physician's knowledge.

Tolerance for great amounts of barbiturates can be built up by the body. I have withdrawn patients taking as much as 40 gr. a day.

Barbiturate addiction greatly resembles the picture of alcoholism. In fact, both may occur in the same individual. Alcoholics are very prone to this addiction, and the drug should be used sparingly if at all with them.

Because of the mental status of a barbiturate addict, he usually appears as an unkempt individual whose gross and finer muscular control is poor. His gait may be staggering. His sensorium will be clouded and, like the alcoholic, his judgment will be greatly impaired.

The continued use of barbiturates, unlike opiates, is mentally deteriorating, and organic changes are to be seen on the electroencephalogram.

The abrupt cessation of barbiturates or even too rapid withdrawal of the drug may produce serious consequences. These withdrawal symptoms may range from gross tremors, disorientation, and hallucinations to tonic-clonic convulsions and hemiplegia.

Of prime importance in the treatment of this addiction is the use of the same drug for withdrawal.[8] *There is no substitute drug for withdrawal.* Treatment must be accomplished by a gradual reduction over a period of from

Downloaded from www.dbraulibrary.org.in

one month to six weeks. Withdrawal symptoms may occur anywhere from one day to a week after cessation of drugs. Needless to say, hospitalization is preferable for withdrawal. However, I have found it possible, by daily contact, to withdraw people quite satisfactorily on an ambulatory basis. In planning a withdrawal routine, it is necessary to specify the time that medication is to be taken. Midmorning, midafternoon, and bedtime are satisfactory for this. Reduction of the daytime medication by one or two pills every other day is a safe procedure. We have found that if the reduction does not exceed 50 per cent of the total dosage within a four-day period, withdrawal symptoms are not likely to occur.

In the event that the patient begins to show serious mental or physical symptoms of withdrawal, they can be quickly stopped by the administration of intravenous barbiturates.

## ¶ Amphetamine Sulfate (Benzedrine) Addiction

The occurrence of addiction to the stimulants Benzedrine and Dexedrine seems to have been considerably lessened in the last five years. This is due in part to the wider knowledge of its occurrence as well as to the manufacturers, who have cooperated in making the drug less easily available for abuse. However, primary addictions to these drugs do exist, and tolerance may reach proportions as high as 1,500 mg. daily.

The symptoms of addiction to amphetamine sulfate include the inability to stop its use, increase of dosage, insomnia, restlessness, irritability, and organic psychoses, including visual and auditory hallucinations.[7]

Unlike the other addicting drugs, the withdrawal treatment can be instituted by abrupt cessation of drugs. There are no withdrawal symptoms of great import.

There is no question that the prescribing of this drug should be under strict medical supervision to prevent the patient from using it as a daily "pickup." Its indiscriminate use frequently becomes the excuse for the patient to begin the use of barbiturates to "quiet him down." Thus the stimulants may usher in a more serious addiction to barbiturates.

CHAPTER 31

# ALCOHOLIC ADDICTION AND PERSONALITY

## (Nonpsychotic Conditions)*

Israel Zwerling
Milton Rosenbaum

Downloaded from www.dbraulibrary.org.in

The use of alcohol to induce a state of altered consciousness extends back into the earliest history of man—Noah (Gen. 9:21) was, perhaps, the first inebriate—and extends, as well, over virtually all of the earth. The varieties of beverages created to provide the alcohol, and of techniques for their preparation, are almost countless. A recent estimate cited by Keller and Efron[19] is that 68,000,000 persons in the United States drink alcoholic beverages, and Lewis[26] has noted that the annual expenditure in this country for alcoholic beverages exceeds the entire national expenditure for education. In itself, and as a reflection of man's ingenuity in inventing sources of pleasure, this is a phenomenon which would merit psychological investigation. Far more compelling of attention, however, is the population of alcoholics:

> . . . those excessive drinkers whose dependence upon alcohol has attained such a degree that it shows a noticeable mental disturbance or an interference with their bodily and mental health, their interpersonal relations and their smooth social and economic functioning; or show the prodromal signs of such developments.[46]

The magnitude of the population of alcoholics clearly establishes this entity as a major mental-health problem, and there is evidence that the prevalence has increased during the decade

* We are grateful to Professor Raymond G. McCarthy, Yale University Center of Alcohol Studies, for his critical review of this chapter and his valuable suggestions.

since Jellinek's classic estimate of alcoholism rates.[17] Keller and Efron, after converting total numbers of alcoholics with and without complications into rates for persons over twenty years of age, find a steady increase in the total prevalence rate in the United States from 1920 to 1953. For the latter year they estimate a total rate of 4,390 per 100,000 adults (7,590 per 100,000 men and 1,320 per 100,000 women) and a total of 4,589,000 alcoholics. The impact of this large population upon medical and hospital services, upon the national economy, upon judicial and correctional institutions, and upon family and community life is again of the highest order of significance.

A number of difficulties inherent in the study of alcoholism are pointed up by the very definition of this entity. Although there is no unanimity in support of the World Health Organization definition stated above, most current writers are in accord on the basic elements contained in this definition, perhaps with more specific attention to the compulsive character of the drinking. To begin with, the definition is descriptive and symptomatic, rather than etiologic, in character. It embraces a triad of phenomena at different levels of integration—physiologic, psychologic, and social—which not only characterize alcoholism clinically but also provide crucial data concerning etiology and treatment. Again, there is no possibility of quantification in such a definition, so that only qualitative estimates of the several elements may be made. Finally, the crucial criteria for the condition are social, and this introduces the temporal, ethnic, and class variability of, for example, standards of "good" and "poor" interpersonal relations, or of "good" and "poor" social and economic functioning, into the establishment of a psychiatric "diagnosis." One reflection of these difficulties has been the profusion of qualifying terms—"primary" versus "secondary" alcoholism; "symptomatic" versus "addictive" alcoholism, etc.—which may have some descriptive value but, in the end, add little more than new borderline states. The formal resolution of the Committee on Alcoholism of the Council of Mental Health of the American Medical Association (1956) that it and ". . . the profession in general recognizes this syndrome of alcoholism as illness which justifiably should have the attention of physicians" is a reflection of these difficulties in definition; there are, indeed, few diagnostic entities which were voted into the official nomenclature. Furthermore, the recency of this decision—that alcoholism is a medical rather than a moral problem—merits comment. The basic moral attitude to alcohol has been to characterize it as an evil, and its use as sinful. The Book of Proverbs enjoins, "Look not upon the wine when it is red, when it sparkleth in the cup, when it goeth down smoothly; at the last it biteth like a serpent and stingeth like an adder" (23:31, 32). In the sixteenth century, Sebastian Franck cautioned in his text *On the Horrible Vice of Drunkenness* that "More men are drowned in the glass than in the sea." A very recent pamphlet, which earnestly and intelligently stresses that alcoholics are sick people rather than hardened sinners, is yet entitled *Strong Drink is Raging* and pleads for "reverent understanding" that "Alcoholics are God's children, too—unlovely, perhaps, but God's." Undoubtedly, the persistence of the moralistic attitude toward alcoholism, in both lay and professional persons, and present at both conscious and unconscious levels, has seriously retarded the development of research and treatment programs.

The greatest difficulties in the study of alcoholism derive from the fact that data from physiologic, psychologic, and sociocultural fields are of such immediate relevance as to require that any approach to etiology, pathogenesis, or treatment take cognizance of all three. The observation, for example, that alcoholics may tend to be overly dependent in their adaptation does not readily suggest an application to the finding that a disproportionately larger number of persons of Irish descent, and a disproportionately smaller number of persons of Chinese descent, in the United States, are alcoholics; nor, again, to the finding that 17-hydroxycorticoid excretion is reduced in alcoholic patients. The philosophic problem of dealing simultaneously with entities at different levels of integration is as old as the mind-body problem, and a recent attempt at a resolution in application to be-

Downloaded from www.psychiatryonline.org

havioral science by Gerard[8] is noteworthy. The plan of the present chapter is to describe the conceptualizations concerning relationships between personality and alcohol addiction, and then to attempt an integration of psychodynamic and sociocultural formulations.

## Nonspecificity Formulations

A number of excellent summaries of the psychiatric literature on the etiology and pathogenesis of alcoholism have been published (Lemkau, Gibbins, Lorand, etc.), and an additional review is not justified. However, attention is called to the frequency with which the opinion is offered that there is no single specific personality disorder basic to alcoholism, at the same time that there is virtually no existing study which denies the coexistence of *some* personality disorder with every instance of chronic alcoholism. Diethelm[6] has noted, "There is not sufficient evidence to support the claim that specific personality types predispose to alcoholism." In the same volume Sherfey reviews the variety of psychiatric diagnostic categories found in a population of alcoholics, and concludes ". . . that alcoholism is not a single entity or disease, but a symptom associated with several illnesses or syndromes." A variant of this view is developed by Higgins[11] whose concern is rather with dynamic than with clinical diagnosis. He writes:

> In short then, a revised hypothesis can be briefly expressed in the following way: A predisposed person (*and the predisposition may represent fixations at various levels of personality development*) [emphasis ours] is confronted with a difficult life situation; the difficult situation may or may not be one which has as its primary component an oral threat; an attempt is made, through drinking, to handle the anxiety aroused by this conflict. The drinking may serve as a defense through various channels; it may bring diminished awareness of internal or external stress, or it may facilitate defenses previously inhibited.

It will be noted that two quite separate viewpoints are involved. The first holds that the finding of various clinical psychiatric diagnoses in a population of alcoholics is evidence of the lack of specificity of the psychopathology of alcoholism. This appears to the present writers to be a confusion of process and content: a constellation of traits may well be hypothesized to be basic to the etiology of addictive drinking, and yet be embedded in such a diversity of character structures as to be obscured to eyes focused only upon the most dominant integration of the total personality. A model is suggested by a perceptual test used by one of us in the study of alcoholism, the "Embedded Figures Test." A simple geometric figure (say, a pyramid) may be exposed to a subject, who will then experience difficulty in identifying it when it is re-presented but obscured within a complex geometric design. Patently, this is a mechanical and far more simple situation: the pyramid is not itself altered by the complex form in which it is embedded, and we would not expect a basic character pattern to be similarly impervious to broader integrative patterns of the total personality. But, the observation that a wide range of clinical diagnoses may be found among addictive drinkers does not preclude the role of a specific personality constellation as basic to the etiology of chronic alcoholism. The conclusion of nonspecificity reflects an approach to psychopathology which ignores unconscious processes.

The second viewpoint denying a unitary personality basis for alcoholism derives from the observation that conflicts at various personality levels may elicit drinking as a defense against anxiety—to make instinctual impulses more acceptable, or to make defenses more acceptable, or to narcotize the individual against the pain of the conflict. Again, as with the observation that many clinical diagnoses are to be found among alcoholics, this is readily verified in the course of the psychiatric study of alcoholic patients. The nonalcoholic who must "prime" himself for a sexual, or assertive, or aggressive situation, or who finds that a cocktail or a beer before dinner picks him up after an arduous day's work, is quite familiar, and the alcoholic who traces a binge to a dependency threat, a homosexual threat, a heterosexual threat, the threat of the crup-

Downloaded from www.pbookshop.com

tion of powerful hostile impulses, or whatever, is equally familiar. But the existence of an underlying personality disorder common to alcoholics is not at all precluded by the observation that alcohol may be pressed into the service of the personality at all levels of conflict and in association with all varieties of defense. The question as to why the addictive pattern develops in some of the army of imbibers, and not others, remains quite unsolved by such observations. It is not crucial to the thesis that the addictive *process* develops on a specific personality base, that any specific addictive *practice* must similarly trace to conflicts derived from this same base. It is the view here proposed that alcoholism may be found in the setting of any clinical diagnostic state, and that specific drinking episodes may occur in relationship to conflicts at all personality levels, but that the addictive process does develop in a specific character matrix.

## ¶ Psychoanalytic Formulations

A number of contributions attempting a description of the psychodynamics of alcohol addiction have been developed out of experiences with the psychoanalysis or psychotherapy of alcoholics; those of Rado,[33] Knight,[22] and Lolli[27] will be briefly summarized.

Rado starts by stressing that ". . . not the toxic agent, but the impulse to use it, makes an addict of a given individual" and further, that ". . . we feel impelled to regard all types of drug cravings as varieties of *one single* disease" which he terms "pharmacothymia." He finds, in the potential addict, ". . . a certain active preparedness for the pleasure-effect of the elatent drug." This derives from their membership in ". . . the group of human beings who respond to frustration in life with a special type of emotional alteration, which might be designated tense depression . . . marked by great painful tension and at the same time by a high degree of intolerance to pain." This condition is remarkably improved by alcohol, which brings about a sharp rise in self-regard and an elated mood. Rado stresses that this magical effect is brought about by the ego itself: "A magical movement of the hand introduces a magical substance, and behold, pain and suffering are exorcised, the sense of misery disappears and the body is suffused with waves of pleasure." This state is, however, inevitably followed by the rapid return of the tense depression, and with it the renewed craving for elation: ". . . the ego is now maintaining its self-regard by means of an artificial technique." The sexual life of the patient is rapidly caught up in the addictive illness—"all elatents poison sexual potency . . . the pharmacogenic attainment of pleasure initiates an artificial sexual organization which is autoerotic and modeled on infantile masturbation . . . the pharmacogenic pleasure-effect discharges the libidinal tension associated with these (oedipal) fantasies. The pharmacogenic pleasure process thus comes to replace the natural sexual executive." The self-destructive aspects of the pattern inevitably are presented to the addict: by illness consequent to the addiction, by pressure from family and friends, and by the increasingly transient nature of the pleasure. The addict characteristically handles the crises which arise by a transient flight into a free interval; alternatively, suicide or psychosis may be seen. This free interval can only be a brief interlude, and the pharmacothymic process reasserts itself. Rado views homosexuality in addiction as a fusion of genital erotism and masochism—as retreat from active heterosexual pursuit, denial of castration, and the pursuit of the passive goals of masochism. In his recent restatement of his views,[32] the essence of the addictive process remains unchanged, but with the substitution of the adaptational concept of hedonic regulation for the classic libido theory, there is less specific concern for the symptomatic manifestations of the replacement of the sexual pleasure apparatus by the pharmacothymic pleasure system.

Knight presents a summary of his observations on the psychodynamics of the alcoholic as follows:

His childhood experiences have given him a personality characterized by excessive demands for indulgence. These demands are doomed to frustration in the world of adults. He reacts to

Downloaded from www.pdfchm.org

the frustration with intolerable disappointment and rage. This reaction impels him to hostile acts and wishes against the thwarting individuals for which he then feels guilty and punishes himself masochistically. As reassurance against guilt feelings and fears of dangerously destructive masochism and reality consequences of his behavior, he feels excessive need for affection and indulgence as proof of affection. Again, the excessive claims, doomed to frustration, arise, and the circle is complete. The use of alcohol as a pacifier for disappointment and rage, as a potent means of carrying out hostile impulses to spite his parents and friends, as a method of securing masochistic debasement, and as a symbolic gratification of the need for affection is now interweaving itself in the neurotic vicious circle.

He observes that the mother of the alcoholic is characteristically overprotective and indulgent, and ". . . by fostering the pattern of soothing the infant through oral pacifying, she builds in a pattern of tremendous strength." It is out of this course that alcoholism develops as an attempt to cure or solve some emotional conflict. Knight denies any specificity as to the type of emotional conflict—"any type of neurotic conflict may be present"—but traces the development of addiction to early experiences which produce the impulsive character structure which cannot tolerate frustration, which responds with rage and, in turn, guilt and masochistic repair, and which sustains itself through proof of affection which is unrealistic and insatiable, and thus continuously feeds frustration back into the addictive cycle.

Lolli has approached alcohol addiction as a manifestation of a diseased food attitude, and has noted the significant parallels between compulsive drinking and obesity. His most recent summary formulation of the psychodynamics of alcoholism may be quoted:

> The alcoholic experiences unconscious and to a certain extent conscious longings for physical warmth, pleasurable skin sensations, maternal coddling, liquid and warm feelings in his stomach which are not differentiated from longings for security, reassurance, self-respect, independence and, at times, omnipotence. In contrast to the infant, the alcoholic is denied in real life the experience of undifferentiated pleasure of body and mind for which he is hopelessly yearning. The revelation that alcohol is able to provide a blended pleasure of body and mind marks the beginning of the addiction. . . . Under its influence (i.e., alcohol) the alcoholic first disregards and finally denies the reality of the world he lives in. . . . The alcoholic is an individual who lives under the tyranny of his past, of his very early childhood. The confusion between pleasures of the body and pleasures of the mind which is normal in the infant hinges around the alcoholic's adult life. Thus, the beverage alcohol is closely linked with the beverage milk which quenches the infant's thirst, satisfies his hunger, and gives him the security and power of mother's love. Alcohol gives the alcoholic adult what milk gives the normal infant. . . . Experience teaches that an inadequacy—real or fantasied but felt as real by the alcoholic—is found in his childhood relation to his own mother. The tyranny of these early events is enormous. Later experiences in life can minimize but never really nullify the meaning of a mother-child relation in which the complete satisfaction of an instinct, hunger, only can occur through and is not distinguished from the perfection of a secure, mutually rewarding association.

Lolli's formulation emerges from his religio-existentialist philosophy and his extensive clinical and research experience with alcoholics, Rado's current approach is from the framework of adaptational psychodynamics, and Knight writes from his experience with and interest in the application of classic psychoanalytic dynamics and of modifications in classic therapeutic technique to borderline states. Yet it is not difficult to detect the consistent thread which runs through the contributions of all three, as well as of Schilder,[35] Bergler,[2] and others: in essence, the alcoholic is seen as having been rendered vulnerable, by early security-threatening experiences of deprivation, to addiction to a magical fluid which dispels tension and depression, relieves the sense of aloneness, places an instantaneously available source of pleasure at his disposal, permits the mastery and simultaneously the expression of unmanageable hostile feelings, and has a virtually built-in and guaranteed array of sufferings and punishments which serve both to

Downloaded from www.ubpnitrariers.in

appease the conscience mechanism and to feed back stress stimuli for continuing the cyclic addictive process. There is a parallel in this formulation to recent views of the pathogenesis of psychosomatic illness, in which disease processes are seen as originating in relation to specific patterns of conflict between personality organization and life situation, but as coming eventually to serve as channels which drain conflicts quite removed from those of specific etiologic significance.

## ¶ Learning Theory and Conditioned-Reflex Formulations

Concurrent with the growing psychoanalytic interest in ego psychology, there has developed increased attention to learning theory in psychiatry.[12] Although there has been no systematic attempt to develop an approach to the etiology and pathogenesis of alcoholism in terms of the principles of learning and conditioning, this appears to the present writers to be a most likely development. Certainly, a number of clinical observations readily suggest a relationship between the paradigm of Skinnerian conditioning and the development of alcoholism. The pattern, anxiety → alcohol → relief from anxiety, is practiced repetitively and becomes highly overlearned; the reinforcement (that is, relief of anxiety) is immediate, in contrast with the delayed reinforcement of other, alternative, adaptive maneuvers for handling the anxiety; the conditioned reflex (that is, drinking), as is characteristic in conditioning, progressively pre-empts the field of response choices, which narrows rapidly down to virtually this one response for the widest range of stimuli; and finally, the conditioned reflex is essentially nonadaptive, and therefore contributes to the perpetuation of the anxiety to which it has become a response.

Two series of animal studies provide supportive evidence in this general direction. Masserman and Yum[30] observed that alcohol "disintegrated" conditioned responses in cats, and had selectively greater effects on more complex and more recently learned responses. Masserman *et al.*[29] had previously demonstrated that alcohol protected cats from developing "experimental neuroses" when subjected to conflicting fear and hunger motivations. In the 1946 study, the authors report the development of "experimental neuroses" in twenty-one cats, who were rendered incapable of simple goal-directed behavior by the "neurosis." Alcohol "disintegrated" the neurotic patterns, and permitted simple food-getting responses to supervene. While "neurotic," the cats preferred alcohol to alternative fluids equally available; however, as the "neurotic" symptoms receded, the "addiction" disappeared. They conclude that, while alcohol ". . . partially disintegrates . . . all behavior patterns . . . nevertheless, along with these general effects there occurs a particular disorganization of highly complex neurotic patterns themselves, so that, with small doses of alcohol, more nearly elementary and better established reactions . . . remain relatively intact and reappear in overt behavior."

Conger[4] ingeniously advanced the work of Masserman and Yum a significant step further by demonstrating in the albino rat (1) that alcoholized animals resolved a simple approach-avoidance conflict, while control animals continued to hesitate in approaching the feeding box where they had received electric shocks; (2) that the resolution was produced by a diminution in the avoidance (or fear) response rather than by a heightening of the approach response; and (3) that alcohol given only when the animal was shocked impaired the development of a discriminatory conditioned reflex, in contrast to alcohol given only on nonshock trials, although eventually the discriminatory response was established. Conger proposes that the differential reduction of fear is the crucial reinforcement which makes the learning of the drinking response so efficient in the alcoholic. In another paper[5] he and, independently, Shoben (cf. Kruse[23]) have offered some perspectives for a research program in this area. Both writers point out that there is no necessary conflict between reinforcement theory and psychodynamics, but rather that the two approaches may supplement each other. It is the feeling of the present writers that the systematic investigation of the laws

Downloaded from www.cambridge.org

of conditioning with specific reference to alcohol addiction presents a meaningful line of research. However, it can be anticipated that the crucial obstacle will be the variability of the reinforcement value of alcohol in humans as against the presumably constant reinforcement value of, say, food following a defined starvation period in animal studies. There is an enormous gap between the roles of externalized and reality-borne sources of fear and conflict, and internalized, unconscious, and irrational sources.

## ¶ Psychological Test Data

The literature on psychological test data bearing upon personality structure and alcoholism is extensive and is rapidly expanding, so that a complete review is not possible within the confines of the present chapter. Sutherland, Schroeder, and Tordella,[88] and Gibbins[9] have critically summarized a number of studies reported through 1952. The issue of character specificity in alcohol addiction is again central in these studies, and again there is a sequence of reports of negative findings as to specificity but positive findings as to pathology. Again, strikingly, these seem to evoke further studies of similar design and, inevitably, similar findings and conclusions. It is abundantly evident that no reliable difference in objectifiable and tabulable performance data from any of the standard projective and nonprojective personality tests uniquely characterizes alcoholic patients and differentiates them from normal controls or from nonalcoholic mentally or emotionally ill patients. Again, the significance of negative evidence of this sort must be seen as subject to several limitations, including the relevance of test items to personality structure and especially to personality in alcoholism, availability of personality disturbances in alcoholism to quantification and tabulation, and variability in the manifestation of underlying disturbances with variations in other personality dimensions. It is the latter problem in particular which the present authors wish to stress.

Similar dependence-independence conflicts, for example, based on similar early life experiences, but integrated (1) into an obsessional character structure with crucial concern with power struggles against authorities, (2) into an hysteric character structure with crucial concern with establishing a sexual identification, and (3) into a schizophrenic character structure with gross disturbances in affective and thought processes, will not reveal themselves as similar if psychological test performances are subjected to quantitative item analyses. The alternative procedure, that is, the clinical analysis and evaluation of the test performance as a whole, is hazardous in research, since it invites the bias of the investigator to select from the productions of the patient those responses which are most consistent with the bias. It seems fair to state that most studies in which the test data have been itemized, quantified, and tabulated have provided negative results, whereas most studies in which the test data have been analyzed and evaluated as a whole have led the investigators to positive conclusions concerning the specificity of psychopathology in alcoholism. Sutherland *et al.* sum up their review by stating that "No satisfactory evidence has been discovered that justifies a conclusion that persons of one type are more likely to become alcoholics than persons of another type." On the other hand, a number of careful clinical studies have led the investigators to strikingly parallel conclusions. Billig and Sullivan[8] studied the Rorschach responses of 29 hospitalized and 11 jailed alcoholics, and found consistently (1) an unrealistically high level of aspiration coupled with limited achievements; (2) poor restraint or control of impulses; (3) tendencies to withdraw from the environment, linked to an inability to effect smooth reality relationships; (4) self-centered thinking patterns, with rich imaginativeness; and (5) wide and poorly controlled mood swings. Halpern[10] contributed a summary of psychological test data obtained from 47 patients whose psychiatric histories were separately reported. She stressed the impulsive, willing-to-take-chances approach, the use of the mechanism of denial, the underlying wish for a passive role, and the need for self-punishment. Her composite picture of the

Downloaded from www.dbraulibrary.org.in

alcoholic from his Rorschach performance is illuminating:

He is a maladjusted, immature individual who has developed few techniques for alleviating his feelings of discomfort. Actually, his attitude implies that he will not recognize limitations or inadequacies in his personality, will not admit them. In order to convince himself that he has no need to compromise or inhibit his reactions, he deliberately exposes himself to irritating and challenging stimuli instead of insulating himself against them. There is a certain "grandiosity," a certain omnipotence in such behavior. This refusal to accept his personality problems in a way that would enable him to work with them and build up the more acceptable forms of compensation is one of the most striking characteristics of the alcoholic personality as revealed in the Rorschach Test protocols. If he cannot accept the idea of limitations or inadequacy, the conflict must be outside himself, and he proceeds to externalize it. While there is tremendous aggression of a kind in such an attitude, and it is part and parcel of the general highhandedness found in many of his reactions, the alcoholic does not really strive for activity and aggression. He is satisfied with the passive role in the majority of instances, and it is important to him to find a passive way of handling his difficulties, a way which will put the problem outside himself and make no active demands on him.

Klebanoff,[21] using the Thematic Apperception Test in a study of 17 nonpsychotic chronic alcoholics, reported the predominance of intoxication and rejection themes in the productions of his subjects, along with pervading concern for power or dominance-submission struggles in which the central character generally failed.

There is consistency in these and other studies with regard to the findings of poor reality testing, depressive trends, difficulty in impulse control, and struggle with activity-passivity conflicts. The further consistency between these findings and the psychodynamic formulations of Rado, Knight, and Lolli summarized above is immediately apparent.

## Physiologic Data

Studies concerning the possible role of various physiologic factors in the etiology and pathogenesis of alcoholism are as rife with disagreement—at times quite bitter—concerning the nature of the physiologic defect as are the conflicting views of the partisans of a physiopathologic theory with those of a psychodynamic theory. There can be no question of the gross physiologic and neurologic derangements associated with acute intoxication, nor with the gross metabolic and nutritional disturbances associated with chronic alcoholism, nor again with the diffuse organic symptoms associated with the abrupt withdrawal of alcohol from an addict.[14] These are not issues germane to the present chapter, however. Our concern is with the role of physiologic factors in the development and maintenance of the addictive cycle. A number of diverse approaches have recently been offered. Williams[44] has developed a genetotrophic theory on the basis of his demonstration that rats deprived of B vitamins select, with variable readiness among different strains, a dilute solution of alcohol in preference to water. His theory is complex, and a brief summary may not do justice to his views. He holds that genetically determined and partial enzymatic defects render carbohydrates less readily metabolized and consequently inadequate as sources of rapid energy, and alcohol, experienced as a replacement source, is craved for precisely this effect. His theory explains cultural differences in incidence on the same basis—for example, the difference in incidence of alcoholism between people of Jewish and of Irish descent is presumed to be due to hereditary differences in the intactness of the metabolic apparatus for handling carbohydrate dissimilation. Lester and Greenberg,[25] however, demonstrated that under identical experimental conditions, but with an additional fluid choice to the water and alcohol solutions in the form of 11.5 per cent sucrose solution, the rats drank the latter and none took the alcohol; fat and saccharine

Downloaded from www.pdfbooksfree.pk

solutions and solid sucrose also diminished alcohol intake, although to lesser degrees.

Smith[36] sees a biochemical and clinical similarity between delirium tremens and Addisonian crises: in both, plasma potassium and nitrogen are elevated, sodium and chloride are decreased, and acidosis, malaise, vomiting, slowed pulse, and low blood pressure are present; in both, terminally, a rapid and thready pulse, high fever, and markedly elevated respiratory rate are noted. He reports findings of similar, though less severe, biochemical changes in acute alcohol intoxication and adrenal cortical insufficiency, and posits in alcoholics (1) a constitutional susceptibility of the adrenal to alcohol, genetically transmitted, and more heavily clustered in Celtic and Scandinavian people, and (2) the development, especially during the period of heightened susceptibility at the time of the male climacteric, of adrenogonadal deficiency which in turn, by implication (this is not directly stated by Smith), creates a craving for alcohol as an adrenocortical stimulant. Wexberg[48] has systematically reviewed Smith's work and convincingly argued for adrenogonadal hypofunction as a complication of, rather than a cause of, prolonged drinking.

Mardones[28] has offered a systematic experimental approach in support of an organic theory of etiology in alcoholism. A series of autoselection experiments with rats led him to postulate a specific dietary factor—"$N_1$"—a lack of which causes an increase in the voluntary consumption of alcohol; this is aggravated by thiamine deficiency. The defect has been localized in the pyruvate-to-acetyl coenzyme A step in carbohydrate metabolism. Studies with tagged ($C^{14}$) carbohydrates, however, indicate an absence of alcohol dehydrogenase in brain tissue, which would render the role of alcohol in repairing the defect which Mardones postulates as doubtful. Evidence for this "$N_1$" factor seems compelling, however, and his own summary may be quoted:

> All the facts . . . induce us to believe that voluntary alcohol intake is increased when a difficulty in the utilization of the energy of carbohydrates or fats is present, and that this difficulty does not interfere with the utilization of the energy of the alcohol. They also induce us to suspect that, in some cases, the excessive ingestion of alcohol is not the cause but the consequence of nutritional or metabolic difficulties.

There have been a number of other organic approaches which merit passing mention. One finds repeatedly in the literature—though no systematic presentation of supporting data has come to the attention of the present writers—reference to the idea that alcoholism is the behavioral consequence of an "allergy" to alcohol. Fleetwood and Diethelm[7] reported evidence for "anxiety," "tension," and "resentment" factors in the blood of all humans; in alcoholics, the resentment factor would characteristically be found to rise over a period of days or weeks, with no conscious awareness by the patient or manifest change observable by an examiner; when it reached an intensity of 25 gamma or higher, the alcoholic would drink, and the titer of resentment factor would disappear within an hour. Various other writers have implicated thyroid deficiency, defects in the hematoencephalic barrier, and toxic products of alcohol metabolism with direct addicting effects upon the cortex.

The variety of physiologic theories reflect the experimental dilemma which faces the investigator: to study objective human behavior or subjective reports of feelings of craving involve the investigator in dependent variables too complex to permit of definitive conclusions from any body of data; alternatively, to study animal behavior under controllable conditions permits of limited conclusions with reference to the nature of the role of alcohol in the behavior of the animals and only highly speculative applications to alcoholism in humans. Furthermore, animal studies are inherently limited to demonstrating that certain physiopathic states produce a *preference* for alcohol and never a *craving* for alcohol. Again, the clinical phenomenology familiarly observed in alcoholism would appear to require rather unfamiliar physiologic mechanisms which would not only be operative during the period of withdrawal but would remain operative after the disappearance of withdrawal symptoms and through years of total abstinence. In the light of the frequent observation of alcoholics in-

Downloaded from www.PsychiatryOnline.org

gesting hair tonics, skin and shaving lotions, and various other ill-tasting fluids, it becomes apparent that the craving is not in response to altered taste and smell sensation, as is the case in animal studies in which atypical food preferences are created by either deficient diets or experimental alteration of metabolic processes; rather, it is a craving for the *effect* of the alcohol. In the same vein, such experimental studies have always dealt with the absence of necessary metabolites, and to posit an "alcohol-deficiency state" in consequence of which the subject craves alcohol seems doubtful. Critical reviews of physiopathic theories of the etiology of alcoholism have been contributed by Wexberg[43] and by the Joint Expert Committees on Mental Health and on Alcohol of the World Health Organization (cf. Jellinek[18]). It remains an open question as to the role of a biochemical or physiological predisposition to alcohol, as well as to the role of alcohol itself in establishing a bodily state of greatly enhanced readiness to consume more alcohol.

## ¶ Sociologic Approaches

Although there is no systematic sociocultural study of prevalence rates of alcoholism, there is substantial indication that there are reliable differences in male-female rates.[19, 20] The World Health Organization estimates the following prevalence rates of alcoholism with and without complications (data approximately for 1953):

| RANK ORDER | COUNTRY | RATE PER 100,000 ADULTS |
|---|---|---|
| 1 | United States | 4,390 |
| 2 | France | 2,850 |
| 3 | Sweden | 2,580 |
| 4 | Switzerland | 2,385 |
| 5 | Denmark | 1,950 |
| 6 | Canada | 1,630 |
| 7 | Norway | 1,560 |
| 8 | Chile | 1,500 |
| 9 | Finland | 1,430 |
| 10 | Australia | 1,340 |
| 11 | England | 1,100 |
| 12 | Italy | 500 |

A number of approaches to these data merit review.

Horton[13] analyzed 56 primitive societies for which data were available as to the amount of alcohol consumed, the relative subsistence security, and the accessibility of alcoholic beverages. He was able to demonstrate a convincing relationship between a high degree of subsistence anxiety—inferred from the level of subsistence hazards or inadequacy of subsistence techniques—and "strong degrees of insobriety": the greater the anxiety concerning drought or flood or crop failure, or concerning the potential disruption of food supply by more powerful neighboring societies, the greater the amount of drinking, except as this relationship might be influenced by nonavailability of alcohol. Horton makes special note of the tendency, among members of those societies in which ceremonial drinking would take on a near-compulsive quality and continue to the point of total unconsciousness, for aggressive behavior to emerge during the drinking bout. In essence, Horton proposes that alcohol has the "unequivocally significant" property of reducing anxiety, and that it will be differentially used among different societies, depending upon the level of basic security anxiety, regard being given to its availability.

Bales[1] has proposed a complex and encompassing theory relating social organization and cultural practice to alcoholism. He sees three bases for the relationship: (1) "the degree to which the culture operates to bring about acute needs for adjustment, or inner tensions, in its members"; (2) "the set of attitudes toward drinking which the culture produces in its members"; and (3) "the degree to which the culture provides suitable substitute means of satisfaction." He adds to the Horton data, in connection with the first point, observations by Bunzel on the Chichicastenango Indians in Guatemala, and by Hallowell on the Northeast Woodlands Indians in the United States, and offers a description of Irish social structure in which many stress areas are noted. With reference to his second basis for relating culture and alcoholism, Bales states that "The crucial factor seems to be whether a given attitude towards drinking positively suggests

Downloaded from www.libtool.com.cn

drinking to the individual as a means of relieving his inner tensions, or whether such a thought arouses a strong counteranxiety." He describes four cultural attitudes: the abstinent, ritual, convivial, and utilitarian. Complete abstinence, or total prohibition, is well illustrated by the Moslems. Bales notes that "An attitude capable of restraining strong impulses in all members of a group cannot be created by fiat," and that, indeed, "The breaking of this taboo becomes an ideal way of expressing dissent and aggression" and anticipates that this prevailing attitude will be variably associated with high and low alcoholism rates, depending upon the pressure of anxiety. The ritual attitude is illustrated by the drinking patterns of orthodox Jews: the crucial aspect of this attitude is that precisely because drinking is so intimately a prescribed part of a substantial number of religious rituals,

> . . . the wine is sacred and drinking is an act of communion . . . repeated again and again, and the attitudes toward drinking are all bound up with attitudes toward the sacred in the mind and emotions. In my opinion this is the central reason why drunkenness is regarded as so "indecent"—so unthinkable—for a Jew. . . . Drunkenness is a profanity, an abomination, a perversion of the sacred use of wine. Hence the idea of drinking "to become drunk" for some individualistic or selfish reason arouses a counteranxiety so strong that few Jews ever become compulsive drinkers.

Snyder,[37] in a series of articles, has applied Bales's proposal to a more thorough and systematic appraisal of nondrinking among Jews, and similarly concludes, ". . . the orthodox Jew cannot, as it were, split the concrete act of drinking from the controlling elements in his conscience." The "convivial" attitude seems hardly to merit a separate description from the "utilitarian" attitude, in which drinking is "

> . . . calculated to further self-interest or exclusively personal satisfaction."

Here are included drinking as part of economic transactions, or drinking to celebrate all the principal occasions in the life cycle where the drinking is not part of any attendant religious ritual itself but is part of the conviviality, or—perhaps most clearly "utilitarian"— drinking to get over a hangover. In such a setting, the inebriate is likely to be treated with kindly care, or even with envy—and Bales notes that the characteristic Irish mother's attitude to her drunken son is that he is "the poor boy." Bales cites drug addiction (for example, in Jews, Japanese, and Brahmins, who have low alcoholism rates) as prominent among alternative provisions by the culture for dealing with the tensions which it creates. Bales sees his three modes of relating culture and drinking as simultaneously operative. "They all work together, and the rates are complicated end-results." Barnett (cf. Diethelm[6]) has offered an analysis of the strikingly low incidence of chronic alcoholism among the Cantonese living New York City's Chinatown area, which at first glance appears to offer contrary data to Bales's formulation of convivial and utilitarian drinking attitudes as consistent with high rates of alcoholism. He notes that, "Within the home, and at social gatherings, drinking represents an important social function. At meals and banquets heavy eating is accompanied by considerable alcohol consumption." It is clear, however, that in this instance, the role of religious sanctification is taken by the sanctification of the revered parental figure, in whose presence intoxication would be looked upon as an affront. Furthermore, Barnett stresses that the drinking pattern is consistent with the fundamental expectations and obligations of Kwangtung culture, to the extent that, even when intoxicated, the drinker remains quiet and is kept from public view. He sees a role, as does Bales for the Jews, for the factor of minority-group status as forcing upon the Chinese in the United States a need for maintaining control and avoiding scandal and persecution.

A quite different sociologic approach is exemplified by the study of Mowrer and Mowrer.[31] Their specific hypothesis concerning alcoholism as ". . . an escape mechanism by which the individual seeks to reinstate in adult social relationships a preferred superior role achieved in the early family group," is not the concern of the present writers so much as their application of the "ecological approach." Their

Downloaded from www.dbpublishing.com

specific ecological hypothesis is that alcoholism is etiologically associated with the

> . . . differentiation of areas of varying rapidity of social change and disorganization, the rates of which are roughly inversely related to the distance from the center of the community. . . . Thus, rates of inebriety . . . present a pattern of bands in the general form of concentric half-circles; the highest rates occur in those communities which form the axes of the arc, and the rates decline progressively to the peripheral band of communities, in which they approach zero.

Their own data show how dubious is the regularity of the relationship they posit, but the desirability of an ecologic approach to the etiology of alcoholism can hardly be doubted. Gordon (cf. Kruse[28]) poses an epidemiological approach to alcoholism as a medical problem in which *any* use of alcohol is subsumed under "alcoholism," and addiction and alcoholic psychoses are seen as merely the end states of the total process: by analogy with diphtheria, abstainers are like those with no diphtheritic infection, the social drinkers are like those with inapparent infection, the symptomatic drinker like the patient with atypical clinical diphtheria, the alcohol addict like the typical diphtheritic, and the deteriorating organic psychotic like the patient with black diphtheria. Such a biologic gradient, coupled with an ecologic approach involving considerations of agent (that is, type of beverage), dosage, host, and environmental factors, offers the basis for a program of prevention and control more promising to Gordon than a program of clinics for the treatment of the alcoholic: "A program based on treatment of the exaggerated illness is temporizing and with no great promise of productive result; it is good clinical medicine but poor public health."

Still another sociologic approach is offered by the methodology of Ullman.[39] He reports significant differences in the memory of the first drink among alcoholic and nonalcoholic subjects: the alcoholic has more frequently a clear and vivid memory of the event; it occurred in places in which it is unusual to drink; it occurred at a later age than in the nonalcoholic; and there is a clear recollection of some remarkable effect—for example, 40 per cent reported getting sick. Those normal drinkers who did recall their first drink had it at home or at a gathering or event at which alcohol is ordinarily consumed as a matter of course, had it at an earlier age, and less frequently recalled any particular effect. If the nonalcoholics are tabulated according to per cent recalling their first drink, the rank order was Irish, English, Scandinavian, Jewish, French, German, and Italian, corresponding fairly closely to the rank order of his populations in incidence of alcoholism.

These and other studies in class and national differences in alcoholism rates permit of no simple summary formulation. There is little room for doubting that, whatever the dynamic social forces and counterforces involved, cultural determinants of alcoholism are of decisive significance. The consistency with which certain national and ethnic groups persist in manifesting significantly high or low prevalence rates, in an era of rather little variability with regard to the availability of alcohol in the culture or to subsistence anxieties, indicates the prepotent influence of cultural attitudes to drinking and inebriety. It would appear that the impact of these forces reaches the individual early in development, and the direction imparted may be detectable by family studies, and especially longitudinal studies, of alcoholic and nonalcoholic subjects. The implications of the sociocultural data concerning alcoholism for a predictive study have never been fully explored.

## ¶ Interdisciplinary Approach to Alcohol Addiction

Specific methodologic concern with multifactorial etiologic approaches in psychiatry is provided elsewhere in the present text. Data derived from an interdisciplinary study of 46 alcoholic subjects, of whom 23 were currently drinking and 23 had been "dry" for two or more years at the time of study, may be drawn upon for a summary statement on alcohol addiction and personality. Psychiatric histories were obtained in five hours of anamnestic

Downloaded from www.dbraunbrary.org.in

interview by one of the present writers, who also served as project director, under the general guidance and supervision of Dr. Howard M. Potter, Professor of Psychiatry at the State University of New York College of Medicine at New York City. A battery of paper and pencil and projective personality tests were administered, scored, and interpreted. Social and family histories were obtained from the subjects and from a family informant. Perceptual tests, and physiologic and metabolic studies were conducted. The study was conducted at the State University Alcohol Clinic, State University of New York College of Medicine at New York City, from 1954 to 1956. Separate initial reports from each discipline are currently in preparation for publication.

### *Psychiatric Interviews*

Life-history data revealed a range of nosologic entities, including virtually all categories of neurosis, functional psychosis, and character disorder. The spectrum of alcoholic phases described by Jellinek[18] could be identified in each subject. The early readiness to respond to alcohol was a prominent finding; one subject put it, "I could hardly wait until I was sixteen and could start drinking." The significant psychiatric finding was the consistent presence of a number of descriptive-dynamic states which suggested a basic character disorder underlying the varied psychopathologic pictures found in these subjects:

1. The subjects are *schizoid*. There is a basic sense of estrangement or isolation from people, associated with a characteristic quality of egocentricity and with the use of autistic, immature modes of thought. Even in subjects with a façade of outgoing, sociable behavior, it becomes quickly apparent that not far beneath is a pervasive emotional detachment from people. Not infrequently, this finds expression in paranoid concern about the motives or roles of those closest to them; frequently it is expressed as a direct awareness of a sense of aloofness and separateness—a feeling of being an outsider or of not belonging—by the subject. The egocentricity has the quality of an absolute conviction of omnipotence and invulnerability, and appears to us to reflect a basic narcissistic core, as well as to represent a reparative function against feelings of dependence and of great vulnerability. The autistic thinking may reflect in a range of distortions, from areas of infantile thought out of keeping with the intellectual capacity of the subject, through moderately severe associative defects, to prelogical primary process productions. One would grow a mustache each time he fought with his wife, and shave it off with each reconciliation. Another is described by his oldest sister as follows: "He had very few friends. Children just didn't like him. He always gave the impression of being different." Repeatedly, the subjects would report, "I prefer to be by myself," or "I guess I must have been born with five times my share of alcoholic luck, or I'd have been dead by now." In addition, fully one-half of the subjects had been diagnosed clinically either as schizophrenic, or as mixed character disorders in which schizoid character features were a component.

2. The subjects are *depressed*. There is a basic sense of hopelessness, sadness, and futility which ranges in its manifestations from sporadic expressions of personal worthlessness to repeated and grim suicide attempts. The facade of joviality and gaiety which many of our subjects wore bore no regular relationship to the depth of the underlying depression, which in any event was never less than moderate in severity. Frequently, the depression is stated in less direct terms than sadness, or the blues, or feeling "down in the dumps," but as overwhelming boredom, or as loneliness, or moodiness. The severity of the familiar "vegetative signs" of depression similarly provided no regular guide to the depth of the depression, because of the frequency of insomnia, anorexia, and a semistuporous psychomotor state as concomitants of the drinking. There was elicited a history of suicide thoughts or attempts in more than one third of the subjects; another quarter gave a history of repeated "accidents" of life-threatening seriousness. Always there were references to intense feelings of loneliness or sadness.

Down loaded from www.brainlibrary.org.in

3. The subjects are *dependent*. There is an irrational reliance upon external agents for security and care. This is manifest in two closely related behavioral trends—an infantile orientation to other persons as the providers of insatiable demands for food, love, acceptance, and comfort, and a pervadingly passive attitude toward the world as essentially beyond his influence and determining his fate without reference to his behavior. Because of the sense of estrangement from and distrust of people, the dependence is far more frequently manifested as a concealed, "taking," relationship rather than a trusting, openly dependent one. The passivity is often concealed behind a great deal of aggressive, vigilant "activity" whose purpose is either the immediate or impulsive gratification ("taking") of a wish, or protection against the felt threat of the loss of the dependency object, or protection against destruction at the hands of some representative of implacable fate. Adaptation through a basic reliance upon the self, in a setting of give-and-take relationships with dependency objects, does not occur. One joined the army "to be certain of a place to eat and sleep." Another married a woman sixteen years his senior who owned the flophouse he had used during binges. Many reported earliest memories about food; one was certain he recalled the difficulties his mother had in arriving at the right formula for his bottle.

4. The subjects are *hostile*. There is reflected in their patterns of adaptation a marked, and sometimes overwhelming, amount of chronic rage which suffuses the personality and enters into all aspects of ego-function. No uniform pattern of dealing with the hostility is found. In some subjects it is overtly expressed as outwardly directed destructive behavior—generally only evidenced in inebriety but sometimes as well in sober states. In some subjects it is outwardly directed but remains concealed and controlled, even in inebriety, and is reflected only in murderous hallucinations during delirium tremens or nightmares. Perhaps in all subjects there is a strong component which is directed inwardly, against the self, and is varyingly expressed in verbalized self-loathing or overtly self-destructive acts. The most frequent fear following blackouts was that the subject had killed somebody. One subject would regularly surrender himself to the homicide division of a police station in order to request hospitalization. Another had the repeated hallucination in each episode of delirium tremens of killing his mother and attending her funeral procession. Several heard voices telling them to kill their wives. One subject, particularly impressive because of his stable life situation seven years after he stopped drinking, had been stopped just in time from pushing his father out of an upper-story hotel window during his last drinking spree.

5. The subjects are *sexually immature*, with a basic and serious failure in masculine identification. This ranges in verbal expression from reaction formations against implied feminine identifications to angry yet wistful observations that, in the end, the woman has the preferred lot. In sexual behavior the manifestations range from markedly reduced heterosexual behavior to active homosexuality. In no instance among the 46 subjects was there the complete abandonment of heterosexual activity and the full acceptance of homosexual activity; indeed, in only one subject was there a greater amount of participation in homosexual than heterosexual behavior. On the other hand, in a striking number of instances there had been episodes of homosexual behavior in adult life, generally but not exclusively during inebriety. One subject was described by his wife as constantly complaining that "women have an easy life. I think secretly he was sorry he was born a male." Another told of the shock he experienced on his wedding night on discovering that his wife had a vagina—"I thought intercourse was through the backside." Still another, who owned seven fishing poles though he never went fishing, who had had extended adolescent homosexual experiences, and who limited intercourse in his marriage to once in two months for reasons of health, told the following story for TAT card No. 13: "He gets layed and he loses his cherry. He goes out and gets drunk—he looks ashamed of himself. She looks like she's well satisfied."

Downloaded from www.dbraulibrary.org.in

## *Psychological Tests*

Psychologic test data were derived from a battery which included the Rorschach, 11 cards of the TAT, Machover Figure Drawing, the Blacky Picture Test, Wechsler-Bellevue, Word Association, the M-F Scale of the Minnesota Multiphasic Personality Inventory, the F Scale, the Allport-Vernon Scale of Values, Animal Choice, and the Sims SCI Occupational Rating Scale. Individual detailed clinical interpretive summaries were prepared for each subject. These were then reviewed, and entries found in 60 per cent or more of the summaries were listed as follows: schizoid character deviation; use of withdrawal and maintenance of social distance; generalized defense attitudes; narcissism; excessive mother involvement and dependency; feelings of insufficiency; oral receptivity problems; excessive hostility; high level of tension and anxiety; difficulties in expressing hostility; feelings of frustration; excessive general ambivalence; obsessive patterns; mechanism of denial; castration problems; sex-role ambivalence; female identification; homosexuality; low self-esteem; depression; general guilt feelings. Each of these entries is carefully defined: the following is quoted from the draft report of the psychological testing program as an illustration of the procedure followed:

*Schizoid character deviation.* Subjects were regarded as significantly schizoid when they showed evidence, on the tests, of excessive social isolation, weak ego-boundaries, excessive self-absorption and fantasy, autism, affective shallowness, excessive distance from objects. As examples of test evidence for schizoid character deviation may be cited the following:

Subject NJ: Rorschach devoid of color percepts, percepts distant and unreal, e.g., flying lobsters, weird animals from another age; figure drawings self-absorbed, fragmented line-quality, general impression of concreteness, flatness or insensitivity.

Subject SC: Word-Association Test, 95th percentile for contrast responses; Rorschach, feeling of diffusion and loss of reality, e.g., on Plate I: "two skaters whirling at high speed toe-to-toe and holding hands," on Plate II: "two persons walking side-by-side, climbing stairs in the dark, holding a torch," Plates IX and X rejected with avowal of fear of going off on flights of imagination; TAT, Plate 13 MF, "he murdered the girl in order to help his condition so that he could continue with his sexual urge."

Subject XB: TAT, distance and symbolism as on Card 2: "the girl in the picture is looking at a picture. In the card she sees fertility and in the man's back she sees vitality." Rorschach, neither people nor animals are seen, only "images" of people and animals.

Subject LP: Rorschach, loss of distance and ideational over-fluidity as on Plate II: "this is the drops of blood, it was dropped on this paper, here are the lungs, and these are the digestive organs or the female privates, either one"; and on Plate VII: "islands, but I don't recognize them, I know the maps of many territories and I've never seen them before"; Figure Drawings have markedly distant, self-absorbed facial expressions and lines weak, unsure, light, scarcely contacting the paper.

## *Perceptual Tests*

The perceptual test program utilized the procedure described by Witkin[45] in which the subject is presented with three sets of tasks: (1) In a completely darkened room, seated before a movable, faintly luminous, but clearly visible rod surrounded by a square frame, the subject is asked to adjust the rod to the true vertical, the frame being fixed at various angles to the true horizontal. (2) Seated in a tilted chair, within an independently tilted room, the subject is asked to adjust himself and his chair to the true vertical, the room being kept at various angles to the true horizontal. (3) A simple geometric figure is presented to the subject, and then the subject is asked to identify this figure from a complex figure within which the simple figure is obscured or "hidden." Previous studies had indicated a range of performances continuously distributed between two broad patterns of perception: the "field-dependent" and the "field-independent" patterns. In the former, subjects are unable to resist the pull of the field, and a typical per-

Downloaded from www.dbraylibrary.org.in

formance will consist of (1) adjusting the rod so that it is aligned with the tilted frame, and accepting the rod in this position as "vertical" even though it may actually be at an angle as great as 60 degrees from the true vertical; (2) adjusting the chair so that it is parallel to the walls of the tilted room and using this position as "vertical," even though, again, it may be, in reality, at an extreme angle from the true vertical; (3) losing the embedded figure in the more complex pattern. The field-independent pattern is given by subjects who are able to stand up against the field, resist its pull and achieve a close approximation to the true vertical, or, in the embedded-figure test, resist the distraction of the complex pattern and identify the simple figure promptly. The field-dependent pattern was felt, from earlier studies, to represent a more primitive perceptual pattern, associated with a passive-dependent orientation. Alcoholic subjects produced a striking perceptual pattern on these tests, unique to an astonishingly significant degree from any other group tested, and consistent despite the range of psychiatric diagnostic entities noted. The draft report summarized the performances of the alcoholic subjects as follows:

In the rod-and-frame and embedded-figures tests, where the task is, perceptually, to "hold on" to an external item (a rod, or a simple geometric design) against the influence of the field surrounding it, alcoholics "yield" to the field in an extreme way. In the body-adjustment situation of the tilting-room–tilting-chair test, where the body is surrounded by a tilted field and the task is to adjust the body to the upright, alcoholics are as capable as other groups to perceive the body independently of the surrounding field. Thus, when the body itself is at issue, alcoholics are far better able to escape the "tug" of the field than when an external item is the object of perception.

A pattern score was invented, to permit the expression of this pattern in a single symbol rather than in three separate scores, through a multiple correlational analysis using point biserial correlations with the criterion variable. A cutoff point halfway between the mean score of alcoholic subjects with two or more years of sobriety and the mean score of the control subjects (college students) distinguished between members of the two groups with a diagnostic accuracy of 86 per cent. The alcoholic pattern is interpreted by the experimenters as a manifestation of a pervasive passive dependent attitude, coupled with a primitive, insulating narcissism through which the field is not so much resisted as the preoccupation with the body and its sensations is responded to. The experimenters offer the following conclusion in their draft summary:

We would suggest that the person who gives a straight field-dependent performance has failed to develop beyond the most primitive level, involving a lack of awareness of body as separate from the field and a diffuse, global-dependent mode of perceiving the environment. The person who shows the perceptual pattern encountered among alcoholics, has progressed to the point of developing distinct body boundaries, although not a well-defined body concept, nor has he achieved a level of self-differentiation necessary for a field-independent orientation. Finally, the person who gives a straight field-independent performance has made the greatest progress in development, having achieved a well-integrated body concept and a degree of self-differentiation which makes possible an active, manipulatory, analytic approach to the field. In this conception, the first two levels must be regarded as fairly similar to each other, involving persistence in a global, field-dependent way of perceiving, which, from developmental studies carried out in our laboratory, we know to represent an earlier, more primitive way of perceiving. An alternative conception which needs to be considered is that the pattern type of perceptual performance occurs in basically passive, field-dependent persons who, as a result of early traumatic experiences, have developed compensatory devices involving overinsulation of body boundaries. These defensive techniques are particularly likely to be operative in situations in which the body is directly at issue, as in our body-adjustment test, where such defenses make possible fairly effective separation of body from field. Yet, in other kinds of situations, the basically passive orientation of the person

Downloaded from www.cbtculibrary.org.in

expresses itself in an extremely field-dependent mode of perception.

## *Physiological Tests*

Data from the physiologic studies of the subjects suggest three interrelated areas of findings which merit closer study: liver function and protein metabolism, autonomic-nervous-system function, and endocrine activity. Possibly associated with the first are irregularities in glucose-tolerance curves, with an increased rate of decline and an increased incidence of hypoglycemia. Protein studies appear to indicate a significant lowering of total circulating proteins, marked among the alcoholics who were dry for two years or more, as well as among those actively drinking; this finding will require further study. Autonomic activity is, widely in degree but regularly in direction, vagotonic, with the preponderance of parasympathetic over sympathetic tonus manifested by decreased cold pressor responses and increased salivary flow. The endocrine studies reveal reduced 17-ketosteroid excretion, which generally is interpreted as secondary to liver impairment, with consequent reduction in testicular androgens. However, the excretion of 17-hydroxycorticoids was normal or mildly depressed in the alcoholics who were actively drinking, but significantly decreased in the alcoholics who were dry two years or more. Furthermore, when alcohol was given to normals and to actively drinking alcoholics, the excretion of 17-ketosteroids was not significantly affected, but the excretion of 17-hydroxycorticoids was significantly increased. A number of studies have linked the combination of vagotonicity and low 17-hydroxycorticoid excretion with depression and states of debility, and it has been demonstrated that chlorpromazine and reserpine act to increase 17-hydroxycorticoid production. The concept that alcohol acts as a tranquilizer for tense and depressed persons is suggested by the physiologic data. Further, although no reliable clue as to the genesis of the physiologic disequilibrium which is "corrected" by alcohol is afforded by present data, it is extremely significant that the physiologic changes induced by prolonged consumption of alcohol are precisely in the direction of creating and maintaining the very state which is temporarily relieved by more alcohol, but inevitably also worsened so that still further disturbance results, presumably with a still greater discomfort, quite reminiscent of the addictive cycle in which the alcoholic drinks to relieve the symptoms of the previous day's drinking.

## *Social Histories*

The social and family data obtained in connection with the 46 subjects are not of relevance to the etiological issue, since the study was focused upon current social relationships. Descriptive data concerning the subjects are as shown in Table 1.

TABLE 1. **Comparison of Inactive with Active Alcoholics in Matching Criteria**

| | GROUP I INACTIVE ALCOHOLICS | GROUP II ACTIVE ALCOHOLICS |
|---|---|---|
| Age | | |
| Range | 27–55 | 26–56 |
| Mean | 41.96 | 41.79 |
| S.D.* | 7.48 | 7.97 |
| Highest school grade (years) | | |
| Range | 8–20 | 8–18 |
| Mean | 12.17 | 10.65 |
| S.D.* | 2.75 | 2.82 |
| Ethnic background | | |
| Irish | 13 | 13 |
| Anglo-Saxon | 4 | 2 |
| Scandinavian | 2 | 2 |
| German | 2 | 3 |

*Summary*

The parallel findings of the psychiatric, psychological, and perceptual tests in the present study are patent, as are the essential similarities between these data and those reported by other investigators and summarized above. A tentative formulation concerning personality and alcohol addiction may then be offered in summary form.

Disruption of the mother-child relationship in the period of dependency sets into motion a series of developmental trends evolving into sequences of (1) distrustful withdrawal, with attendant experiences of isolation and estrangement in addition to persistence of atypical, magical thinking processes; (2) persistent passive-dependent longings, with resultant distortions in object relationships; (3) inevitable frustration in the insatiable omnipotence and dependency demands, with resultant impulsive grasping behavior and chronic rage; (4) conflicted, ambivalent dependency relationships which must frequently be ruptured, repeatedly establishing the setting for depressive reactions; and (5) conflicted, ambivalent sexual role-playing with immature modes of sexual behavior. The sequences noted are not assumed to develop independently into a series of separate "traits" but are unified in a single pattern of the character structure. The character disorder described is conceived as existing through a range of severity, in terms of the extent to which it dominates the adaptive systems of the individual, at the same time that other forces in the adaptational dynamics variably influence the character of the total integration of the individual. The character disorder described is frequent in our culture and is not unique to alcohol addiction. It is conceived as necessary, but not sufficient, in the etiology of alcoholism. Variations in cultural attitudes to drinking are conceived as the crucial co-variable: where permissive and utilitarian attitudes prevail, then relatively mild adaptive disorders may enter into the formation of an addiction cycle; where cultural attitudes arouse powerful counteranxiety, more severe character disorders will be necessary for the cycle to be initiated. An inference, readily substantiated in the clinical experience of the present writers, is that psychopathology will be more severe in alcoholic patients from cultures in which alcoholism is infrequent than in patients from cultures in which it is frequent.

Physiologic factors may conceivably play a role in the initial readiness to addiction in alcoholic subjects, through a disordered metabolic state which is specifically relieved by alcohol. It seems certain that prolonged and heavy drinking produces distressing physiologic symptoms which are relieved by alcohol, and therefore these physiologic disturbances may significantly enter in the pathology of the addictive cycle.

## ¶ Therapy

Little can be stated with reliability concerning the factors which enter into the successful treatment of the alcoholic patient (cf. Muench, in Kruse[28]). It is the repeated experience of treatment centers (cf. Zwerling[47]) that between a quarter and a third of unselected volunteer applicants for treatment never return following their first visit, an additional one third will discontinue treatment within the first month, and about 10 to 25 per cent may be expected to remain in treatment at the end of a year. Discouraging as such results must appear, there has nevertheless been a sufficient experience to provide some clues to factors in treatment. It is, additionally, a particularly difficult task to define criteria for success in the treatment of alcoholism. Without entering fully into the issue, the present writers share with many the view that the measure of abstinence alone is a grossly insufficient and even misleading index, and would seek additional indices in terms of family, social, and vocational functioning, as well as in terms of alternative symptoms emerging during a period of abstinence.

A variety of replacement therapies—with vitamins, hormones, sedatives, tranquilizers, and special carbohydrate preparations, depending upon the bias of the therapist as to the

Downloaded from www.brad library.org.in

etiologic deficit in alcoholism—have all had their enthusiastic supporters, but their number speaks for the lack of notable success enjoyed by any one of these. Often such therapeutic regimens are described, with a note concerning the need for "psychotherapy" which remains undefined. The writers know of no adequately controlled study in which any replacement factor has proved to have significant advantages over placebos in the treatment of alcoholism. In those instances in which there is a clinical deficit state, it is patently good medical practice to treat this appropriately. In addition, possibly more than in the treatment of any other psychiatric state, the prescription of a substance representative of the doctor and taken in orally by the patient is of enormous consequence, particularly in the early phases of a therapeutic relationship.

Two special physiologic treatment modes merit specific mention: disulfiram (Antabuse) and aversion or conditioned-reflex-therapy. The former traces to the demonstration by Jacobsen and Martensen-Larsen[15] that tetraethylthiuram disulfide alters the metabolism of alcohol so that a toxic product, generally thought to be acetaldehyde, is formed. As a consequence, within minutes following upon the ingestion of alcohol, a patient taking Antabuse has a reaction which includes flushing, nausea and vomiting, a sharp drop in blood pressure, marked palpitations, and quite regularly a feeling of impending death. A daily dose, generally between 0.25 and 0.5 gm., is prescribed, and all alcoholic beverages are absolutely proscribed; since disulfiram is slowly metabolized, patients are generally told not to drink for three to four days following ingestion of the last dose. Aversion therapy (cf. Voegtlin[41]) employs emetine or apomorphine to produce a sudden and intensely debilitating reaction, including nausea and vomiting, timed to commence immediately following the sight, smell, and taste of the patient's favorite alcoholic beverage. With repetition, the nausea and vomiting become the conditioned responses to the presentation of the alcoholic beverage, and, in successful cases, a strong aversion replaces the previous craving for alcohol. Although the general experience is that a higher improvement rate is associated with these modalities, their use depends upon some initial period of sustained contact with the therapist, and the greater success may be an artifact of the more prolonged initial contact. Furthermore, these are again not without unconscious emotional meaningfulness to the patient, as Usdin[40] and Wallerstein[42] and their collaborators, and others, have stressed. Thus, disulfiram is perceived by many patients as a powerful conscience symbol incorporated from the therapist; others see its use as the substitution of a "good" parentlike regulatory mechanism for a "bad" one, alcohol; still others ritualize its use and bind, in the compulsive taking of the drug, precisely as they previously did with alcohol, the components of the passive-dependent and defiant-independent conflict which may be central in their adaptive systems. Although the initial enthusiasm for the use of both these techniques has waned considerably, they remain significant adjuncts in the management of alcoholic patients.

Psychotherapy remains the most uniformly endorsed therapeutic approach in alcoholism. However, there is little uniformity in the type of psychotherapy prescribed. Indeed, few techniques of psychological treatment have been described which have not been applied to alcoholic patients. There is rather general agreement about a number of principles, which may be stated in summary form:

1. The goals of treament may vary with factors in the patient, the therapist, and the therapeutic situation, with reference to all parameters save one: abstinence must be total and lifelong. The writers know of no authenticated treatment programs in which the capacity to drink in moderation is restored.

2. The massive use of denial by the patient must be dealt with, preferably at the earliest occasion. A number of writers have described the beneficial use of Jellinek's chart of the phases of alcoholism during the first interview.

3. The sensitivity of the alcoholic to a therapist who has moral discomfort about drinking, or who is subjectively concerned with the fate of the family of the alcoholic, or who has omnipotent needs to have his way about preventing drinking, is notorious. The "motiva-

www.freeclassicbooks.com

tion of the patient," classically described as weak because of the pleasure derived from drinking, turns out to be fully as much a problem in the motivation of the therapist. The alcoholic may be expected to react with great promptness to countertransference distortions of this nature, and his reaction is his familiar solution to effect the reduction of anxiety from any threatened source.

4. Classical psychoanalytic techniques rarely succeed—possibly because of the intensity of the transference relationship fostered, possibly because of the absence of immediate supportive-reassuring comfort from the therapist. Severe character disorders present difficulties to analysis at the very best, and these become virtually unsurmountable when the acting-out propensity has the consequences which inhere in protracted alcoholic binges.

5. There is available a most valuable adjunct to therapy in the form of Alcoholics Anonymous. This is a loosely organized, voluntary association of alcoholics which now numbers well over 5,000 groups or clubs throughout the world and has a membership estimated as upwards of 150,000 in the United States alone. The A.A. *Grapevine*, a monthly newsletter published by the organization, describes A.A. on its masthead as follows:

> Alcoholics Anonymous is a fellowship of men and women who share their experience, strength and hope with each other that they may solve their common problem and help others to recover from alcoholism. The only requirement for membership is an honest desire to stop drinking. A.A. has no dues or fees. It is not allied with any sect, denomination, politics, organization or institution; does not wish to engage in any controversy, neither endorses nor opposes any causes. Our primary purpose is to stay sober and help other alcoholics to achieve sobriety.

A member of A.A. once described it to one of the present writers as a cafeteria from which one could take whatever one felt to be his cup of tea; aside from the rather characteristic oral framework of the analogy, it does communicate the varied psychological needs it serves. In terms of the specific character problems of the alcoholic, offered above, the multiple purposes served by A.A. may be seen in dynamic perspective. It has its greatest strength in the awareness it imparts of comradeship among fellow alcoholics—the individual alcoholic feels "understood" and less isolated. He senses the impossibility of rationalizing his drinking among people who have themselves all used the same devices. He knows that although the group will not condone drinking, it will not be punitive about "slips"; with many patients we have observed, the consequent subsidence of rage is striking. The practice of programing autobiographical accounts of drinking encourages frank introspective reviews by each member. Dependency needs can be gratified through identification with the group or with the new member being cared for, without shame, and with little incitement to rebellion. The active role in helping other alcoholics serves as a powerful social deterrent to relapse, lest the brother being worked on be lost. At the same time, we have often seen it serve as a socially valuable expression of omnipotent and even sadistic needs. One patient considered himself a specialist on "tough pigeons" and would transfer alcoholics to other A.A. brothers as soon as they had recovered beyond the stage of repeated anguished cycles of delirium tremens, recovery, remorseful vows of sobriety, further drinking, further delirium tremens, etc. In many instances we have observed, during the early phases of sobriety, that participation in A.A. work keeps the patient away from home and in the fellowship of men who share his concerns about alcohol fully as much as did his previous drinking and saloon companions, though with an entirely different impact and prognosis: the ritualization of nondrinking is patently more adaptive. Finally, many groups are led by intuitive and skillful group leaders, and the sessions take on the character of good group-therapy programs. Referral to A.A. should be considered as an adjunct to the treatment of any alcohol addict.

6. Finally, the value of a family treatment orientation to the management of the chronic alcoholic may be noted. The alcoholic, along with every other emotionally disturbed adult, may be counted upon to reproduce the interlocking pathological relationships of his own

Downloaded from www.brainlibrary.org.in

early family experiences in his marriage. The problems posed to an individual therapist who attempts to deal with the spouse or with the couple are extremely difficult, and the advantage lies with a clinic or team approach in which separate support can be offered to the spouse in a setting which can adjust with flexibility to the unique needs of the patient, the spouse, and the special relationship they share.

CHAPTER 32

# GENERAL CONCEPTS OF PSYCHOSOMATIC MEDICINE

Theodore Lidz

Downloaded from www.dbraulibrary.org.in

THE TERM "PSYCHOSOMATIC MEDICINE" currently is in disfavor because it perpetuates a dichotomous orientation and because misuse has blunted its meaning. Its modern usage arose because there was need for a name that would describe the influence of emotions and personality maladjustments in producing physiologic dysfunction and disease. Many of the early studies focused upon illnesses in which emotional disorder seemed to constitute an essential factor in etiology, such as peptic ulcer, essential hypertension, rheumatoid arthritis, ulcerative colitis, bronchial asthma, and hyperthyroidism. Therefore the word "psychosomatic" filled a vacuum and spread rapidly, and it now would be difficult to eradicate and replace. As with any other word, particularly when the area it is supposed to symbolize is diffuse, its usage can become difficult to control.

As medicine turned from the search for single causes of illness to consider multiple factors that could upset the homeostatic defenses of the organism, more room was found for emotional determinants of illness. It became apparent that personality factors can influence the onset and course of virtually any sickness. Even in the acute infectious diseases, emotional disturbances can undermine resistance directly, or indirectly, by fostering unconscious neglect or exposure. The boundaries of psychosomatic medicine grew indefinite. Then, when physicians became systematically involved in patients' problems of living and reacting emotionally, they moved into essential related interests—the effects of illness upon behavior, the therapeutic use of the doctor-patient relationship, the emotional difficulties created by specific therapies, and, in planning treatment, the importance of the patient's personality structure and defenses. When psychosomatic medicine refers to all of these areas, little of its original connotation remains. A term such as "psychotherapeutic medicine" would seem to be more descriptive of a holistic, patient-oriented medicine that utilizes knowledge achieved by dynamic psychiatry in treating patients. "Psychosomatic" could then regain

its use as an adjective to indicate studies of the influence of emotions on physiologic dysfunction and certain illnesses in which emotional maladaptation plays an essential role. Of course, there is no place for the common misuse of "psychosomatic" as a euphemism for "neurosis" because it sounds more stylish or acceptable or as a way of telling the patient that his complaints are imaginary.

The developments in psychosomatic medicine profoundly influenced psychiatry as well as other fields of medicine. Dynamic psychopathology required reorganization to include a type of emotional disorder that left the person vulnerable to severe physiologic dysfunction and tissue damage instead of evoking neurotic defenses or psychotic withdrawal. Psychiatry was firmly related to other medical disciplines through common interest and because it was useful to them in their research and therapy. The possibility of testing psychoanalytic and psychodynamic concepts against observable physiologic responses of patients brought new research interests and theoretic ferment. The provocative hypotheses which related specific developmental dynamics to types of physiologic responsivity helped sharpen and alter some basic psychiatric concepts.

As poetry and folklore testify, there is nothing new in the idea that emotions profoundly influence physiologic activity and can lead to illness or even death. Homer dramatically recounts the impact of fear on the viscera even in his heroes. Hawthorne, for example, reflected the spirit of his day at the dawn of the scientific era of medicine over a hundred years ago when he wrote, "A bodily disease, which we look upon as whole and entire within itself, may, after all, be but a symptom of some ailment in the spiritual part" and "He [the physician] deemed it essential . . . to know the man before attempting to do him good. Whenever there is heart and intellect, the diseases of the physical frame are tinged with the peculiarities of these." Such views recurred in medical literature before the advent of histopathology and microbiology turned medicine toward the laboratory conquest of many diseases. Then psychiatrists, seeking to follow the medical trend in a search for specific physical causes of disease, turned away from considering spiritual, or emotional, causes of insanity. In an effort to gain scientific respectability by basing its hypotheses on the study of the central nervous system, genetics, and biochemistry, psychiatry became increasingly useless to its patients, itself, and medicine as a whole. Paradoxically, psychiatry achieved a significant place in medicine only after psychiatrists began to follow the leads provided by their own patients and developed theories of human functioning that deviated from those held by other medical scientists. The concentration of interest upon psychosomatic disorders had to await the historic developments of the past twenty to thirty years in both medicine and psychiatry, as well as for the emergence of leaders.

The good physician has always been interested in the emotional problems of his patients, but it was necessity that finally forced a scientific interest in psychophysiologic problems. As the conquest of infectious diseases neared, attention turned increasingly to the unsolved problems presented by metabolic and chronic illnesses. The alert internist recognized that emotional difficulties played a significant role in producing peptic ulcer, ulcerative colitis, hypertension, etc. His customary investigative techniques and his reliance upon laboratory animals did not provide approaches to such problems. Some psychiatrists had become interested in related problems, for they had recognized that the physiologic abnormalities which had been painstakingly examined as possible causes of emotional disturbance were, rather, concomitants of the emotional turmoil. Owing to the influence of Freud, psychiatrists had become increasingly interested in the neuroses and then found that the problems of the neurotic patient were but exaggerations and distortions of normal behavior. Basic principles that were clinically useful in understanding human behavior began to guide psychiatric treatment. Studies of unconscious motivations, the phases of libidinal development, the mechanisms of defense, etc., brought insights just as useful in work with medical as with psychiatric patients. Interviewing methods and scientific utilization of the doctor-patient

Downloaded from www.dbtlibrary.gov.in

relationship developed from the technique of free association. Methods for study and therapy awaited application in psychosomatic disorders. In addition, psychiatrists had come to think of overdetermination of a symptom or about multiple factors leading to illness and had, through necessity, learned to think in meliorative rather than curative terms; both of these attributes fitted into the changing needs of contemporary medicine.

Psychiatry's most significant contribution to medicine as a whole has not been stated explicitly, because it involves a philosophy of medicine rather than a tangible technique or discovery. Medicine, by and large, had sought to understand man and his ills by focusing upon the unfolding of his genetic biologic endowment through interaction with his physical environment while protected by his epidermis and his highly developed homeostatic systems. This frame of reference left little room for consideration of emotional problems except as manifestations of physiologic disorder or impairment of the brain. It could not encompass the interrelationship between mind and body, or between the stresses of interpersonal relations and physiologic activities. Psychiatry, however, focused increasingly upon man's development as a social being, reluctantly abandoning animal models to concentrate on man's uniqueness among animals. It became apparent that the infant must not only mature physically but also assimilate the mores and instrumentalities of his social environment in order to become a person. These two heritages, the cultural and genic, are inextricably intertwined, affecting physiologic functioning as well as emotional and interpersonal behavior. The infant's helplessness at birth and his long period of dependency upon parental figures while he grows by introjection, identification, and learning ways of living, as well as through physical maturation, make interpersonal or object relationships assume central importance in man's total functioning. Such relationships are no less real than his physical environment, even though they are intangible. As part of the role of the symbolic processes in human integration which accounts for man's inordinate adaptability, the meaning of an event can be more important than the actual occurrence, and the distant past and remote future, whether perceived consciously or unconsciously, can influence behavior and physiologic reactivity as intensely as does the immediate present; indeed, the repressed and dissociated experiences often influence more profoundly because they are outside of conscious control. The body-mind dichotomy may continue to present a metaphysical dilemma, but for practical medical purposes it has been resolved. The problems that remain and will continue to challenge us concern the precise mechanisms by which thoughts and emotions influence given organ systems.

The current status of theory and investigations concerning the structural mechanisms through which emotions and conflictual life situations produce physiologic dysfunction and structural change constitutes an enormous topic beyond the scope of this chapter and of this author. There has been general agreement, often taken for granted, that the changes leading to psychosomatic illnesses are mediated through the autonomic nervous and the neuroendocrine systems. Cannon's[10,11] studies of the defensive functions of the adrenal medulla and the sympathetic nervous system provided the foundation and framework. The work of Wolff and his co-workers,[60] particularly Stewart Wolf, has greatly advanced knowledge of the effects of autonomic defenses upon the various organ systems. Although several theories exist concerning the role of the autonomic nervous system in producing physiologic dysfunction, a general formulation of the problem can be presented briefly. The autonomic nervous system serves two general functions: It prepares the body to respond defensively to danger, and it plays a major part in maintaining homeostasis through its role in respiration, digestion, excretion, and vasomotor control. These two functions can be antagonistic and can lead to diminution of adaptive ability in one or both spheres. Thus, for example, the stomach, while responding to fear or anger, will not meet digestive needs properly. The operation of an organ system can become dissociated or improperly reinforced, causing dysfunction. This statement describes an orientation and does

Downloaded from www.dbraulibrary.org.in

not enter into the complex interrelationship between the central nervous system and autonomic and endocrine mechanisms involved in the translation of the stresses and conflicts of living into visceral reactions and tissue damage.

Recent physiologic and anatomical developments have greatly altered and increased the understanding of the intricate interrelationships and balances involved in the regulation of visceral activities. Although the complexity of the neural and endocrine interconnections can bewilder to the verge of provoking despair, some new and tangible approaches to the pathophysiology of psychosomatic disorders have already emerged. Thus, French *et al.*,[23] through the production of peptic ulcers in monkeys by hypothalamic stimulation with implanted electrodes, have clarified the interrelated influences of the anterior pituitary, the adrenal corticoids, the vagal stimulation, and the reticulospinal pathways on gastric motility and secretion; and the work of von Euler[20] and others on the differentiation of noradrenalin from epinephrine has direct pertinence to the study of essential hypertension.

A few areas of physiologic progress that appear to have particular importance to the understanding of psychosomatic research will be mentioned, and the reader is referred elsewhere for more adequate surveys.[15, 27, 34] The hypothalamus, long recognized as a center of endocrine and autonomic-nervous-system control, is now understood to form a critical juncture in a circular feedback system that mediates and regulates neural impulses concerned with emotions and neuro-endocrine activity.[12] The control that the hypothalamic nuclei exerts over the anterior pituitary secretions appears to be mediated through the vascular portal system between these structures, perhaps by adrenergic secretions.[24, 57] The hypothalamus influences and is influenced by the neocortex, the limbic system, and the reticular activating system as well as various endocrine secretions. The limbic system has been found to perform major regulatory functions, and has been termed the "visceral brain" by MacLean, who considers that it mediates visceral needs rather than ideational functions, being concerned with feelings in contrast to the symbolic activities of the neocortex.[39, 40, 48] The frontotemporal limbic activities may be concerned with primitive self-preservative activities and may exercise a controlling influence upon ACTH secretion, the more posterior regions, the cingulate gyrus and hippocampus, affecting sexual behavior and the sexual hormones. Both the hippocampus and the amygdala are implicated in diffuse emotional states.[26, 49] The connections of these neural complexes with the central gray and the reticulum of the brain stem indicate that they can exert regulatory influences on the neocortex as well as on visceral activities. The explorations of the reticular activating system by Magoun[42] and his associates have, in turn, altered neurophysiologic thinking, particularly concerning the plasticity of the central nervous system in responding to stimuli by filtering out and alerting the flow of neural impulses and by activating various portions of the central nervous system.[37]

Among the many developments in neuroendocrine research, the role of the adrenals in the defenses against trauma have particular pertinence to psychosomatic concepts. The extent of the changes provoked by adrenergic secretions in response to danger or trauma has become clearer through understanding of their influence on the hypothalamus and the reticular activating system. The differentiation of noradrenalin and epinephrine has required revision of the concepts of the diffuse nature of the defensive fight-flight reactions proposed by Cannon, for these hormones can be secreted independently with different physiologic effects;[21] noradrenalin seems to be concerned with hostile states and epinephrine with fear and anxiety.[13, 25] Then, too, the medullary and cortical secretions of the adrenal no longer appear to have such disparate functions. The adrenal corticoids play a very major role in defense of the tissues against trauma, and the adrenergic hormones probably help mobilize their secretion.[35] The importance of the corticoids in the defense against both physical and emotional traumata have been highlighted by the extensive researches of Selye[53, 54] on the general adaptation syndrome, opening new approaches to the understanding of psychosomatic

Downloaded from www.obaulbiam.org.in

disorders. He considers that derailment of these defenses can lead to profound tissue damage and may be involved in the etiology of "diseases of adaptation" such as hypertension, peptic ulcer, arthritis, etc., as well as in the production of certain central-nervous-system damage. The therapeutic use of cortisone in arthritis, asthma, ulcerative colitis, and various collagen diseases has also stimulated much research by others in this general area.

This sketchy and fragmentary review of various neurophysiologic and neuro-endocrine considerations related to the impact of emotional reactions on visceral dysfunction can only serve to remind the reader of the complicated systems of controls that must be taken into account, and of the present state of flux when understanding of these mechanisms is undergoing rapid and drastic revision. It should be noted that relatively little research has been carried out concerning the influence of the various sexual hormones upon mood and mental activity, considering the critical position of libido theory in psychoanalysis. The work of Benedek and Rubenstein[8] upon the influence of the changing hormonal balance, during the menstrual cycle, upon mood and dreams has long awaited confirmation and extension.

Psychiatrically oriented studies have naturally approached the relationship between conflicts in living and physiologic dysfunction from a totally different frame of reference—one concerned with the types of ego-weakness and emotional conflict that dispose to psychosomatic ailments. The relationship between psychosomatic conditions and other personality disorders raises critical questions that have elicited a multiplicity of hypotheses. Most persons suffering from neuroses, including the transitory neurotic symptoms that occur in most lives, also suffer from some physiologic dysfunction that gives rise to somatic complaints. The early psychoanalytic studies of psychosomatic conditions by Ferenczi,[22] Jelliffe,[32, 33] Deutsch,[16] and others conceived of the physiologic disturbances as displaced unconscious symbolic expressions of repressed instinctual drives, very much as they considered conversion symptoms. Ruesch's[52] later theory, suggesting that these patients utilize a regressive body-language to communicate because of their defective ability to communicate by verbal symbols, bears a relationship to those early theories. Alkan[7] initiated a more comprehensive approach, but perhaps psychosomatic medicine became a differentiated field of study when both Flanders Dunbar[18] and Franz Alexander[1, 3] emphasized that the physiologic expressions of emotion need not have any symbolic meaning. The vegetative systems are not under voluntary control, and their activities are concomitants of emotional reactions rather than defenses against them. Alexander[1] wisely suggested that conversion reactions be limited to symptoms that can be produced through cortical discharge or inhibition. Ruesch[51] was among the first to stress the infantile residues in the personality organization of psychosomatic patients as a group. Alternation between psychosomatic illness and psychosis occurs frequently, and the frangibility of at least some of these patients during psychotherapy indicates serious ego-weakness. Such deficiencies in ego-structure have impressed most investigators, and various theories have sought to relate the primitive quality of the emotions experienced to the intensity of the physiologic response. While some psychiatrists simply consider that ego-regression reawakens intense emotions, others, starting with Michaels,[46] have postulated a physiologic regression to explain the damage caused by the physiologic reactivity as well as the choice of the organ system involved. Margolin[43] considers that the range of physiologic fluctuation decreases with age, and that physiologic regression subjects an organ to fluctuations beyond its capacities and leads to tissue damage. Grinker and Robbins[29] have postulated a loss of the differentiated responses acquired through conditioning when the organism is under extreme stress, leading to diffuse infantile reactivity. Szasz[55] has emphasized parasympathetic overactivity as a source of malfunction and considers such parasympathetic responses to be a regressive means of withdrawal from stress. Such theories are difficult to confirm or refute, and Mendelson *et al.*,[45] in a timely review, question whether they are necessary or contribute to an experimental approach.

Downloaded from www.obgyn.cam.ac.uk

The following hypothesis, which helps differentiate psychosomatic illnesses from neurotic and psychotic reactions, may serve to clarify the vulnerability of some persons to physiologic dysfunction in response to emotional traumata. The mechanisms of defense of the ego are varieties of symbolic self-deceptions that ward off recognition of situations which provoke anxiety and other disturbing emotions. Their elaboration leads to organized neuroses. Regression differs, for it is a withdrawal from current conflicts and insecurities by seeking to return to a period of dependent security. It may evoke the price of leaving the individual prey to the fears of the infantile or childhood period. Psychotic regression and withdrawal provide escape from the untenable through abandonment of reality testing. The person who is prey to psychosomatic illness has suffered serious insecurity early in life but has not erected adequate mechanisms of defense to protect against the danger. Rather, he avoids recurrence of the insecurity or trauma by patterning his life so that he will never be exposed again. The critical area of weakness is encapsulated, but the patient neither becomes desensitized to the insecurity nor develops mechanisms of defense to blunt its impact. Superficially, the patient may seem a reasonably stable person, capable of relating well to others. When the defensive pattern of living collapses, he is subject to the emotion as it had been experienced in early life, with intense physiologic reactivity. The very nature of the defensive pattern may make recurrence almost inevitable. The patient with peptic ulcer, who has defended himself against loss of dependency by insistent self-sufficiency, may be overwhelmed by any business setback even though he is already wealthy. The hyperthyroid patient, who, by becoming the good child whom mother will eventually appreciate, avoids repetion of feelings of abandonment by the mother, has not built other object-relationships and will still be vulnerable in adult life when mother dies.[35] In such persons the impact in adult life remains as overwhelming as in childhood, and the illness seems to start when the defensive pattern crumbles.

The problem of why a given organ system is affected in an individual has occupied a central place in psychosomatic theory and research. There are many potential reasons why emotional turmoil provokes dysfunction in a specific organ system. Genetic or constitutional factors may make the organ the weakest link, or predispose toward malfunction through placing the individual at the extreme limits of the normal range of some biologic activity. The apparent hereditary occurrence of hypertension, diabetes, and other illnesses requires such considerations. Prior illness may have conditioned an organ to pathologic response; it has been suggested, for example, that whooping cough may dispose to asthma. A coexistent condition may create a confluence of factors to which one organ system is vulnerable. The emotional disorder need not be the only factor involved but may only be a contributant of greater or lesser significance in different persons and different diseases. Some asthmatics are severely allergic to ragweed and only suffer from asthma during ragweed season; others suffer only when emotionally upset during ragweed season; and some have no allergies and become asthmatic only when emotionally disturbed.

Many investigators, however, have been convinced that a fairly definite relationship exists between specific illnesses and some aspect of the patient's personality structure and functioning. Flanders Dunbar,[18] following her systematic studies of groups of patients by means of analytically oriented interviews, maintained that persons suffering from the same psychosomatic ailment had certain personality traits in common, in a configuration which she termed the personality profile. Although these profiles were highly useful in helping to focus early studies of personality factors, they were not sufficiently dynamic and failed adequately to differentiate patients.

Franz Alexander arrived at a different concept of specificity which many members of the Chicago Psychoanalytic Institute have followed in an important series of clinical studies (Alexander and French[5]). Alexander emphasizes the adaptative reactions of the vegetative organs to "the total situation in which the organism finds itself." He recognizes the im-

Downloaded from www.dbpublishing.org

portance of organ vulnerability but also postulates a "specific correlation between the emotional state and its physiological concomitants or sequelae" (Alexander and Szasz[6]). The nature of the conflict confronting the person and the dynamic configuration of the persons responding to the conflict are important in determining the involvement of a specific organ system. Alexander[4] thus does not stress personality profiles, as Dunbar has, but believes that the unconscious emotional configurations which may be present in differing types of personalities make these persons sensitive to similar conflicts. Dependency needs and the strivings for reactive self-sufficiency are placed in a central position in the dynamics of patients suffering from psychosomatic disorders. In a general way, the parasympathetic overactivity when the patient regressively seeks a position of dependency is considered important in the production of peptic ulcer, colitis, asthma, etc. The sympathetic overactivity when patients seek an active overcompensatory position may lead to migraine, hypertension, arthritis, etc. A recent study of Engel's[19] concerning the alternation between ulcerative colitis and headaches with the shift in the patient's basic position to dependency points in the same direction.

Harold Wolff[59] and many of his co-workers, with primary interests in neurology and medicine, have viewed the problem from a different perspective. Emphasizing the defensive adaptive nature of physiologic responses to stress, Wolff believes that the choice of an organ depends upon how the organ is implicated in a biologic pattern of defense or offense in a given individual. An individual may react to different types of stress with a similar physiologic reaction as determined by his constitutional make-up. Of course, differing emotional states can also provoke different physiologic responses in the same individual.

Interest in the mother-child interaction, with emphasis upon the mother's characteristics as a determinant of the patient's reactivity, can fit into any dynamic theory. Bruch and Touraine's[9] study of obese children was an early classic in such research. Similar interest in the mother-child relationship has been an expressed or implicit part of many studies of hyperthyroidism, asthma, eczema, ulcerative colitis, and other conditions.

Specific repressed emotions have been related to symptoms and illnesses. Thus weeping has been related to urticaria, the suppressed cry for help to asthmatic attacks, and hungering for love to peptic ulcer, etc. Such observations are usually placed in a broader theoretic context.[5]

Moving away from the individual, but by no means opposing psychodynamic or physiologically oriented hypotheses, Ruesch[52] has drawn attention to the importance of social change and mobility in the genesis of specific conditions, and Halliday[31] has emphasized the role of social issues, such as working conditions and morale, in the production of miner's nystagmus.

Some of the divergencies result from interest in different segments of the total field or from different systems of reference rather than from opposing observations. As the entire area of study started but a few decades ago, observations concerning specificity must be considered as opening hypotheses for further explorations rather than as established facts. Still, because of dissatisfaction with some hypotheses, because of inability to validate findings stated in the literature, or through misunderstanding of inadequate formulations, many workers have tended to turn away from specificity concepts and the attempt to relate conflict situations or personality factors to the type of illness. Although such scepticism may be healthy and may lead to new and more useful approaches, no clear substitutes have appeared as yet. There is some danger of prematurely discarding concepts that have served as useful guides in both practice and research. Some of these difficulties may have arisen because relatively few psychiatrists have worked intensively both with many patients with one illness and with many patients with a wide variety of diseases. Critical differences can be overlooked because similarities are found in the external and internal situations of some patients with different ailments. Many of the experienced people in the field continue to find definite differences, even though precise description may present difficulties. Basic differences be-

Downloaded from www.dbraulibrary.org.in

tween patients suffering from ulcerative colitis and peptic ulcer are almost taken for granted. It is, for example, unlikely that Margolin[44] would have selected patients with peptic ulcer for the same type of anaclitic therapy which he attempted with patients with ulcerative colitis. Dependency problems are important in both hyperthyroidism and peptic ulcer, but the patients have, by and large, striven to cope with these problems in very different ways. (Further comments on specificity concepts and their utility will appear in subsequent chapters.)

Fortunately, effective therapeutic work with patients does not depend upon knowledge of how emotional conflicts are translated into physiologic malfunctioning or upon resolution of problems concerning specificity. The physician who orients treatment to the patient rather than simply to the disease and who can utilize the doctor-patient relationship therapeutically can often alleviate emotional problems and ameliorate the physical illness. The general principles which guide psychotherapeutic efforts with patients suffering from psychosomatic disorders are similar to those used in other psychiatric conditions.[36, 50] Some of the general problems frequently encountered in medical and surgical patients, though differing in setting and context, are basically similar to those of psychiatric patients. Unconscious forces often make the patient's motivation ambivalent, and failures to adhere to a therapeutic regimen must be accepted as part of the therapeutic problem, as in general psychiatry. Understanding of the regressive tendencies provoked by any illness can help both physician and patient cope with trends toward undue passivity and invalidism. The benefits of secondary gains resulting from illness to a person confronted by seemingly unsolvable problems tempt the unconscious of all types of patients. The psychiatrist, accustomed to treating for improvement rather than cure, is often better prepared than are other specialists to practice the melioristic medicine that the treatment of chronic illness has made essential. Opportunity for ventilation and emotional catharsis can by itself sometimes produce striking changes in the course of an illness. Skillful psychotherapy with medical and surgical patients need not differ from any other psychotherapy when patients are selected carefully.

Nevertheless, when a psychiatrist works with patients with psychosomatic ailments or serves as a consultant to a medical or surgical service, specialistic knowledge not acquired through experience in general psychiatry or in psychoanalysis becomes essential. Some of the special problems arise because of the differences between patients who become ill through physiologic expression of emotional disturbance and those who suffer neuroses and psychoses or act out antisocially. Other problems originate from the need to consider medical and surgical exigencies in planning and carrying out treatment.

Initiating a useful psychotherapeutic relationship often presents disheartening difficulties. The patient has sought help for his physical condition, but, not only may he fail to grasp the need for help with emotional problems, he may strongly resist it. The psychiatrist finds the patient poorly motivated, and, rebuffed, turns from that patient to be of use to the many others seeking his services. But this problem must be faced, for the manifestation of serious physiologic disturbance may be related to the patient's need not to recognize, or to admit to, emotional difficulties because of his inadequate defenses against the expression of intense emotions of an infantile quality. The achievement of a working relationship often depends upon the psychiatrist's ability to interview skillfully, with the objective of having a patient talk about himself until he inadvertently tells about his difficulties or hopelessness over life situations. When he realizes that he would be very unhappy, even if well, help can be offered for these problems without insisting that psychiatric treatment is required because of the medical ailment. The psychiatrist need not seek to have the patient gain insight into the relationship between his ulcer or asthma and his personality problems. Here, as elsewhere, insight refers to gaining understanding of the sources of emotional turmoil and unhappiness. Psychiatric treatment is directed toward these

Downloaded from www.cbpathlibrary.com

emotional difficulties, with the hope that amelioration of the interpersonal and intrapsychic disturbances will be accompanied by improvement in the medical condition.

Often, the illness provides secondary gain through fostering the acceptable passivity that forms a necessary defense for the threatened or crumbling ego-structure. The illness thus helps maintain repression and permits a façade of normality because responsibilities need not be faced. Premature or poorly timed uncovering techniques can either increase the physiologic disorder and endanger life or provoke psychotic withdrawal. Therapy with such patients, therefore, approximates that used with borderline schizophrenics. A firm transference relationship must be established before entering upon the patient's role in producing the untenable situations. Increasing feelings of guilt or worthlessness in a patient struggling to maintain some semblance of self-esteem can force the use of pathologic projection.

Although many patients have been amenable to intensive analytically oriented therapy and even to psychoanalysis, the treatment of most patients with psychosomatic disorders requires plasticity of approach from the therapist. These patients cannot be fitted into a single technique. Therapy involves weighing a multiplicity of factors—the type and severity of the illness, the danger of acute exacerbation, the emergency measures available in case of exacerbations, the extent of the risk worth taking, etc., as well as the factors usually considered in carrying on psychotherapy. Rarely can all of these potential influences be evaluated properly at the start of treatment. In some conditions, such as ulcerative colitis, therapy that requires resolution of the transference neurosis is unlikely to succeed without skirting or entering into psychotic episodes. With most patients, therapy is not directed toward fundamental changes in personality structure, but lesser measures should not be derogated and may require great skill on the part of the therapist. The patient may be helped in many differing ways. Often, one hopes to modify a basic attitude that seems critical in perpetuating a destructive emotional reaction. However, the support afforded by the therapeutic relationship may, of itself, turn the patient from preoccupation with death or help him carry through a critical phase of an illness. The experience of being heard and understood can be a unique one to some patients, and it may alter their perspective. Providing firm support or opportunity to talk and weigh a significant decision concerning treatment can change the entire course of an illness. In brief, the therapist often concerns himself with critical problems and with finding ways of helping the patient meet them.

The effects of the psychiatrically oriented intervention may be difficult to predict, at times bringing results that seem disproportionate to the effort expended: A woman with advanced myasthenia gravis, who is seen because of her depression and obsessive fears of killing her daughter, spends several hours venting her bitterness toward her husband, traces the effects of her introjected rage upon her illness, considers her impotence to change her life situations, and experiences almost complete remission of her myasthenia. A girl with a disfiguring atopic dermatitis cries through a two-hour interview as she tells of her shame at having married a pervert, a story which she could not confide to her punitive mother. The vascularity of the skin changes perceptibly during the session, and the course of her illness alters abruptly. Such responses are unusual and unexpected, but others are more predictable. Attacks of status asthmaticus can cease abruptly when the patient can be provoked into sobbing while telling of feelings of hopeless desertion. Patients with ulcerative colitis may respond to ventilation of pent-up mourning reactions and also to firm decisiveness on the part of the physician. This may happen frequently enough to guide the therapist's efforts and his attitude toward the patient.

The psychiatrist must be able to collaborate closely with other medical specialists, which demands reasonable familiarity with the medical problems involved rather than just exchange of opinion. Knowledge of the potential courses an illness might take and the therapeutic methods available permits the psychiatrist greater security and latitude. The choice of a therapeutic regimen sometimes depends

Downloaded from www.dbraulibrary.org.in

upon the personality problems of the patient as much as it does upon the medical exigencies, and it may, in turn, influence the psychiatric problems. An obsessive diabetic patient may become unbearably insecure if told that weighing food and testing urine three times a day are unnecessary, whereas other patients who cannot tolerate dietary restriction without becoming depressed can be treated quite adequately and more accurately if placed on a relatively "free" diet. Certain illnesses as well as certain treatments are apt to provoke rather similar problems in many patients. The psychiatrist who is aware of these problems has a head start in treatment and can communicate with the patient more meaningfully. The use of a respirator in polio patients, the strict bed rest imposed following coronary occlusion, the informing of a patient that he suffers from tuberculosis, the creation of artificial stomata, and many other situations are apt to provoke hidden turmoil that can be prevented or aborted only if they are anticipated.

The psychotherapist who is not thoroughly familiar with the potential vicissitudes of an illness can precipitate a critical exacerbation through improper timing of an interpretation or by altering the transference relationship. On the other hand, he may be unwilling to assume risks lest an emotional upheaval result, even when they seem necessary to save a life or to prevent serious suffering.

Here, as elsewhere, experience and knowledge of the literature can furnish direction. The value of specificity hypotheses is not simply theoretic but highly practical. The nature of the illness has often served to alert the therapist to the importance of situations that might otherwise seem of casual interest. The failure of a salesman to achieve an annual bonus greater than the preceding year could be easily rationalized, but to an ulcer patient this fact was a threat to his reactive strivings sufficient to produce a recrudescence. Marriage of the particularly favored child may not always be a cause for rejoicing to the mother, but in a woman who develops hyperthyroidism it could shatter her lifelong defensive maneuvers against abandonment. A young woman's recognition that she failed to stem her husband's alcoholism even more abysmally than her mother had failed with her father could undermine an entire self-concept and constitute a significant factor in her mounting hypertension.

Psychotherapeutic medicine constitutes an enormous field of endeavor that has received systematic attention for only a relatively short time. The internist and psychiatrist have much to offer one another and their patients. Although often an alluring field to the psychiatrist, the difficulties that arise in working with other physicians who speak a different language and with patients who often resist and resent psychotherapeutic efforts can be disheartening. The expectation that a firm grounding in psychiatry suffices to permit successful work with medical patients can also lead to discouragement, for more than casual success is unlikely unless the therapist becomes steeped in the special problems involved. Yet when experience finally provides familiarity and orientation, those who have moved into the field are stimulated by the new discoveries and unanticipated successes that reward those who venture into newly opened territories.

CHAPTER 33

# PSYCHOLOGY OF CARDIOVASCULAR DISORDERS

Morton F. Reiser
Hyman Bakst

Downloaded from www.dbraulibrary.org.in

THE PSYCHOPHYSIOLOGY of the circulation constitutes an important issue in the theory and practice of psychiatry, since the circulatory apparatus is so intimately involved in phenomena of central importance in psychological life, namely, in the motor expressions of anxiety and other affects. By virtue of this fact, that is, that emotions mobilize, or are associated with, changes in the circulation, physicians dealing with patients who have cardiovascular disorders find that psychological problems are extensively involved in their work, and the clinical psychiatrist is frequently called upon for help in the diagnostic and therapeutic problems encountered. This is so not only because of the role of emotional forces in contributing to clinical disorders of the circulation but also because circulatory disorders, in themselves, frequently constitute sources of psychologic stress for patients and create problems in this sphere. Particularly in patients with heart disease (and to almost as great an extent in patients with hypertension), these psychological problems in reaction to the physical disorder are frequently more intense, and hence more serious, than the generally encountered reactions to the "threat of illness" in a nonspecific sense. Not only may they be more intense, but they may in themselves mobilize further affect which then imposes more burden upon the diseased system, and, in this way, self-reinforcing cyclic reactions may arise. These will be described in detail later in the chapter.

Clearly, the interrelationships between psychological and physiological phenomena may become highly complex in problems of this nature, and in any single patient there may be an admixture of reactions that follow psychosomatic, somatopsychic, and somato-psycho-

somatic sequences. To begin with, two things should be made clear: The first is the fact that psychologically determined motor changes in the circulation will inevitably exert some effect upon *any* pathological condition involving the circulatory apparatus, since these motor effects will constitute demands for function upon tissues compromised by underlying disease. The second is the fact that any disorder of the cardiovascular system, by virtue of the symptoms and functional limitations it produces or merely because it exists, may present a serious problem in psychological adjustment to the patient. In this sense the cardiovascular problems that are affected by emotion or that exert effects upon the psychological condition of the patient constitute a broad spectrum of disorders, starting with structural heart disease and its attendant problems of congestive failure at one end, and ending with neurocirculatory asthenia at the other. Indeed, there is now a vast literature on the "psychosomatic" aspects of congestive failure, coronary artery disease, essential hypertension, peripheral vascular disorders, migraine, cerebral vascular accidents, syncope, and neurocirculatory asthenia. A comprehensive and systematic review of such a spectrum would be beyond the scope of a single chapter, but there is an additional and more cogent reason for limiting the field to be surveyed here. This is simply stated as follows: "psychosomatic medicine" is better regarded as a way of approaching medical problems than as a new or special field.[91, 127, 128] It seems, then, more appropriate to illustrate the approach by focusing mainly and in some detail on the psychodynamic and psychophysiologic issues encountered in one major cardiovascular problem area. The problem chosen for review is that of the patient with structural heart disease leading to diminished functional cardiac reserve and the associated clinical problem of congestive failure. The principles so illustrated apply to the wider range of problems and can be extrapolated to them. Observations about emotions and disease have accumulated in the literature at a very rapid rate, and this may well be expected to continue. Compilations or reviews of these new observations are available elsewhere.[34, 122, 128] It will be our aim here to select data relevant primarily to the problem of congestive heart failure and to make an attempt at integrating them into a broader understanding of the clinical psychosomatic issues encountered.

## ¶ Psychophysiologic and Psychodynamic Problems of the Patient with Structural Heart Disease

### *Physiologic Considerations*

The basic physiologic problem involved in structural heart disease that leads to congestive failure can be understood as one of supply and demand. With the progressive decrease in cardiac reserve that results from the heart lesion, there ensues progressive difficulty in maintaining circulatory equilibrium, namely, in maintaining adequate cardiac output in response to varying functional demands.

Congestive heart failure will develop whenever myocardial capacity is inadequate to meet the metabolic demands of the body. Certain events then occur which lead to the classical picture of congestive failure, and chief among them is the impairment of normal renal mechanisms with resultant retention of salt and water.[75] The ultimate responsibility for this fluid and electrolyte imbalance must be assigned to the circulatory inadequacy, but the immediate and crucial mechanism is altered renal function.[77] Any consideration of congestive failure must therefore be concerned not only with disordered circulatory dynamics but with the physiologic factors controlling the disposition of sodium chloride and water by the kidney.[59]

The balance between tissue needs and the ability of the heart muscle to meet them may be disrupted by increasing the demand or by reducing the functional cardiac reserve. Infection, exertion, increase in blood volume, certain paroxysmal arrhythmias, and emotional stress are all factors which may lead to a relatively abrupt increase in the demand for cardiac work. Diminution in coronary blood supply, inflammation (myocarditis, myocardosis), arrhythmias which reduce efficiency of cardiac

Downloaded from www.dbraulibrary.org.in

function, and emotional stress are all factors which may lead to relatively rapid decrease in the heart's capacity to perform work. Furthermore, increased demand and decreased capacity may occur in combination, and as reserve decreases with time and advancing disease, progressively smaller loads determine the limits of compensation.

There is a direct relationship between cardiac output and effective renal plasma flow; diminished cardiac output lowers the glomerular filtration rate, thereby producing a decrease in salt and water excretion.[54, 68] This is not the sole regulating mechanism however, and it has been established conclusively that the renal tubule may operate independently of the glomerulus in this respect. Indeed, the renal tubule is the second discrete regulator of sodium chloride and water balance. For purposes of simplification, the glomerulus may be considered to be affected primarily by hemodynamic changes. Tubular function, on the other hand, is modified chiefly by humoral agents.[59]

The humoral agents which affect tubular function include the antidiuretic hormone of the neurohypophysis (ADH), which promotes water reabsorption, and the adrenal corticosteroids, which promote sodium retention. Of the latter, the most potent is aldosterone, but other steroids (hydrocortisone, corticosterone) also exert an appreciable effect.[59] Furthermore, norepinephrine can cause marked change in sodium excretion. On the basis of available data, one can state that both adrenal activity and altered circulatory dynamics are necessary for the development of edema, the prime feature of congestive failure. There are many factors which evoke increased aldosterone activity in congestive failure, including dietary restriction of sodium, impaired hormone degradation due to hepatic congestion, and elevated serum potassium levels. In addition, those adrenal steroids which are under ACTH control all have sodium-retaining activity and can, at times, tip the balance in the direction of failure. The role of emotional stress in increasing adrenal cortical activity is well known and will be referred to more fully in the following section when the emotional factors in congestive failure are discussed.

In attempting to clarify the mechanisms underlying the clinical phenomena which concern us, it is pertinent to consider the ways in which psychological stress may affect circulatory equilibrium either by increasing current demand or by decreasing available supply, and/or by altering renal function.

## *Physiologic Concomitants of Psychologic Stress Which Add to Demand for Cardiac Work (Psychosomatic Sequences)*

It has been repeatedly demonstrated that "emotional stress" may be accompanied by measurable changes in arterial blood pressure, heart rate, stroke volume, cardiac output, and peripheral resistance.[5, 8, 38, 45, 50, 57, 58, 86, 88, 98, 108, 112, 113, 118, 129, 131] Perhaps the most carefully and extensively documented study, to cite as representative from a physiologic point of view, is that of Hickam and co-workers[50] who utilized a spontaneous, nonspecific stress situation—an important academic examination—in order to demonstrate differences in measurements reflecting circulatory dynamics obtained during "tension" from measurements obtained during relative relaxation. Twenty-three healthy medical students served as subjects. Each student was studied just before the critical examination and then again a day or two later, after having been informed that he had passed. The average cardiac index (volume output of the heart [in liters] per minute per square meter body surface area) before the examination was 2 liters per minute per square meter greater than that measured during relative relaxation. When this figure was converted to "work load," it corresponded to a load which would be demanded by increasing oxygen consumption by an amount equal to the basal metabolism.

In Hickam's work as well as that of the many other authors cited above, the meaning of the psychologic stress and the nature of the reaction to it were not specifically studied in the individual subjects. Hickam noted that the pattern of mobilization varied in his subjects, and described three patterns. For the largest part of the group, anxiety was accompanied by an increase in cardiac index, decrease in peripheral resistance, and relatively small rise in mean

Downloaded from www.medicalbooks.ir

arterial pressure. In a smaller second group, the "anxious state" was associated with a slight to moderate rise in peripheral resistance, with a rise in mean blood pressure and no change or a slight decrease in the cardiac index. In three subjects there were rises in cardiac index but large moment-to-moment fluctuations in stroke volume and heart rate.

A great deal of research has been done in an effort to determine whether specific differences in pattern of circulatory response may be related to specific differences in the concomitant emotion involved. The investigative group headed by H. Wolff at Cornell, through the use of structured stimuli (introduction of conflictual topics during interview), have described relationships between different directly observed (and subjectively reported) affects and different patterns of circulatory mobilization.[129, 130, 131, 132] Funkenstein *et al.*,[36] working with groups of healthy subjects subjected to a specified stressful task, have described three patterns of emotional response which they designate: "anger-in," "anger-out," and "anxiety." On the basis of ballistocardiographic, heart-rate, and blood-pressure recordings taken simultaneously, they reported that subjects showing the "anger-out" pattern developed circulatory changes similar to changes produced by administration of noradrenalin. (This resembles the second pattern described by Hickam.) Subjects showing "anxiety" and "anger-in" reactions demonstrated changes similar to those that would be produced by injection of adrenalin (similar to the first pattern described by Hickam). Ax[8] and Schachter,[98] working on subjects who were exposed to laboratory situations deliberately staged to evoke either anxiety or hostility, reported differences in pattern of circulatory changes similar to those described by Funkenstein.

The general implication of all this is that outwardly displayed anger is accompanied by a release of norepinephrine, whereas anxiety and anger directed inward are accompanied by release of epinephrine. It should be noted, however, that these implications have been drawn by indirect inference from measurement of circulatory functions, and the studies did not include assays of the hormone levels in the blood. The inferences drawn are also open to criticism, since they were based upon quantitative amplitude measurements of ballistocardiographic tracings obtained by the use of direct body pickup instruments which cannot be satisfactorily calibrated. The issue may be far more complicated than this, since Lacey and co-workers have advanced a great deal of evidence to show that individual differences in pattern of response may be, in large part, reflections of constitutional differences, and may only partly reflect specific connections between specific affects and particular patterns of response.[57, 58] Reiser, Weiner, and Thaler,[88, 89] in recording circulatory functions during projective psychological testing, observed both of the first two patterns reported by Hickam, as well as an intermediate group which, like Hickam's, seemed too variable from moment to moment for adequate qualitative classification. In all subjects, brisk responses (of the same magnitude as those reported by Hickam and others) occurred in association with surprisingly little directly observable or subjectively reportable evidence of affect. The amount of affect which could be identified in this way was not sufficient for classification. Differential patterning of the circulatory responses appeared to be related more to differential attitudes toward the examiner, but the experiment did not allow for adequate exploration of the unconscious aspects of this relationship, and much more data are needed about this issue. Although the question of specific relationships between affects and physiologic patterns of circulatory response must still be left open, there is no question that these studies singly and collectively demonstrate that emotion is accompanied by circulatory changes which may greatly increase the amount of work required of the heart. Stevenson *et al.*, in another significant datum, have demonstrated that the circulation recovers from the effects of exercise slowly and inefficiently during states of emotional tension, thus prolonging the strain upon the heart.[113]

Most of the studies referred to thus far deal primarily with changes in healthy subjects whose circulatory systems were presumably normal. The studies of Hickam and H. Wolff,

Downloaded from www.ubpathinstitute.org.in

among others, were also extended to patients with valvular disease and limited cardiac reserve, with similar results. Particularly striking is Hickam's demonstration in a patient with severely limited cardiac reserve that the effects of exercise and anxiety were similar and were in the direction of developing congestive failure. Cardiac index and pulmonary arterial pressure were determined by cardiac catheterization. With anxiety as well as with exercise, there was a failure of the cardiac index to rise, accompanied by an increase in pulmonary arterial pressure.[50]

### *Physiologic Changes in Association with Emotional Tension That Lead to Decreased Myocardial Capacity (Psychosomatic Sequences)*

Diminution in functional cardiac reserve during tension may occur as a result of interference with intrinsic cardiac mechanisms governing heart rate and rhythm. Changes in the electrocardiogram reflecting such interference with cardiac mechanisms have been repeatedly demonstrated by numerous workers, including Katz *et al.*,[65] Mainzer and Krause,[65] Wendkos,[123, 124] and Crede *et al.*[21] This literature has recently been reviewed by B. Weiss.[119]

### *Physiologic Changes in Association with Emotional Tension That Alter Renal Function (Psychosomatic Sequence)*

There have been few studies which bear directly on the role of emotional factors as they affect renal function. Diuresis has been reported in both animals and man following emotional stress, and in recent years investigations have been conducted on the effect of specific emotions on fluid and electrolyte balance. Schottstaedt and his co-workers have recently reported a series of such studies, and indicated a direct correlation of certain emotional response patterns with specific types of alteration of water and sodium excretion. For example, they found that feelings of anger, uneasiness, and apprehension produced increased rates of water and sodium excretion, whereas feelings of depression were associated with decreased rates.[16, 100] Confirmation of these findings by other investigators has not been reported as yet, and further research on these psychophysiologic relationships is needed.

There is more evidence, however, which bears directly on the relationship between emotions and adrenal cortical activity[32, 33, 102] and between adrenal cortical activity and renal tubular function.[59, 77] By inferential reasoning, one step removed, one may hypothesize a sequential psycho-adreno-renal pathway as an important factor in the clinical manifestations of congestive failure.

### *Clinical Observations—Association Between Psychological Problems and Clinical Course (Psychosomatic Sequences)*

In view of the pertinent psychophysiologic findings summarized above, it should in no way be surprising to find that stressful life events often precede the development of episodes of congestive failure in patients with established cardiac disease and limited reserve. Indeed, this expectation can be affirmed readily on the medical wards of any hospital. Chambers and Reiser interviewed twenty-five consecutive patients who were admitted to the wards of the Cincinnati General Hospital because of congestive heart failure.[18] An acute emotionally stressful experience had immediately preceded the development of congestive failure in 76 per cent. In each instance these events seemed to have highly specific meaning for the patient in relation to his previous life experiences and conflicts, and in most they were superimposed upon a chronic state of sustained emotional tension.* An important aspect of these findings lies in the fact that most of these patients had been through similar conflictual crises previously without having developed congestive heart failure, that is,

* It should be noted here that a similar study of personality and life situations in patients with acute coronary occlusion has been carried out by Weiss *et al.* They found evidence of gradually mounting emotional tension prior to the onset of occlusion in 49 per cent of the forty-three patients studied. In addition 37 per cent of them had shown acute emotional stress which in 9 per cent of the instances was added to the tension just before the onset of the coronary occlusion.[122]

Downloaded from www.pdflibrary.com.cn

similarly stressful experiences occurring before critical limitation of cardiac reserve had developed had not resulted in clinical disturbance of the patients' circulatory equilibrium. It was only after the underlying progressive heart disease had resulted in serious loss of cardiac reserve that the stressful life events assumed clinical importance in respect to circulation. All of the patients in this series were seriously ill and exhibited advanced forms of heart disease and serious degrees of cardiac decompensation. In other words, they were the type of patient in whom the extent of underlying cardiac pathology might so impress the physician that he might well not feel it necessary to search for a specific precipitating factor. Still it is of utmost importance to recognize that the extent of the underlying heart damage does not ordinarily account for the nature of the forces immediately responsible for the abrupt onset or worsening of congestive failure. In the same study it was noted that marked improvement in clinical status coincided with providing the patient an opportunity to share and discuss his difficult life situation with the physician. It was further observed that a continuing supportive relationship with the physician aided in avoiding further unresolved emotional crises and stabilized the clinical course to a great extent (without, of course, effecting any change in the extent of underlying heart damage).

In summary, the tenuous balance between work load and cardiac reserve in patients with structural heart disease and diminished cardiac reserve may be seriously disturbed by the various circulatory responses that accompany psychological stress. In this fashion, serious episodes of congestive heart failure may be precipitated and sustained by emotionally stressful life situations.

## *Somatopsychic Problems in Patients with Structural Heart Disease*

In the interest of logical sequence it seemed appropriate for a summary of psychosomatic mechanisms and sequences to precede this section. This was mainly because the psychological sequelae may, and usually do, include a large component of unresolved anxiety which then may channel back through the psychosomatic pathways and lead to worsening of the patient's condition. The cyclic reaction thus set in motion may develop to critical proportions, and for a long time such reactions preempted the major attention and energies of workers interested in psychologic aspects of cardiac disease.

While the importance of these cyclic phenomena (which will be discussed in more detail below) has in no way diminished, in recent years our attention has, in addition, been called dramatically to a much broader field of somatopsychic reactions which manifest themselves mainly in the field of behavior. The importance and frequency of the latter reactions could not be fully appreciated until brought into sharp relief by experiences with patients who reacted in "paradoxical" fashion to corrective cardiac surgery. Although the exact incidence of such reactions is not accurately known, the phenomenon constitutes a major challenge to physicians in selecting patients for surgery. Perhaps even more important is the fact that these extreme instances have greatly broadened and deepened our understanding of the somatopsychic sequences which are present to some degree in all patients with major cardiac difficulties.

In a discussion of these problems, it is useful to identify those factors intrinsic to cardiac disease which may operate as stressful agents in the psychologic sphere and thus demand attempts at adjustment on the part of the patient. In the last analysis the ultimate clinical effects of each of them stem from the fact that they act as sources of anxiety. The end results may come about in two ways—either as the result of untoward effects of free anxiety and other affects, upon the tenuous circulatory balance, or as the result of indirect consequences of anxiety, namely behavior which stems from maladaptive use of ego defenses against anxiety. These maladaptive behavioral phenomena, in turn, may complicate or aggravate the circulatory problem. Thus they may lead to behavior which interferes with the patient's ability to utilize a prescribed medical regime, for example, refusal to take digitalis. They may also be reflected in more general aspects of the patient's personality adjustment and lead to psy-

Downloaded from www.dpmultimedia.org.in

chiatric problems (e.g., depression) which do not immediately affect circulation but nonetheless may require therapeutic attention in their own right. The complexity of these direct and indirect consequences, and the manner in which they may in themselves lead to mobilization of additional anxiety (thus completing feedback cycles), is schematically illustrated in Fig. 1.

The psychological burden imposed by the onset and/or diagnosis of heart disease may stem from any or all of three general sources. The first source is constituted by the symptoms themselves. The abrupt onset of sensations, such as breathlessness, severe precordial pain, palpitation, dizziness, etc., is in itself understandably terrifying. The initial anxiety so generated at the onset of an acute episode may in itself impose considerable additional burden upon the already compromised circulation.

The second source is the threat inherent in the diagnosis of heart disease. Any illness may generate anxiety by virtue of actual or threatened damage to bodily integrity, but in the case of the heart these issues usually are exquisitely exaggerated. The reasons for this are general and universal. The central indispensable role of the heart in maintaining life provides an appropriate background for the use of its mental representation as a symbolic object of the deepest and most awesome unconscious fantasy fears of all types. Added to this is ample reinforcement from folklore, symbolic language conventions, and a vast popular literature, some of which is quite fearsome —whether intended to be or not. It is probable that the diagnosis of heart disease universally activates, to some degree, fantasies of sudden, unexpected, and catastrophic death. The real danger implied by the diagnosis is not to be minimized here, but it should be pointed out that fantasy fears may exaggerate and amplify it to proportions far beyond the realities. For example, the unconscious threat may be no less intense in the patient who is informed of the discovery of a functional cardiac murmur than it is in a patient confronted by a diagnosis of serious advanced rheumatic heart disease. Beyond these generally present potentials for threat inherent in the diagnosis, there may,

Downloaded from www.dbraulibrary.org.in

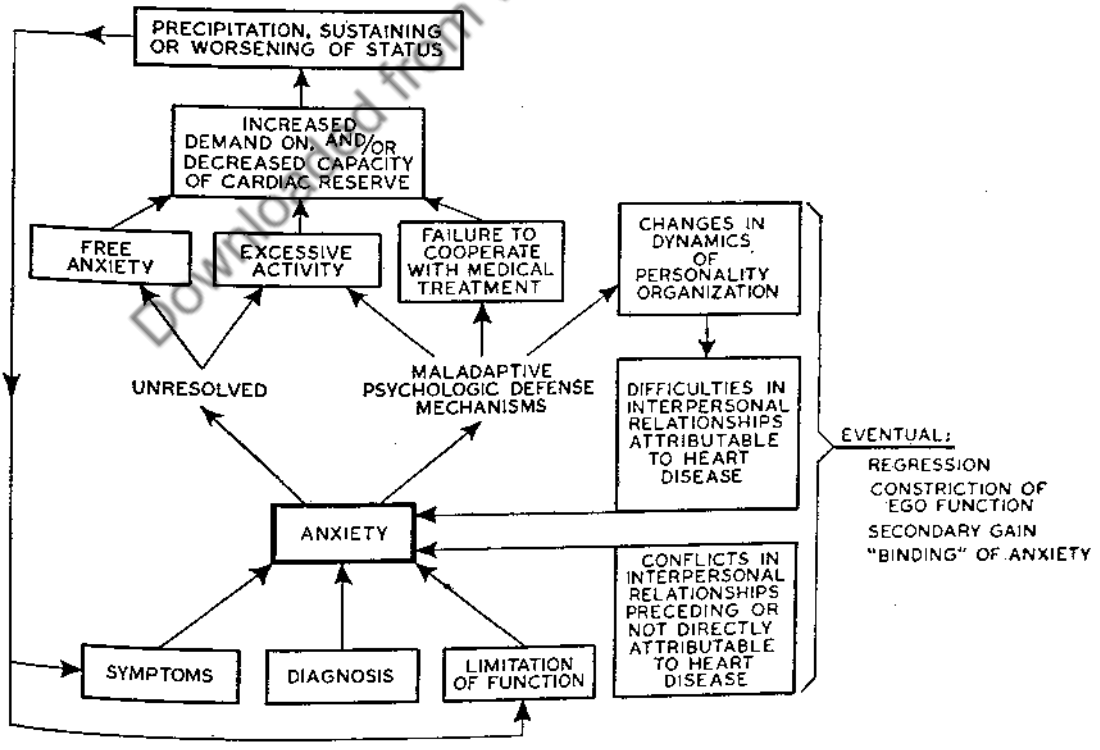

FIG. 1. *Feedback cycles in cardiac disease.*

in individual cases, be specific additional potentials for conflict and turmoil. For example, consider the case of a patient who has had a highly charged ambivalent relationship to a relative or close friend who died of heart disease. Here problems of identification and guilt may add considerable fuel to the fire.

The third source of anxiety stems from the fact that the patient experiences (or can anticipate) a real limitation of his physical capacity, and knows that this will be progressive and result in increasing loss of power in his most vital organ. The adaptive task imposed upon the patient cannot and should not be underestimated. Successful or ideal adjustment necessitates realistic acceptance of the loss and the attendant limitations which it imposes, and also necessitates rearrangement of living patterns which take these limitations into account and at the same time make maximal utilization of residual capacities. Many factors influence the degree to which the patient succeeds in meeting this challenge. Among them, most important are: the severity of the specific emotional impact of heart disease upon him; the strength of his personality make-up; the specific reactions and attitudes of medical personnel, particularly his doctor; and the reactions of important people in his personal environment. Naturally, the psychologic trauma inherent in the development of a cardiac disorder may severely aggravate a pre-existent psychiatric problem, and in some instances it serves as a precipitant for development of major psychiatric difficulties in a previously satisfactorily integrated personality.

There are a number of ways in which things can go wrong. Inadequately resolved anxiety (free affect) may worsen the medical condition, as described above. In addition, psychologic mechanisms which ordinarily have the function of defending against anxiety may be inappropriately and maladaptively mobilized in the patient's attempt to defend against the threat. For example, specific ego defenses such as denial (for example, of illness) and reaction-formation (for example, against dependent wishes) may lead to open, unrealistic, and rebellious unwillingness to adhere to a prescribed medical regime. This is a problem frequently encountered in middle-aged men with coronary disease, and such behavior may be seriously, though unwittingly, self-destructive. In so far as it contributes to progression and aggravation of symptoms and further actual constriction of the patient's physical capacity, it creates new anxiety, and in this indirect way another type of vicious cycle is established.

Disturbances in the sphere of behavior may not be restricted to issues centering about the physical disorder and its care. Rather profound changes may develop in the basic functional organization of the personality. Extensive reliance upon defenses such as projection and displacement may lead to drastic changes in the patient's view of the world and his reactions to specific people in it. Unconsciously determined changes in significant and important relationships may result—for example, dissolution of business associations, divorce, etc. These too may represent fresh sources of tension and conflict which lead to still another type of feedback cycle. Even without this, symptomatic behavior of this magnitude represents major psychopathological development and demands therapeutic attention in its own right.

As the situation progresses, more far-reaching long-term changes may become evident. As in any major illness, strong regressive tendencies develop, and when these are added to and combined with the kinds of developments described above, a process is instituted which may eventuate in serious constriction of all aspects of ego-function in general, and, in particular, in restriction of the defensive operations of the ego to relatively few mechanisms that are for the most part maladaptively utilized. The cardiac status becomes part of the self-image, and the personality becomes constricted, rigid, brittle, and fragile. The cardiac status may become a nuclear part of the patient's style of conducting interpersonal relationships, and this is most often manifested by behavior which exploits the physical condition in the service of secondary gains which may acquire considerable value.

One additional mechanism should be mentioned, which can be described as a form of "binding of anxiety." Whenever serious physical disease (or a physical condition which can be treated as "serious") develops during a

Downloaded from www.psychosomaticmedicine.org

period when the patient is grappling with a serious unconscious psychological conflict, the physical disease may be seized upon as a way of resolving the conflict. For example, the illness may provide a way of avoiding the issue by precluding the conflictual activity and may thus reduce the importance of the conflict to a state where it is of academic interest only. Two typical and frequently seen examples of this mechanism can be cited. The first is the example of the patient in early adolescence who has not yet reached a satisfactory resolution of problems centering on issues of sexuality and independence; chronic invalidism for such a patient may provide a very convenient way out. The second example is that of the overtly aggressive and ambitious man who harbors unresolved problems about success. Here again, even early manifestations of cardiac disease may offer a face-saving occasion for retrenchment and retreat from vocational growth. In other words, the status of illness may acquire powerful psychic value by virtue of the fact that it offers opportunity for "acceptable" avoidance of serious conflicts that would be activated in a fuller life sphere. All of these mechanisms and phenomena are particularly well illustrated by experiences gained in subjecting patients with long-standing cardiac disabilities to surgical procedures which literally restore the circulatory capacity to levels of competence that permit a wider sphere of activity.

## *Emotional Aspects of Cardiac Surgery*

In the past fifteen years, tens of thousands of people with heart disease have undergone cardiac surgery. From this accumulated experience there has evolved a growing awareness of the major role of emotional factors in all phases of this therapy. In the selection of suitable candidates, in the preparation for operation, in the management of immediate postoperative recovery, in the assessment of postoperative results, and in the patient's adjustment and adaptation to a new life situation, psychological factors heavily weight the course at each step.

In the last few years, reports from various centers have drawn attention to the high incidence of major psychiatric complications following heart operations and to some of the mechanisms involved. In 1954, Little and Pearson reported on a patient who developed an acute schizophrenic psychosis following cardiac surgery. The psychosis was characterized by catatonia, with an admixture of delusional patterns. Treatment consisted of combined insulin coma and ECT. The patient survived this therapy, and responded satisfactorily. They suggested that "with the rapid increase in cardiac surgery and the resultant new way of living, other psychotic reactions may develop which will require shock therapies."[64] This prediction was confirmed in subsequent reports from other observers. In the same year Fox, Rizzo, and Gifford, who had been impressed by the large number of psychiatric consultations requested by the cardiac surgical service and had therefore undertaken a study of psychological mechanisms and reactions before and after valvulotomy, reported a high incidence of major psychiatric complications in their series.[34] In 1955, Bliss, Rumel, and Branch, having encountered two patients who developed severe schizophrenic psychoses after mitral commissurotomy, carried out a retrospective survey of thirty-seven cases and reported that eleven of them had developed major psychiatric complications.[13] Kaplan studied eighteen patients who had experienced mitral commissurotomy and stressed the importance of the individual personality structure and life situation as determinants of the ways in which these people responded to improved cardiac function.[53] In 1957, Priest and his coworkers, confronted with a higher incidence of psychoses after cardiac surgery than after general major surgery, studied a large group of patients undergoing heart operations. They emphasized the uniform high degree of anxiety in cardiac patients approaching surgery, particularly in those with rheumatic heart disease, and related this to the disproportionately high incidence of psychiatric complications. They drew attention to the difficulty in evaluating surgical results because of the postoperative persistence of psychogenic subjective symptoms of disability, particularly dyspnea and fatigue.[79] This problem of the interference of psychological factors in achieving accurate appraisal

Downloaded from www.drsharma.org

of surgical results had already been discussed in a Cornell therapy conference and had been remarked upon by other observers.[11, 20, 53] On the Psychosomatic Service at Montefiore Hospital, a limited retrospective review of patients who had undergone mitral commissurotomy revealed the anticipated high incidence of postoperative psychoses, suicide attempts, and prolonged depressions.

The specific emotional reactions to cardiac surgery can best be viewed through the frame of reference of the long chain of relevant circumstances beginning with the diagnosis of heart disease and ending with the readaptation following "surgical rescue." The anxiety-laden somatopsychic sequences have already been discussed, and they hold for this group of patients with one significant difference, namely, that there is now the opportunity of halting or reversing the deteriorating course of the disease. With the widely popularized information about heart operations, "hope" has been engendered for many people whose only outlook had been progressive disability and death. A noted cardiac surgeon has commented on the striking difference in overt attitude between patients referred for cardiac surgery and those referred for other major surgical conditions. The latter hope they will be told that surgery is unnecessary; the cardiac patient hopes that he will be accepted for surgery.* However, it is well to remember that all surgery carries with it unconscious fear and dread of mutilation and death, and additional anxiety is evoked when a highly emotionally charged organ, such as the heart, is involved.[23] Herein, then, lies the conflict which confronts all prospective candidates for a cardiac operation and which only serves to heighten the already anxious state. Once such a patient embarks upon the process of evaluation of suitability for surgery, the realistic and unconscious stresses multiply with mounting intensity. The routine procedures which are carried out, including angiocardiography, cardiac catheterization, and repeated examinations by members of the cardiovascular surgical team, are tedious, usually frightening, and carry some risk. Tension is further heightened by the necessity to wait for "the verdict" from the panel of experts.

Depending upon the nature of the long-term defenses, patients may look forward to the operation in different ways. Those who have realistically accepted the burdens of heart disease but continued to be truly dissatisfied with the restrictions it imposes may view the operation as a chance to revert to previous healthy living. Those in whom the heart disease has led to increased dependency, ego constriction, and avoidance of mature responsibilities may then be loathe to give up the illness and face a normal life with its implied independence. Those who have become chronically depressed by a life of increasing invalidism may see the operation as a "sanctioned suicide" in which the real rescue is death.

Once the patient is accepted, and the prospect of surgery is a reality, the original conflict between the desire for and the dread of surgery is intensified, and the patient must supplement his existing and sometimes limited repertoire of long-term defenses with emergency psychological mechanisms. These emergency defenses are seen quite clearly as the time for operation approaches, and they include immobilization (to avoid the fear of disintegration), belligerence (last attempt to deny weakness), excitement or elation (to cover depression and fear), desperate denial (last-minute maneuvers to delay the operation), or total failure to mobilize emergency defenses, in which case overwhelming panic may ensue, with the patient being convinced that his heart will stop during the operation and that he will die. In other cases, where defenses are inadequate, major hysterical mechanisms such as amnesia may appear, or an acute psychotic episode may develop. Hallucinatory states, depersonalization, and even well-developed paranoid or depressive states may be seen. As an example of the last possibility, a patient with mitral stenosis, whom we recently observed, developed an acute schizophrenic type of psychosis following cardiac catheterization.

More commonly, however, the major psychiatric complications occur following rather than before surgery. The surgical experience itself carries with it great somatopsychic impact,

* Hurwitt, Elliott, personal communication.

Downloaded from www.psychosomaticmedicine.org

involving as it does the physiological shock of a major thoracic operation and the serious disruption of homeostasis that results from prolonged anesthesia, direct tissue injury, hypothermia, and other procedures. Often there are unavoidable periods of cerebral hypoxia, which contribute to subsequent postoperative organic confusional states. Another source of shock is the threat to integrity of body-image which confronts the patient when he awakens in the recovery room. He finds himself attached to a variety of tubes, such as nasal oxygen, thoracic drains, intravenous infusions, and sometimes with tracheotomy and suction. With the return of consciousness, the patient once more reacts to his immediate situation in terms of his original aspirations. The emotional tone may vary all the way from elation that he has survived the operation and will be well again, to deep depression and despair at being alive and having to face the future. If the unconscious conflict has involved a reluctance to give up the illness and its secondary gains, successful operation will represent a danger, and emergency ego defenses may once more be required.

Of great importance in the long-range convalescence and surgical success are the postoperative depressive reactions. These are often disguised as physical symptoms, such as intractable pain, excessive weakness, and disturbances of appetite and sleep. Not uncommonly, the full psychopathological response is delayed until the patient's return home, where he is expected to behave as though he no longer has heart disease. This may involve the assumption of economic responsibilities; marriage, which had hitherto been deferred or avoided; and, similarly, pregnancy. It is in this period of adaptation to a new way of life that the frustrations of dependent drives are experienced most keenly and may become intolerable. The psychodynamic pattern seen in such instances is that of a separation reaction, that is, unconsciously the patient reacts as if he had lost an important ambivalent love object. This sequence of events underlies the delayed psychoses and suicides that have been reported after apparently successful surgical results.

The cardiac surgeon looks to other hospital services to deliver the patient to him in the optimal state of preparedness, and much progress has been made in refining the methods of selection of suitable candidates and in the preoperative physiological preparation. The effects of psychological unpreparedness are beginning to be understood and appreciated. Psychiatric evaluation is now being carried out in some centers as part of the selection of cases, and patients whose personality structures presage serious emotional difficulty are being rejected or the operation is postponed to allow for further psychological preparation. In this way, many so-called surgical failures can be avoided, and patients who cannot benefit from the operation may be spared needless suffering and risk. Better and more exact criteria and methods for preoperative selection and preparation are sorely needed, and this constitutes an urgent challenge for further serious study of these problems.

## Comments on Psychological Issues Related to Essential Hypertension and Other Cardiovascular Disorders

As stated earlier, most of the interrelationships between mind and body that are encountered in cardiovascular disorders find apt illustration when the problems surrounding structural heart disease are examined in a comprehensive way. For the most part, the principles involved can be extrapolated as other cardiovascular disorders come up for consideration. There are, however, certain additional issues that arise in connection with diseases in which emotional stress may directly activate the pathophysiological mechanisms underlying the disease process. These can be best illustrated by proceeding to a consideration of the additions necessary to complete the picture of psychosomatic interrelationships as they are encountered in essential hypertension. In this instance the main additional fact that must be taken into account is this—in the cardiac patient, emotional stress is a factor which adds to the burden of the already diseased system, but it does not contribute to the basic lesion in any way. On the other hand, in the patient

Downloaded from www.dbraumley.com

with hypertension, psychologic factors may also contribute to the disorder, since in this disease emotional stress may be discharged through the very same autonomic and endocrine mechanisms which are responsible for the diffuse arteriolar constriction and increased peripheral resistance which characterize its basic pathological physiology.[31, 40, 73, 76, 85, 118, 121, 130, 131, 132] Although the precise nature of these mechanisms is not fully understood, it has been repeatedly and convincingly demonstrated that they may be activated in conjunction with psychological conflict, and in this way stressful life situations may contribute to onset of the disease itself and may precipitate symptoms, complications, and acceleration.[1, 4, 5, 82, 87, 120, 121, 130, 131, 132] It should be emphasized that while linkage between emotional and pathophysiological phenomena of this order is more immediate than in the case of structural heart disease, it still does not constitute a pathogenic connection in the ultimate etiologic sense. In other words, available data indicate mainly that emotional stress may and does drive or activate what might be termed "available hypertensive mechanism(s)," regardless of the nature of the still-unknown factors that may in the first place be responsible for the existence of such mechanism(s) in some individuals.

While the literature is replete with observations which tend to implicate psychologic problems as contributors along with other factors in the genesis of the basic hypertensive mechanism(s), such a role has not been finally demonstrated. Reviews of this literature are available elsewhere.[6, 24, 85, 122, 130]

The important points to be extracted from it are the following:

Regardless of the ultimate etiology, there can be little doubt that emotionally charged life situations may play a major role in affecting the time of onset and the clinical course of the disease process once it has been established in susceptible individuals.

Study of the life situations associated with precipitation of the disease, or its aggravation, demonstrate that these situations have specific emotional meaning for the individual patient by virtue of their relation to previous life experiences and unresolved conflicts and are conflictual for the patient because of these connections.

Most investigators now agree that there is no specific "personality profile" associated with the disease. In general, the data from various authors are in agreement in respect to the observation that the psychologic problems encountered in patients with hypertension frequently stem from extremely early psychological trauma (predominantly pregenital). This observation is in no way unique for patients with hypertension but rather seems to characterize patients with all of the so-called "classical psychosomatic diseases."

Some authors, including Alexander, *et al.*,[6] Binger, *et al.*,[12] and Reiser, *et al.*,[85, 87, 117] place particular emphasis on strongly ambivalent conflict in dependency relationships with extreme difficulties in handling aggressive impulses in such object-relationships. Binger and Reiser emphasize that patients with hypertension are particularly fearful of the persons from whom they seek dependent gratification.

Reiser, Weiner, and Thaler[86, 117] have recently presented evidence that these patients tend to "insulate" themselves emotionally in interpersonal relationships, and they suggest that this type of defensive operation may be a reflection of an inborn vascular hyperreactivity rather than a direct pathogenic mechanism by virtue of its restraining effect on the expression of "hostility." These issues, however, should properly be relegated to the realm of theory and should not influence the clinician's appraisal of the individual psychodynamic problems in each individual patient.

One additional point which carries considerable clinical importance remains to be discussed. It has to do with the genesis of symptoms in the patient with essential hypertension. In this condition a unique kind of feedback cycle may be seen with some frequency, as illustrated in Fig. 2. Emotionally determined symptoms may arise in any of three ways, only one of which reflects activity of the basic disease process. However, symptoms occurring on the basis of purely psychologic mechanisms (for example, conversion) and

Downloaded from www.dbsiwebofsci.ir

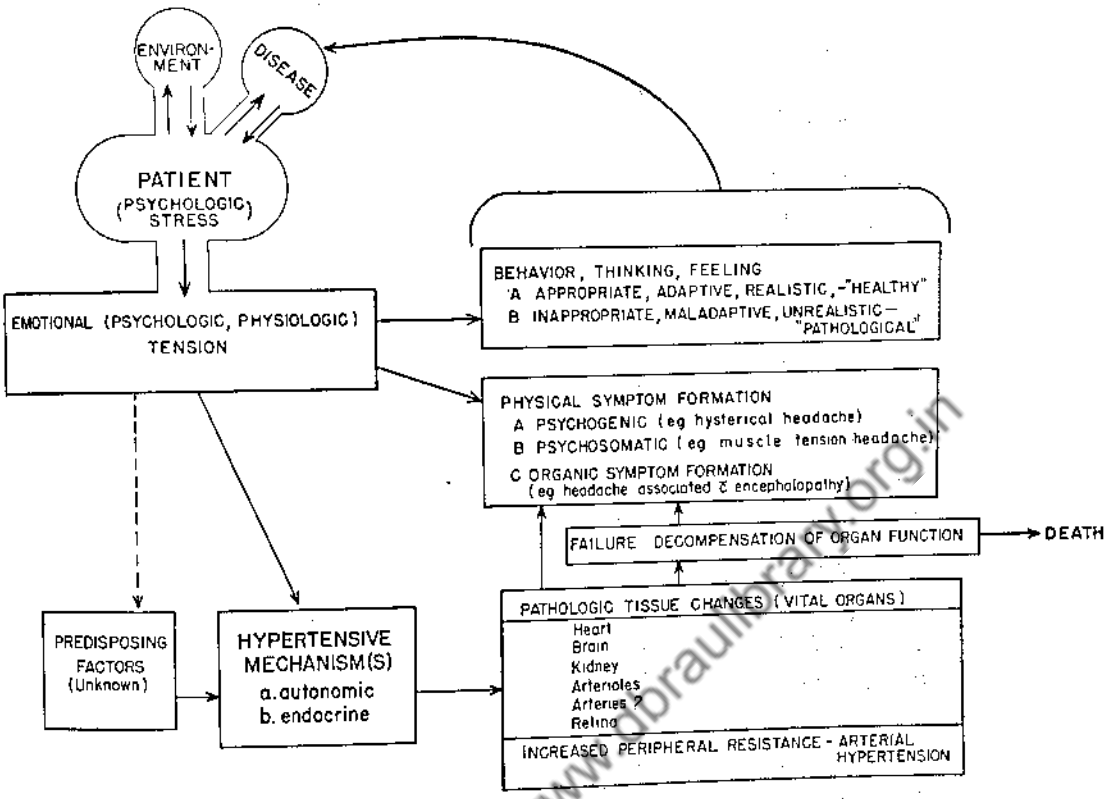

FIG. 2. *Feedback cycles in hypertension.*

Downloaded from www.dbraulibrary.org.in

symptoms arising on the basis of purely psychosomatic mechanisms involving other body systems (for example, muscle-tension headache) may be regarded by the patient as evidence of progression or worsening of the basic hypertensive disorder. The anxiety evoked in the patient in response to symptoms so interpreted may then channel back through the basic hypertensive mechanism(s) and, indeed, lead to the very thing the patient originally feared, namely, elevation of pressure and an aggravation of the disease process itself. The implications of this phenomenon for management are obvious. Careful formulation of symptom mechanisms and direct reassurance in instances where symptoms are actually unrelated to the underlying hypertensive process may yield distinct therapeutic gains by interrupting this cycle which otherwise could lead to progression of the hypertensive process.

In summary, there are a number of ways in which psychologic issues may be intimately involved in essential hypertension. Emotionally charged situations, by virtue of their capacity to activate vascular mechanism(s) underlying diffuse arteriolar constriction, may contribute to onset of the disease, to the occurrence of symptoms arising from organic lesions of the disease, and even to acceleration of the hypertensive disorder. Symptoms may also arise on the basis of unrelated psychologic and psychosomatic mechanism(s), and anxiety in response to these symptoms, along with those related to the hypertensive process, may also activate the underlying pathophysiologic mechanism and lead to progression of the disease. Long-term psychologic problems of adjustment to the disease may include all of the mechanisms and consequences described for patients with structural heart disease. Personality disturbances antedating the onset of the disease are frequently found in patients with hypertension, and these can be related to severe difficulties that occurred very early in development; whether or not these are significant factors in the genesis of hypertension is still unknown.

Among the other cardiovascular diseases, there are several in which it appears likely that basic disordered vascular mechanism(s) may be triggered or activated by emotional factors. These include Raynaud's disease,[2,72] migraine,[28,35,134] various forms of syncope,[27,122] and neurocirculatory asthenia.[19,71,122] Ordinarily, the effects of emotional stress upon problems of coronary circulation have been best formulated in a similar fashion to the effects of psychologic tension in valvular heart disease, that is, through disturbances in the balance between demand (for coronary blood flow) and supply (that is, capacity of the coronary bed to deliver). There is, however, some interesting current work in progress[44,46,110] which may eventually implicate emotional factors as contributors in the pathogenesis of atherosclerosis, through elevation of serum cholesterol. Occurrence of cerebral vascular accidents and aggravation of various other peripheral vascular disorders are probably also best considered, on the basis of available evidence, in the same category with structural heart disease and coronary problems. While there has been much speculation in this regard concerning the role of arterial spasm, the actual role of such mechanisms in conjunction with clinical disorders has not been clearly demonstrated. However, there is at least one suggestive set of observations, namely, those of Seidenberg and Ecker.[101] Stasis and disturbances of clotting have been discussed as factors in cerebral, coronary, and peripheral vascular accidents. Some data suggest that clotting time may accelerate during periods of emotional tension, but their ultimate significance remains to be determined.[99]

## ¶ Role of the Psychiatrist and Treatment Implications

It should be clear from the foregoing that the psychodynamic and psychophysiologic problems that may be encountered are multiple and complex. It follows from this that treatment must be based upon careful and meticulous diagnostic evaluation and formulation of each patient's individual problems. The first and most critical task for the psychiatrist is that of formulating as clearly as possible the nature of the relationships and the sequential connections between the patient's psychological problems on the one hand and the clinical manifestations of the underlying cardiovascular disorder on the other. Careful and comprehensive psychiatric diagnosis (which includes clinical diagnosis, identification of current sources of conflict, underlying genetic conflicts, major ego-defense mechanisms, appraisal of ego-strength, and appraisal of environmental problems and supports) constitutes only a preliminary but indispensable step. Until these have been brought into perspective, vis-à-vis the cardiovascular problem it is not possible to formulate realistic treatment goals and techniques.

Determination of goals for therapy rests upon both psychological and medical issues and is the next step in planning therapy. The principles involved in this step and in carrying out treatment plans have been discussed in detail elsewhere,[62,81,91,106,122,132] and cannot be elaborated here. Clearly, psychotherapeutic considerations and activities are to be integrated into a sound medical-treatment regime and should be added to a program of standard medical measures rather than in any way replacing them. The psychiatrist's role may be mainly that of consultant and adviser to the internist or may develop into that of conducting intensive psychotherapy in close teamwork with the medical specialist. Psychotherapy may be indicated for specific short-term purposes such as preparing the patient for and supporting him through surgery, or it may be undertaken with more far-reaching goals, for example, with the aim of extensive analysis and reintegration of the personality. These issues will vary with the individual clinical problem and with the personnel and facilities available. This area is both challenging and important. Work in it requires the utmost skill, understanding, and effort on the part of the physician—sometimes with only meager therapeutic returns but frequently with major and satisfying gains for doctor and patient alike.

CHAPTER 34

# PSYCHOLOGY OF GASTROINTESTINAL DISORDERS

Theodore Lidz
Robert Rubenstein

Downloaded from www.dbraulibrary.org.in

DESIRES AND GRATIFICATIONS and the experiencing of pleasure and unpleasure during the first years of life are largely centered in the gastrointestinal tract. The infant relates to the world through sucking, mouthing, and biting, and first experiences emotional security in being nursed and emotional deprivation in being hungry. Feelings of trust and of being loved are initially experienced in being fed, hostility is first manifested in biting, and erotic excitation is experienced with the pleasurable sensations which accompany sucking. The site of tensions and gratifications gradually shifts to the other end of the alimentary canal and the feces, and the processes of their retention and expulsion become central in the experiencing of pleasure, mastery, and unpleasure. Feelings of autonomy, of accomplishment, of possessiveness, of shame and doubt, and of rebellion are experienced with the sensations which accompany the retention and expulsion of feces and with the process of attaining bowel control in compliance with parental demands. The gastrointestinal tract thus is fundamentally involved in the early molding and expression of individual behavior patterns, attitudes, feelings, and of the character of relationships with others.

The gastrointestinal system is a common site for the expression of a wide range of emotional disturbances. Behavioral problems of childhood often involve difficulties in feeding and bowel training. Characterological problems may be reflected in overindulgence, restriction, or idiosyncracies in eating, as well as in constipation or colonic overactivity. Vomiting,

excessive eructation, and globus can be hysterical. Delusional ideas may involve the stomach and bowel in schizophrenia and the depressive psychoses. Periodic intestinal pain is a symptom accompanying the psychoses of porphyria. Dysphagia, cardiospasm, dyspepsia, pylorospasm, and mucous and spastic colitis are physiologic dysfunctions that can be primarily psychologic. Peptic ulcer, regional ileitis, and ulcerative colitis are conditions involving tissue breakdown that are, at least in part, determined by emotional problems. Surgeons as well as psychiatrists have become interested in emotional factors in the symptoms of cholecystitis and pancreatitis. The list may be extended to the consideration of such dental problems as caries and bruxism, and to the relationship between hemorrhoids and chronic constipation. Disorders of appetite may be serious complications in other illnesses, as when obesity is present along with heart disease, diabetes, or hypertension, and when the patient with tuberculosis suffers from anorexia. Disturbances of function involving each unit of the gastrointestinal system, including disorders of appetite and eating, of swallowing, of digestion, and of elimination, may thus reflect psychological difficulties.

Emotional problems clearly require consideration in many of these complaints and may be of primary significance to the understanding and treatment of some. In psychotherapeutic work with patients with these disorders, the relationships between the psychological phenomenology of gastrointestinal functioning and the early phases of psychosexual development are frequently confirmed. During treatment the interplay between emotional disturbances and exacerbations of symptoms or physiologic dysfunction can often be documented in convincing detail, but, in many gastrointestinal disorders involving psychophysiologic dysfunction, relatively little of a definitive nature is known beyond the existence of such a relationship. Peptic ulcer and ulcerative colitis, however, are among the most carefully studied psychosomatic disorders, and the clarification of the psychological and physiological conditions necessary to their appearance is more advanced than in other gastrointestinal problems. They are among the most serious illnesses encountered by the physician, and the importance of psychological factors in their development and course has long been recognized. We shall therefore devote this discussion to the consideration of peptic ulcer and ulcerative colitis as illustrative of the psychosomatic approach to diseases of the gastrointestinal system.

## ¶ Peptic Ulcer

Correlations between the physiology of the stomach and the emotional life of the person were first demonstrated by Beaumont[6] in his observations of his patient, Alexis St. Martin, who was left with an opening from his stomach through the abdominal wall to the exterior as the result of a gunshot wound. Beaumont followed the course of digestion with different foods, under varying conditions of health, and with alternations in his patient's emotional reactions. More recent observations include those of Wolf and Wolff[79] on the gastric functions of a man with a gastric fistula. They correlated his feelings with his gastric secretions, motility, and vascularity, finding these functions depressed when he was sad or frightened, and increased when he felt angry, resentful, or anxious.

Mirsky, *et al.*[53, 54, 55] have sought to correlate pepsinogen levels in urine and blood with the emotional experiences of persons as reported and observed during psychoanalysis, psychotherapy, and by other means over relatively long periods of time. Pepsinogen excretion was found to be much higher in patients with peptic ulcers. It has been suggested that the level of blood pepsin is determined early in life, perhaps genetically, and tends to remain relatively constant. The pepsinogen level in urine, however, appears to fluctuate. Marked increases in excretion levels were observed, in persons both with and without ulcers, in response to particular life situations, such as reaching a decision to have a child, a patient's wife becoming pregnant, and the arousal of rivalrous feeling toward a sibling. Such experiences often failed to evoke any reactions of

Downloaded from www.dbraunary.com

which he was aware in the person. Thus unconscious responses, largely concerning dependency problems, were accompanied by increased activity of the peptic cells of the gastric mucosa as measured by pepsinogen-excretion levels.

Margolin[51] undertook the psychoanalytic study of a twenty-two-year-old unmarried college girl with a gastrostomy created two years earlier following a suicide attempt with caustic lye. Independently of this psychotherapeutic work, physiological observation and experimentation were conducted regularly, including studies of gastric motility, vascularity, and secretion under varying conditions, with quantitative determinations of hydrochloric acid and pepsin concentration. Regularly recurring gross patterns of gastric functioning were observed and reported to be repetitively and predictably associated with specific unconscious constellations. An important aspect of this work was its demonstration of the effects on gastric functioning of the unconscious meaning to the patient of the experimental procedure, of the extent to which she became aware of these responses, and of the adequacy of the mechanisms of defense which she utilized in dealing with them. These responses included the erotization of the gastrostomy and experiencing the physiological experiments as an intolerable and frightening sexual violation. Crider and Walker[13] had worked with this patient earlier and had observed a decrease in gastric secretion with anger and resentment, in contrast to the report by Wolf and Wolff[79] of an increase in gastric secretion associated with these emotions in their male subject. Margolin's work suggested that the difference in response resulted from the different unconscious meaning of the experimental procedure to a woman.

The effects of emotions on gastric functioning have thus been grossly demonstrated by Beaumont, related to the arousal of specific emotions by Wolf and Wolff, and correlated with unconscious responses by Mirsky and by Margolin. There are difficult problems involved in the further clarification of these psychophysiological correlations. The observational and experimental procedures themselves affect gastric functioning. The study of experimental subjects with gastrostomies and gastric fistulas permits the direct observation of gastric functioning, but they constitute special subjects because their functioning is affected by these bodily alterations. Other problems include the temptation to oversimplify in the effort to unify extremely complex psychotherapeutic and physiological data; the complexity of physiological processes which hinders the identification, isolation, and measurement of single functions; and the difficulty of obtaining psychophysiological data of a sophisticated order on an adequate population.

Recent work promises a further elucidation of the neural pathways involved in peptic ulcer. French, Porter, Cavanaugh, and Longmire[28] have described the experimental production of gastroduodenal lesions in monkeys following the application of electrical stimulation to the low midline axis in the hypothalamus for periods of thirty to eighty-six days. All of the animals who had been chronically stimulated in this central hypothalamic region developed gastroduodenal lesions, including diffuse changes in the stomach, "ulcers" in the duodenum, and focal lesions in the pyloric antrum.

William Brinton[9] wrote of anxiety as a cause of peptic ulcer. Cushing[14] observed that all clinicians know that high-strung persons are particularly susceptible to peptic ulcer, that ulcers become symptomatically quiescent or heal when the patient is physically and mentally put to rest, and that symptoms tend to recur with the patient's return to his former activities and responsibilities. Alvarez,[5] Hartman,[35] Draper and Touraine,[22] and others have tried to describe the personality and character traits of the ulcer patient. The psychoanalytic studies of Alexander and his co-workers (Alexander,[1,2] Szasz *et al.*,[75] Szasz,[71] and Van der Heide[76]) have shifted the emphasis from the delineation of the personality type of the ulcer patient to the elucidation of a typical conflict situation which characteristically precedes the ulcer formation or recrudescence, even when the patients' overt personality characteristics are quite divergent. This represented a shift from the description of personality on an overt

Downloaded from www.ubaldirao.org.in

level to an emphasis upon dynamics, including the consideration of the unconscious determinants of behavior. They observed that the wish to remain in a dependent infantile situation, to be loved and cared for, was in conflict with the adult ego's pride and aspiration for independence, accomplishment, and self-sufficiency. In their overt behavior patients react to their unconscious dependence by being exaggeratedly self-sufficient and ambitious. The repressed wish for a dependent relationship is reinforced by the struggle involved in this overcompensatory behavior, constituting the unconscious psychological stimulus for those physiological processes which lead to ulcer formation. Other ulcer patients are overtly expressive of their oral desires, being outwardly dependent, demanding, and disgruntled. Their dependent tendencies are frustrated by external circumstances rather than by internal repudiation. It was postulated that the frustration of these oral-receptive longings would lead to a regression from the wish to be loved to the wish to be fed. The repressed longing to receive love and help mobilizes the innervations of the stomach, associated since birth with the process of receiving food. With this persistent stimulation, the stomach responds as if food were being taken in or about to be taken in, with a resultant chronic hypersecretion and hypermotility.

The work of Kapp, Rosenbaum, and Romano[38] has confirmed the importance of this dependency conflict and of the varying defensive personality façades which Alexander and his co-workers described. In addition to the hard-driving, exaggeratedly self-sufficient, and the overtly dependent, demanding groups of patients described by Alexander, they encountered a third group who reacted to their dependent desires by giving in to them partially. They were passive and shy, had had close relationships with mother figures, tended toward feminine identifications, and had strong unconscious homosexual trends.

Mahl[46, 47, 48, 49] has questioned the specificity of the dependency conflict in ulcer formation. His work indicates that hydrochloric acid secretion increases with anxiety regardless of its origin, whether it is associated with sexual, hostile, or passive-dependent wishes, ideation, or motives. This conclusion was derived from the experimental induction of "chronic fear" in dogs and monkeys with a resultant increase in hydrochloric acid secretion, as well as from a study of hydrochloric acid secretion during psychotherapy in two patients. Garma[29] and Pickford[60, 61] have conceptualized the peptic ulcer as "a self-inflicted digestive bite"; their findings are also in disagreement with those of Alexander.

The nature of the relationship between mother and child may be influenced by factors related to the child having a constitutionally high pepsin secretion. Its effects upon feeding patterns, the maternal response, and the character of the interaction with the mother forms an important area for study in the elucidation of specificity in peptic ulcer.

Our present knowledge of physiological and psychological correlations permits only a tentative statement regarding the conditions necessary to the occurrence of peptic ulcer. However, the use of such hypotheses has enabled Weiner, Thaler, Reiser, and Mirsky[77] to predict the appearance of peptic ulcer. They postulated that an ulcer should develop in an individual under the following conditions: (1) a sustained rate of gastric hypersecretion, as indicated by serum pepsinogen concentration; (2) the presence of a conflict related to the persistence of strong infantile wishes to be loved and cared for, and the repudiation of these wishes by the adult ego or the external world, as inferred from projective and psychological techniques; and (3) exposure to an environmental situation which mobilizes conflict and induces psychic tension. After determining serum pepsinogen for each of 2,073 army inductees, 63 with values in the upper 15 per cent and 57 with values in the lower 9 per cent were given psychological tests and a complete upper gastrointestinal roentgenological examination. They were then sent to basic training which constituted the potentially noxious environmental situation in this study. Of these subjects, 107 were re-examined in the last weeks of basic training. From the psychological tests alone, 10 men were selected as most likely to develop an ulcer. The predictions

Downloaded from www.dbraulibrary.org.in

proved accurate for 7, and 2 of the remaining 3 subjects were found to be hypersecretors. Of the entire experimental group, 9 men had a proved ulcer before the end of basic training, 8 were in the upper 5 per cent of the serum pepsinogen distribution, and the remaining man was in the upper 15 per cent. Their presence among the hypersecretors was correctly predicted from the psychological tests. Although neither a high rate of gastric secretion nor a specific psychodynamic constellation could be regarded as responsible for the development of peptic ulcer, the authors felt that their study indicated that these two parameters constitute the essential determinants in the precipitation of peptic ulcer on exposure to social situations noxious to the specific individual. Similarly, Pilot *et al.*,[62] in a study of the development of peptic ulcer in one of two identical twins, both of whom had high blood pepsin levels, related it to the exposure of the one twin to the acute and chronic stresses associated with the deterioration of his marriage. However, the hypothesis that peptic ulcer occurs only in the group of hypersecretors requires further study. Current research should clarify whether serum pepsinogen levels are congenitally determined and relatively constant, or whether they rise appreciably when the person is in circumstances likely to be stressful to him. In the important study by Weiner *et al.*, the determination of the hyper- and hyposecretor groups was made at the time of army induction—a period of separation and anxiety—and this factor may have led to their selecting as hypersecretors those who react in this way specifically to separation.

It has been observed that, among ulcer patients, women often appear emotionally sicker than men (Kezur *et al.*[40]). It seems unlikely that this is due to some difference in physiologic reactivity between men and women, for, prior to 1900, peptic ulcer was reported more frequently in women. There has since occurred a progressive rise in the male incidence of ulcers, a ratio of 12 to 1 having been reported by Mittelmann and Wolff[56] between 1931 and 1939. The over-all incidence of peptic ulcer has remained roughly the same during the period of this change in sex ratio. It has been suggested that changes in the social roles of men and women may have influenced this shift.

The internist, in his medical management of the ulcer patient, and the surgeon, in his treatment of patients in whom complications have occurred where medical management has failed, are becoming increasingly cognizant of the importance of social and psychological problems in this illness. Their approach to the ulcer patient is enriched by this awareness, and psychotherapeutic considerations contribute to the planning of treatment. Information about the patient's family and work, gathered by physician or social worker, can help clarify the role of social and interpersonal aggravations and can help the physician to provide the emotional support needed by the patient by modifying his environment. The group of chronic alcoholic, occupationally unstable, and delinquent ulcer patients are largely seen in community hospitals and in public outpatient medical facilities. The provision there of a continuing relationship with a physician or social worker may supply sufficient gratification of their wish to be taken care of to diminish maladaptive and self-destructive responses to the frustration of their dependency needs.

The psychiatrist may act as a consultant, contributing to the psychological and social assessment of the patient, and making recommendations for his management and the modification of his environment. The psychiatrist may also be called upon to conduct psychotherapy with the patient. Although patients with psychosomatic illness often have profound ego defects and are frequently diagnostically related to the borderline or psychotic groups, this characterization is not as applicable to ulcer patients. They are often responsible people, relatively stable emotionally, in whom the potentiality for psychotic behavior is not a prominent problem. However, psychoses have occurred in the course of their treatment, sometimes after vagotomy.

The psychiatrist does not usually assume responsibility for the management of the ulcer regimen and must, of course, be able to work closely with the physicians who do. Psychotherapy cannot take precedence over certain medical and surgical procedures essential to the

Downloaded from www.psychosomaticmedicine.org

patient's well-being. Thus, for example, surgical intervention for otherwise uncontrollable hemorrhage, perforation, or pyloric stenosis must be accepted as necessary. The psychiatrist then directs his attention to helping prepare the patient for surgery and for its possible consequences.

Psychotherapy with ulcer patients is concerned with the resolution of emotional conflicts and the repetitive maladaptive patterns of living and reacting that lead into anxiety-provoking situations, with the expectation that the physiologic functioning of the stomach will then become more harmonious and adaptive to the digestive processes. In thus working with the broad range of life problems which confront the person, rather than limiting the therapy to difficulties directly related to his having an ulcer, psychotherapeutic procedure with these patients does not differ specifically from any other psychotherapy. However, the knowledge that certain basic personality patterns are often encountered in ulcer patients, and that certain rather specific situations frequently precipitate exacerbations of symptoms, may be helpful to the therapist. Attention often focuses upon the intense dependency needs of the patient and his reactive strivings for self-sufficiency to ward off the intense anxiety experienced when he is bereft of a protecting, "feeding" figure. Collapse or the threat of collapse of the defensive pattern may provoke even more intense strivings, accompanied by digestive difficulties. Such efforts may be displaced, as when a businessman seeks to offset insecurities in his dependency on his wife by trying to increase his sales. Resentment and anger as well as dependency problems require attention, for ulcer patients are prone to feel unappreciated and to hide the resentment they experience when demands to assume responsibilities are made of them. Awareness of situations frequently critical in the ulcer patient's life, including the increased responsibilities of marriage, the responsibilities and feared deprivations associated with the birth of a child, and the need to have a secure work position, can sharpen the therapeutic interaction. For example, the ulcer patient often marries an older, "motherly" woman, and becomes anxious and resentful when he finds that she expects him to assume responsibilities, or when the birth of a child both adds to his financial burdens and produces a rival for his wife's attention. In his work the patient may be unable to make demands upon others, but he may then resent others using his compulsive need to avoid insecurity, or he may become silently hostile when his work does not seem to gain him attention and praise. When he considers leaving his job, he becomes anxious because his security is threatened, and an exacerbation of symptoms may ensue.

It is important to help the patient recognize the potential chronicity of his illness and to be prepared for recurrences during stressful periods in therapy and in living. Helping the patient to work on his emotional and life problems rather than focusing primarily upon his ulcer may present a difficult technical problem. A sounder therapeutic relationship is established when the patient is prepared for a reappearance of symptoms and can begin to use them as a means of alerting himself to his emotional conflicts rather than simply becoming discouraged by them. In delineating those situations which are particularly stressful for the patient, he must be helped to recognize their unconscious meanings to him, and to distinguish these from reality. At times, it is necessary to help him avoid certain situations, recognizing with him that he is just not able to handle them emotionally. At other times, when the illness occurs as part of a flight from responsibility, it is necessary to help the patient work out ways of facing and meeting the demands made upon him.

## Ulcerative Colitis

Ulcerative colitis remains one of the most difficult and challenging problems in medicine. The nature of the somatic process is not well understood, and although there is a widespread consensus that psychological processes are important in this illness, their delineation remains incomplete.

Nurses, internists, surgeons, and others who have worked with ulcerative colitis patients

Downloaded from www.libtibrary.org.in

have been impressed with their infantile character, frequent petulance, jealousy of other patients, and extraordinary demandingness. There is considerable agreement among psychiatrists who have had the opportunity to study these patients intensively concerning their psychological characteristics. The relationship between the anal period of psychosexual development and the character traits, the behavioral modes, and the major conflicts which characterize ulcerative colitis patients has been repeatedly demonstrated, but their dependency and the importance of incorporative modes of behavior associated with orality have also been emphasized.

Murray[58] commented upon the infantile character and the emotional immaturity of ulcerative colitis patients, emphasizing the intensity of their ties with their mothers, and conceptualizing diarrhea in the illness as an infantile response to fear. Alexander[1] has regarded the illness as a regression to the anal phase of psychosexual development, occurring in response to a life situation which the patient experiences as requiring the fulfillment of an obligation, or an accomplishment from him, for which he feels unprepared. However, Szasz[72] and Mary Cushing,[15] although acknowledging the association of the character structure of these patients with the anal period of development, have emphasized the orality of the disease. Szasz refers to the prominence of the gastrocolic reflex in ulcerative colitis patients and, on the basis of psychoanalytic studies, regards colonic and rectal hypo- and hyperactivity as most accurately correlated with changes in the patient's unconscious oral intaking tensions. Cushing refers to the way in which the importance of orality in the illness is frequently suggested by the patient himself in attributing the illness to some food or combination of foods. She reports the analysis of an ulcerative colitis patient whose "problem was to secure enough food, or prestige, or success, or whatever was necessary to at least put off the day when he could no longer meet the demands, when he could only fail and die."

The symbiotic character of the relationship between the patient and one parent, usually the mother, and the intense ambivalence felt by the patient toward that parent, has been observed repeatedly. The mothers of ulcerative colitis patients are frequently borderline or psychotic. Characteristically, they convey to the child the feeling that they will take care of him in every way, that they will always assume all responsibilities for him, and that they will always be able to direct him. Sperling[67] has stressed the contradictory attitude of the mother, unconsciously seeking the maintenance of a lifelong dependence on her for the gratification of her own needs, and, at the same time, having strong unconscious destructive impulses toward the child. She regards ulcerative colitis as a somatic expression of an unconscious rage reaction occurring in response to the frustration accompanying the loss of the mother or a change in the relationship with her. Lindemann[41] has also emphasized the loss of a person important to the patient in ulcerative colitis, and has commented on the depression evident in these patients. Daniels[16, 19] noted the frequent presence of a fixation upon the mother among ulcerative colitis patients, and has described the crises which frequently precipitate colitis attacks as occurring when the patient cannot cope with forward steps in the process of emotional maturation, including engagement, marriage, and childbearing.

In the clinical course of ulcerative colitis, the alternation between active colitis and the appearance of other symptoms or illnesses has been commented upon frequently. Although some degree of depression is usually evident during active colitis, Grace *et al.*[33] have described the appearance of a psychotic depression as heralding the end of the colitis attack. However, the development of a paranoid psychosis in ulcerative colitis patients has been observed more frequently.[1, 19, 41, 42, 67] Engel[27] describes headache as the most common alternative symptom experienced by colitis patients. He observed fifty-six headache periods during the therapy of nine patients. Headaches occurred when the patients felt conscious or unconscious guilt after having taken an active stand, made a decision, thought something through, or felt themselves to be in control. In these instances the patients did not feel helpless or afraid, and others often commented on their

Downloaded from www.psychosomaticmedicine.org

unusual assertiveness which presented a striking contrast with their passive, helpless attitudes prior to their colitis attacks. The occurrence of a headache during an episode of colitis was often found to mark the end of the attack. Engel's work is particularly important in its correlation of different affective states, or configurations of attitudes, in the same patient with different somatic responses, the feeling of helplessness being associated with ulcerative colitis.

The psychophysiological mechanisms involved in the development of ulcerative colitis remain unclarified. Sullivan[69, 70] emphasized the effects of the liquid contents of the small intestine being carried down into the colon as a consequence of an emotionally induced hypermotility of the bowel. He postulated that the enzymes in this liquid may be of a higher digestive power than the normal, or that the natural protective powers of the colonic mucosa may be lowered, leading to a digestion of the mucosal surface of the colon, thus facilitating bacterial invasion and acute ulceration. Portis[63] has emphasized the damaging action of the enzyme lysozyme upon the colonic mucosa by depriving it of its protective mucin. Hiatt *et al.*,[36] however, consider the high concentration of lysozyme in the stools of ulcerative colitis patients to be a result of the inflammatory response rather than its cause, the invading granulocytes being the primary source of the increased lysozyme in the stools. Lium[43, 44, 45] and Groen[34] regard the prolonged spasm of the muscles of the colon, resulting from chronic anxiety, as responsible for ischemia of the colonic mucosa and the appearance of necrosis of the epithelium from which bleeding occurs on the relaxation of these muscles. Grace, Wolf, and Wolff[28] emphasize the association of sustained hyperfunction of the colon in its vascularity, motility, and secretion, resulting in increased fragility of the colonic mucosa with submucosal bleeding and ulceration. They view ulcerative colitis as part of a pattern of ejection unconsciously elaborated by the patient in response to overwhelming environmental demands, with the choice of the colon as the site for the expression of this response pattern constitutionally determined. Sperling[67, 68] views ulcerative colitis as an illness in which conversion mechanisms are operative, its symptoms representing the struggle against the incorporation of the frustrating maternal object and the effort to destroy and eliminate her. Engel[24, 26] and others, however, have questioned the possibility that conversion mechanisms can involve such functional divisions as the mucosal surface of the colon. Although the psychological phenomenology of the illness may include the conflicts described by Sperling, which have been confirmed by others, the illness is perhaps better described as a physiological expression of emotions rather than a conversion phenomenon. Engel believes that the tissue process in ulcerative colitis is nonspecific, associated with a separation reaction but having no primary psychological meaning. When separation is not or cannot be dealt with by psychological mechanisms, physiological changes are initiated in the body which interfere with other adaptive or integrative processes, permitting various types of tissue breakdown, local tissue-growth disturbances, and bacterial and viral invasion. Biological and psychological developmental factors will contribute to the determination of the bowel as the site of the tissue breakdown.

The psychiatrist must recognize the difficult problems involved in the medical management of ulcerative colitis. Although psychotherapeutic intervention may be effective in halting even a fulminating attack, the life-threatening nature and quixotic behavior of this disease requires that the patient be supervised by physicians familiar with its intricacies. A decision to stop all feeding by mouth, to use steroids, to put the bowel to rest via ileostomy, or that the time has come for a colectomy, must reside in experienced hands. However, colectomy is generally considered indicated when the bowel has been transformed by the disease process into a tube with no mucosal surface or with the occurrence of polyposis. Surgical intervention of this order requires careful discussion with the patient in preparation for its consequences, particularly explaining the necessity for and the problems attending a stoma. In psychotherapeutic work with the

Downloaded from www.dbraulibrary.org.in

ulcerative colitis patient, an alertness to his experiencing feelings of loss and helplessness is particularly important. Such feelings may be evoked by an actual object loss, by an imagined or real slight or neglect from a person important to him, or by an event or even a comment understood as requiring that he take more responsibility or that he make a decision. The patient tends to respond well when he has the feeling that someone is in firm, understanding control, and to respond with an exacerbation of symptoms when strong support of this kind is not available or is threatened. The therapist most likely to work effectively with these patients when they are acutely sick is often characterized as willing to "take over," to take the patient and his situation firmly in hand, in contrast to the therapist who avoids directing the patient, or who limits himself to offering suggestions rather than providing firm control. Clearly, work with such a patient is extraordinarily demanding of the physician, requiring that he permit or even encourage an unusual degree of dependency, and that he devote himself to freeing the patient from responsibilities and from any need to make decisions. In addition, other psychotherapeutic measures of an unusual character are often required in the effort to ward off a colitis attack, or during an acute exacerbation.

In the initial phases of treatment it is often expedient to let the patient blame other people for his problems and difficulties, because the intensity of the patient's guilt feelings may otherwise provoke the use of psychotic mechanisms. In undertaking work with the acutely ill ulcerative colitis patient, the physician should be prepared to continue with him through periods of severe depression, of psychosis, and of crippling symptom exacerbations. The offering of extreme support of this kind, in combination with the effort to help the patient abreact feelings associated with their characteristic mourning reaction, is often required in the acute phases of the illness. The recognition of the necessity for these patients to work through their extraordinarily infantile dependency needs led Margolin[52] to attempt "anaclitic therapy" with them. This consisted in fostering their infantilization and then, in the course of treatment, trying to help them achieve a more mature reorganization. Others have stressed, however, that such measures can create more difficulties rather than lead to an improvement in the level of personality organization.

When the illness is relatively quiescent, a more conventional approach in psychotherapy is possible, and the treatment modifications useful in trying to bring an attack to an end, or to avoid an exacerbation of the illness, are not required. The goal of therapy may then be to help the patient make adjustments in his life situation which will enable him to keep his illness under reasonable control. The patient's dependency problems, his indecisiveness, his ambivalent feelings toward the mother, and his crumbling in the face of responsibility are areas of particular importance in this phase of treatment. Sperling[68] reports that her experience with ulcerative colitis patients does not support the contention that psychoanalytic treatment involves the risk of precipitating a psychotic break. She has found it possible to analyze their defenses without undue fear that they will be overwhelmed by the impulses against which these defenses were erected. The use of adrenocorticotrophic hormone has facilitated efforts at intensive psychotherapeutic work by permitting the control of acute toxic exacerbations, and the ataraxics have contributed to the patients' ability to handle anxiety better, often tiding them over crises which would otherwise disrupt treatment.

CHAPTER 35

# PSYCHOPHYSIOLOGIC ASPECTS OF RESPIRATORY DISORDERS

Eric D. Wittkower
Kerr L. White

Downloaded from www.dbraulibrary.org.in

RESPIRATION is the only essential bodily activity under both voluntary and involuntary control. Its initiation at birth marks not the beginning of life but the beginning of the infant's independent life apart from the aquatic confines of the mother's uterus; it is the only instinctual process for which the infant does not require help from another person. The primary physiologic functions of respiration are the exchange of atmospheric oxygen for surplus carbon dioxide in the venous blood of the pulmonary capillaries and participation in the vernier adjustment of acid-base balance. Like the skin, their predecessor phylogenetically as a respiratory organ, the lungs constitute barriers which regulate with exquisite sensitivity a continuous sequence of transactions between the individual and his environment, and in all their activities they are associated intimately with a wide spectrum of emotional responses. Laughing, crying, sighing, pain, anger, fear, and sexual excitement have respiratory and emotional components which are inseparable. Talking, with its variations in pitch, inflection, and volume, may be an important respiratory expression of feeling states. Finally, contemplation of physical activity, particularly in the presence of real or imagined danger, is known to be associated with increased respiratory activity in anticipation of increased metabolic needs.

The respiratory system has three closely integrated components, (1) a distributing system which extends from the mouth and nares to the bronchioles, (2) a musculoskeletal system protecting and operating the respiratory bellows, and (3) an extensive equilibrating system extending from the bronchioles to the alveoli where perfusion with venous blood and diffusion of gases takes place.[27] The primary control of respiration is divided between an inspiratory center in the ventral reticular formation and an expiratory center in the dorsal reticular matter. The former appears to be

the dominant center.[72] A basic postural tone of the respiratory musculoskeletal apparatus and inherent rhythmicity of respiration may originate in the respiratory centers[48] or may be partially subservient to a "pneumotaxic center" in the pons.[73] The latter probably receives afferent stimuli from the hypothalamus and the inspiratory center and contributes, together with impulses initiated by inflation of the lungs and mediated through the vagi (Hering-Breuer reflex) to the regulation of the inspiratory and expiratory phases of respiration. In addition to the stretching of the lungs during inspiration and the discharge of stimuli along the afferent pathways of the vagi, the respiratory center is directly responsive to metabolic demands mediated through changes in carbon dioxide tension and hydrogen-ion concentration, and indirectly responsive to changes in oxygen tension mediated through chemoreceptors in the carotid bodies and the arch of the aorta. Primary anatomic changes in the thoracic cage and in the lung parenchyma with consequent limitations to adequate diffusion of gases or perfusion of blood are reflected in alterations in carbon dioxide tension, hydrogen-ion concentration, or oxygen tension.

From the viewpoint of the present chapter, there seems ample evidence to indicate that the respiratory centers may also be readily influenced by stimuli from cortical and subcortical centers. The precise relationships have not been established clearly, but there is good evidence that medial and ventral cortical structures, perhaps via septal and hypothalamic areas, represent one possible pathway.[58] Changes in bronchiolar regulation of the gas distributing system and in the cardiac and vascular regulation of the perfusing system also may have their origins in the central nervous system as physiologic concomitants of emotion.[11, 13]

In addition to anatomic, physiologic, and behavioral links between emotional responses and respiratory activity, there are phylogenetic considerations which further suggest these intimate associations. On the basis of a clinical study of 100 patients, Harper[42, 43] has postulated the existence of a relatively "primitive" type of nervous system characterized by the coexistence of emotional lability, or "functional" nervous illness, allergic tendencies, and evidence of atavism in the form of pigmented nevi or supernumerary nipples. Support for this association is found in the observation that amphibians use both their skins and lungs for respiration, that coordination of the two is mediated through the nervous system, and that histologically the pigmented mole is a vestigial sensory organ, having a common phylogenetic origin with the cutaneous tactile organs of amphibians. Finally, the vagus nerves which conduct impulses resulting in bronchiolar constriction are embryologically composite nerves representing components to several of the branchial arches in aquatic vertebrates.

Clausen[13] has reviewed the numerous studies of respiratory patterns in relation to emotional states, mental disease, and levels of consciousness, and concludes that, with one or two exceptions, specific correlations are poor. The exceptions include demonstration of the rapid inspiration accompanying surprise and the rapid, shallow respiration accompanying pleasure, and Christie's[12] and Finesinger's[28] demonstration of the sighing, irregular respirations which frequently accompany anxiety and which may be interpreted by the patient as breathlessness.

## ¶ Breath-Holding Attacks

This common condition probably is more alarming than dangerous, but it warrants correct diagnosis and effective understanding at an early stage in order that potentially more serious behavior problems and possible damage from recurrent cerebral anoxia[77] may be prevented. Breath-holding attacks are characteristically a disorder of childhood, usually starting during the first two years of life and occasionally in the first few weeks of life before conscious mechanisms have developed. They customarily disappear spontaneously with the cessation of violent crying between the ages of four and six. However, accounts of voluntary death by breath-holding in adults have been reported.[17] The attacks are more fre-

Download from www.dbraulibrary.com

quently seen in tense, energetic, hyperkinetic children than in placid, hypotonic children. Both sexes are affected equally, and attacks are apparently rare among Negro children and more frequent among mentally retarded children.

The onset of each attack is usually associated with a physically or psychologically traumatic or frustrating event, often of minor character, to which the child reacts with disproportionate rage and violent crying. The latter, in turn, terminates abruptly in expiratory apnea. The position assumed is of interest, since it is the opposite of the inspiratory apnea and controlled expiration employed by the underwater swimmer and the patient with bronchial asthma. The apnea is followed by deep cyanosis, frequently by unconsciousness. Recovery from the attack is spontaneous.

Useful differentiating features in breath-holding attacks include the ready identification of the precipitating experience, the occurrence of crying and cyanosis before any convulsion, the limitation of the latter to the tonic phase, the presence of opisthotonos, and the finding of a normal electroencephalogram. According to Bridge, Livingston, and Tietze,[10] the incidence of epilepsy associated with this syndrome is no greater than in the general population. Other conditions to be differentiated from breath-holding attacks are laryngeal stridor, laryngospasm associated with tetany, and pertussis. In Kanner's series,[54] severe breath holding had developed in 10 per cent of patients following apneic experiences related to whooping cough.

The breath-holding attacks may be only one of several indications that the parent-child relationship is seriously disturbed. In Kanner's [51] experience the parents often are found to be overprotective, and the children are found to be resisting tense, rigid feeding schedules or premature toilet training. Hinman and Dickey[47] have reviewed the problem in detail and conclude that breath-holding spells are the concomitant of rage which is so overwhelming that self-control is lost and that basically they may be regarded as a reaction to feelings of deprivation and inadequacy.

Anticonvulsant therapy is of no avail for the treatment of breath-holding attacks and may be harmful. Careful psychological evaluation of the patient in relation to his family is important, particularly with regard to the manner in which anger and frustration are understood and handled by the parents in an attempt to prevent future behavioral disturbances such as temper tantrums. Clarification of the underlying sources of parent-child conflict, and therapy directed toward improving the parents' own emotional adjustments is usually essential.

## ¶ The Hyperventilation Syndrome

The hyperventilation syndrome is a common condition which has been diagnosed in as many as 10 per cent of a series of 1,000 consecutive ambulant patients.[78] Although primarily a pulmonary expression of emotional conflict, respiratory distress is rarely the chief complaint. In Ames's[2] carefully studied series of 40 patients, 15 denied any respiratory difficulties, 24 had some respiratory difficulty, and only 1 patient indicated this as the main problem. About half the patients present only what they believe to be cardiovascular symptoms,[2,61] and about 20 per cent have cerebral symptoms including "fainting," "black-outs," "feelings of unreality," and loss of inhibition. Some patients have musculoskeletal and peripheral neurological symptoms, and a few have gastrointestinal complaints. They usually have hysterical character structures,[21,31] and fear or anger are apt to be the dominant emotions precipitating the hyperventilation attack. The sources of conflict may be acute and transient, but more often they are deep-seated, chronic, and require prolonged psychotherapy.

Family physicians, internists, and neurologists are most apt to see these patients first; a careful historical review of the circumstances preceding and accompanying the attack and an evaluation of the patient's character structure together with a diagnostic trial of hyperventilation by the patient usually clarify the diagnosis. It is important, however, to realize that hyperventilation may be of two types, (1) deep, fairly rapid breathing with the mouth open—the commonest form—and (2) very fast shallow breathing, or panting.

The physiologic changes which accompany

Downloaded from www.drsulibrary.org.in

hyperventilation explain adequately most of the signs and symptoms. Following a few seconds of overbreathing, the alveolar carbon dioxide tension falls, and the resulting alkalosis produces cerebral vasoconstriction, electroencephalographic changes, and a mean decrease in cerebral blood flow of 33 per cent during active hyperventilation.[56] The peripheral vasoconstriction which is responsible for the characteristic findings of sweating, pallor, and cold extremities is probably mediated through sympathetic pathways, although the afferent path of the reflex is not known.[2] Varying degrees of tetany are observed in response to the diminution in ionized calcium secondary to the alkalosis. There is impairment in the process of nerve "accommodation," and spontaneous impulses arising in the ischemic cerebral cortex traverse sensory and motor nerves to produce characteristic paresthesias and, in the presence of associated neuromuscular irritability, tetany.[60] Peripheral vasoconstriction may also contribute to these phenomena. Precordial pain and diaphragmatic spasm often accompany the increased respiratory effort and are thought to be primarily musculoskeletal phenomena, but the former may also be associated with aerophagy and distention of the stomach. Electrocardiographic changes, which include lowering of S-T segments, inversion of T waves, and premature contractions, may accompany hyperventilation in response to constriction of coronary arteries, changes in the position of the heart, or tachycardia. Finally, the cerebral vasoconstriction of chronic hyperventilation when associated with loss of inhibition may account for certain behavioral changes, in addition to the underlying anxiety which is the dominant factor in initiating the whole process and its subsequent vicious cycle.[2, 61]

Treatment of this condition is best initiated by explaining to the patient the physiologic mechanism of his symptoms, by demonstrating their origin during voluntary hyperventilation, by having the patient rebreathe carbon dioxide from a paper bag held over the mouth and nose, and by the use of relaxation and breathing exercises under the direction of a physiotherapist. Much relief is usually afforded patients by these maneuvers and demonstrations, and the physician is then able to direct his major attention to uncovering the sources of the underlying anxiety.

## ¶ Respiratory Allergy

Bronchial asthma and vasomotor rhinitis usually have been regarded as psychosomatic disorders in the psychiatric literature, often without critical evaluation of *all* the data relating to the influences of various factors or to the physiologic mechanism through which emotional responses participate. The present brief account of these conditions is an attempt to understand the psychological problems in terms of the other elements which participate in the whole disease process.

### *The Allergic Diathesis*

Allergy, or "altered force," is a term introduced by von Pirquet[96] to describe an acquired, specific, altered capacity of the tissues to react which is characteristic of a wide spectrum of disease processes in which interaction between antigens and antibodies is believed to be an important, but not an unequivocally essential, feature. Most of the interest of the allergist and the immunologist has been focused on this important mechanism.[36, 40] Another point of view is that of the pathologist who describes the final local tissue changes responsible for the patient's symptoms. These consist of several of the following phenomena: dilatation of small blood vessels, increased capillary permeability, edema, a cellular response dominated by lymphocytes and eosinophils, contraction of smooth muscles, hyalin degeneration, and secretion of mucus. Finally, there is the viewpoint of the physiologist who is concerned with the pathogenesis of the process and those factors which permit, facilitate, perpetuate, or inhibit the tissue responses. Interest in this area has centered on the roles of acetylcholine, histamine, 5-hydroxytryptamine, and adrenocortical steroids.[3, 14, 33, 34, 46, 82]

If local cellular injury is regarded as the primary anatomic lesion in the allergic diseases, it is quite compatible with available data to view the process as initiated either by

Downloaded from www.pdfbraulibrary.org.in

antigen-antibody reactions which trigger a protease activating system and the release of acetylcholine and histamine, or by stimuli arising in the cerebral cortex and hypothalamic nuclei which trigger the release of acetylcholine, histamine, and 5-hydroxytryptamine. Both mechanisms may operate simultaneously, and both may be modified by the conditioning influences of the adrenocortical hormones.[3,95]

Current concepts of the allergic diathesis and allergic phenomena do not as yet provide adequate explanations for all the problems concerned with localization and the variability of symptoms, the specificity of selected antigens, and the initiation and perpetuation of the whole process. Present evidence is quite compatible, however, with the view that there are "allergic" disorders in which the prime stimulus is an isolated local antigen-antibody interaction, and that there are other "allergic" disorders in which the prime stimulus is experienced in the cerebral cortex. It is also compatible with the view that summation and facilitation may occur when these and other mechanisms are involved concurrently.

### *Heredity*

The role of heredity in allergic disorders has not been clearly established; there is divergent evidence for its role and divergent interpretation of the data.[9] Schwartz[87] concludes that bronchial asthma, vasomotor rhinitis, and infantile eczema are probably related genetically and are different in this regard from other so-called allergic disorders. He concludes that asthma is probably inherited as a Mendelian dominant with failing manifestation, so that only 40 per cent of those who carry the genes ever develop symptoms. Ratner and Silberman[75] conclude from a review of Schwartz's[87] and other studies, as well as from data of their own, that the available evidence does not establish conclusively the theory that the capacity to become sensitized is controlled by genetic factors "within the scope of the antigen-antibody mechanisms." They emphasize, also, that the data do not support the hypothesis that a gene *does not* play *any* role in the production of the allergic state. From the data of Schwartz, they conclude that "what may be inherited is not the capacity to become sensitized, but a respiratory tract which may react with the production of asthma and rhinitis due to a multiplicity of stimuli."

Analysis of the detailed family histories of a small series of ten patients studied by the present authors lends support to the tentative hypothesis that a susceptible respiratory tract and a susceptible neurohumoral substrate may be the genetically determined elements rather than an "allergic" predisposition per se. In our series only unequivocal diagnoses in parents, aunts, uncles, and grandparents were included; the illnesses of the siblings were not included. It was found that strictly allergic disorders in the families of the patients were relatively infrequent in contrast to the frequent occurrences of definite, nonallergic, "psychosomatic" illnesses, that is, peptic ulcer, hypertension, rheumatoid arthritis, and thyrotoxicosis. In addition, the high incidence of fatal pulmonary disease, excluding bronchial asthma, suggested that the respiratory tract, as well as the autonomic nervous system, and neurohumoral regulatory mechanism, may be important areas in which to look for further genetic influences. Any adequate genetic study of bronchial asthma probably should not confine itself to the sole observation of "allergic" tendencies.

## Bronchial Asthma

It long has been recognized that emotional factors may play an important and frequently a dominant role in the onset and course of bronchial asthma, but the precise means by which these influences are related to cellular and molecular events is not understood as yet. The present discussion is based on a review of the literature, particularly the discussions of French and Alexander,[32] Saul,[85,86] and Dekker and Groen[15,16] and intensive medical and psychiatric observations by the authors and their colleagues on 10 patients with severe bronchial asthma.[98]

Downloaded from www.dbraulibrary.org.in

### *Psychological Factors*

Given an inherited substrate of uncertain composition but which may consist of a *locus minoris resistentiae* in the respiratory system and given relatively labile autonomic and endocrine regulatory mechanisms, it is a matter of importance, from the point of view of prevention and treatment, to understand what, if any, nuclear emotional conflicts and associated behavioral and personality patterns are associated with bronchial asthma. The precise role of psychological factors in the etiology of asthma is still an object of study. There is compelling evidence that at least some of the observed emotional conflicts and personality patterns are a response to the presence of a chronic disease, since a carefully matched series of asthmatic and cardiac children did not show significant personality differences on psychological testing.[71]

French and Alexander[32] commented on the disturbed mother-child relationships experienced by asthmatics and on the tendency of the fathers to be passive-dependent persons. Attitudes and feelings toward their parents were discussed with our patients, and the available parents were interviewed. All 10 patients expressed marked feelings of ambivalence toward their mothers; their overt and covert hostility toward their mothers appeared related to the fact that they had been, or at least felt that they had been, deprived of maternal love as children. Four of the mothers had died, and 3 patients had had marked exacerbations of their asthma which temporally and psychologically were related to the bereavement. Nine of the mothers were characterized by the patients as rigid, insecure, and domineering and were described as frequently hostile toward their children. The tenth mother had such a large family that the patient, as the oldest daughter, found herself assuming the role of a second mother for her siblings. Six mothers were described as overprotective in what may have been reaction-formations against their own rejecting impulses or hostile feelings toward their children. Seven mothers apparently showed anxiety and hostility in response to their children's asthma by excessive restrictions, exhortations to "stop wheezing," or by leaving their care to siblings, fathers, maids, etc. Seven of the fathers were apparently meek, passive, dependent, and ineffectual in their homes; the remaining three fathers had died while the patients were young and before asthma had developed. Four of the fathers, either because of their wives' deficiencies or their own needs, assumed the maternal roles, dispensing medicines, nursing the patients at night, and making decisions usually reserved for mothers. All 10 patients revealed by their attitudes, speech, dress, childhood behavior, and marital and occupational histories varying degrees of pseudo independence. This behavior appeared to represent overcompensation of dependent trends and could be related to (1) maternal rejection by a sick or inadequate mother, (2) inability of the normal mother to satisfy excessive dependent demands of the child, (3) maternal demands for premature independence, and (4) maternal overprotection.

There is no evidence to indicate whether or not asthmatics are born with excessive oral drives. However, this instinctual drive had become the focus for emotional conflicts and unusual somatic behavior in all our patients. Bulimia or anorexia before an attack, or relief from an attack while eating or by induced vomiting was noted in 6 patients. (The latter two phenomena may have had a physiological basis.) Three other patients experienced great concern about their capricious appetites, variable weights, and poor physiques. Moderate to marked ambivalence with respect to their smoking habits and attitudes, which often reflected parental edicts and guilt over oral drives, were expressed by 8 patients.

The oral cavity and respiratory tract seemed to represent a *locus minoris resistentiae* for all our patients: 8 had a history of oral surgery, injury, or serious respiratory illness during the day, week, or several months preceding the onset of bronchial asthma; 8 patients had had tonsillectomies, and 7 had had other oral injuries; 9 had had recurrent severe pulmonary infections, 7 had had pneumonia (3 more than once), and 4 had had pertussis; 8

Downloaded from www.utrahub.ir

had experienced morbid fears of tuberculosis, but none had had it.

### *Experiences with Water*

The high incidence, in asthmatics, of dreams utilizing water symbolism and suggesting intra-uterine fantasies and wishes has been noted by French and Alexander,[32] Saul,[85] and F. Deutsch.[20] In the light of these observations, a specific inquiry was made about attitudes and experiences of our patients involving water. All 10 patients had had frightening experiences with water and drowning, and in 9 instances these antedated the onset of asthma. Marked fears of immersion in water in 9 patients seemed to follow these experiences. For example, one patient's mother stated that he had reacted with severe fright when his father tried to force him to swim several months after birth; another patient had been repeatedly threatened with drowning if enuresis did not stop; a third lost her closest sister in a mysterious drowning and shortly thereafter developed asthma; a fourth almost drowned when chased in the water by a vicious dog; and a fifth was forbidden to swim after his cousin "nearly drowned."

Although carefully controlled studies are necessary to establish the significance of such experiences, two tentative interpretations of these data seem possible: (1) The reality experiences of water as a destructive or hostile force initiated the fears in susceptible individuals, or (2) the experiences reactivated preexisting unconscious conflicts relating to the patient's intense wish for reunion with the mother as reflected in the intra-uterine fantasies and water symbolism described by French and Alexander.[32]

### *Observations on Endocrine Responses*

Funkenstein[34] has described the autonomic lability and failure of asthmatics to respond to Mecholyl in stressful situations. Previous endocrine studies[95] differentiated the older intrinsic asthmatics with low excretion of 17-ketosteroids and 17-hydroxycorticoids, which increase to normal or slightly higher levels with ACTH treatment, from the younger extrinsic asthmatics with normal 17-ketosteroids and 17-hydroxycorticoids and a moderate to marked rise with ACTH treatment. Of our patients with long-standing primarily "allergic" extrinsic asthma, 3 had low normal 17-ketosteroids and 17-hydroxycorticoids which changed little with treatment, and 3 patients with long-standing asthma, in which emotional factors predominated, were observed to have wide mood swings and at times had substituted depressive reactions for asthma. Both 17-ketosteroids and 17-hydroxycorticoids were high normal initially in this group, and, with treatment, the 17-ketosteroids rose markedly, but there was little change in the 17-hydroxycorticoids. One of these patients, on leaving the hospital, had a severe panic reaction, lost his asthma, developed a psychotic depression, and, without any treatment, excreted the extraordinarily high 17-ketosteroid value of 140 mg. in twenty-four hours. Similar rapid shifts between asthma and psychotic states have been observed by Funkenstein[33] and Sabbath and Lucc,[83] although the careful work of Knapp *et al.*[58] suggests that a simple reciprocal relationship is unlikely. Another patient of the authors', with infectious asthma of only eight months' duration, had a strong emotional component in her illness and excreted low initial amounts of both steroids which increased to very high levels with only two doses of ACTH.

These limited observations invite further inquiry into the relationship between emotional factors in asthma and the conditioning influence of adrenocortical activity. The problem seems more complex than that of differentiating intrinsic from extrinsic forms of asthma.

### *Psychodynamic Considerations*

There is general agreement among psychoanalytic writers that many patients with severe asthma (1) have an inordinate need for their mother's love, (2) that their attitude to their mothers is ambivalent, and (3) that they are afraid of "losing" their mothers or of "destroying" them. There is less agreement about the determinants of the regressive level of psychological defenses and of symptom choice. The

Downloaded from www.psychosomaticmedicine.org

asthmatic attack may represent an affect concomitant and specifically a repressed cry for the mother's help in response to separation anxiety, as French and Alexander[32] have proposed. This phenomenon seemed important in 2 of our patients, probable in 5, and unimportant in 3. Of our patients, 5 noted relief from asthma with crying, but this may have been related either to the expression of depressive feelings or to the physiological relief associated with the act of crying.

French and Alexander[32] discuss the asthmatic's undue fear of incurring his mother's disapproval, of losing her love, and of activating his underlying separation anxiety. These may occur in a variety of ways, for example, by display of sibling rivalry, by sexual temptation, as well as by real or threatened loss of the mother or a mother surrogate. The guilt experienced by patients in response to their real or fantasied transgressions is further supported by the observation that patients with severe asthma may have a great need to confess and to bring about a reconciliation. Of our patients, 8 had experienced attacks of asthma during sexual excitation; physical activity and increased respiration were not the complete explanation for the episodes, since these particular asthmatic attacks occurred as a very early concomitant of sexual excitement. One patient insisted that she consciously facilitated, if she did not induce, asthmatic attacks to ward off what she interpreted as "alarming" sexual advances by her fiancé, her attitudes toward sex having been conditioned by a mother who repeatedly denounced intercourse as "dirty," "messy," and "sinful."

An alternative interpretation proposes that asthma may constitute an expression of a conflict arising from the unconscious wish to return to the state of intra-uterine union with the mother where independent respiration was not experienced and the infant lived an aquatic existence in the protecting confines of the mother.[35] One of our patients spontaneously spoke of her disgust and anger at the thought of having once been a part of her mother in the uterus. As in the other hypothesis, from a psychodynamic viewpoint the "goal" is union and the "object" is mother. However, the evidence in support of this explanation lies largely in the intra-uterine dreams, children's fantasies,[52] and water symbolism observed by some students of the problem. Saul[86] has reviewed this evidence and concludes that the deep dependent longings, based on intra-uterine fantasies observed in patients with respiratory disorders, may be contrasted to the regressive oral dependent needs of individuals prone to develop gastrointestinal diseases.

Fenichel[25] has suggested that asthma may represent an unconscious attempt by the patient, on a regressive basis, to protect himself permanently and omnipotently from loss of maternal love by respiratory introjection of the ambivalently regarded mother. Fenichel's theory is complementary to Saul's. According to both theories, the aim of the asthmatic patient is to be united with the mother—projectively (Saul), or introjectively (Fenichel). But the patient rejects his wish (which is alien to his adult self), and he rejects the negative aspects of the mother, that is, the mother who has deprived him of love. The mother is then both a loved and a hated object, and the asthmatic seeks to retain the "good" mother and rid himself of the "bad" mother. In effect, the patient's unconscious attitude may be verbalized as follows: "I want to be united with my mother, to be unborn, to hold my breath, to die, but I also want to live an independent life, free from my inhibiting mother, to breathe freely and safely and reject my infantile trends."

Material obtained from several of our patients by interview suggested the presence of introjective mechanisms and of conflicts over introjective trends. One patient felt that his dead (maternal) father was part of himself; another seemed to internalize her coughing, consumptive mother, who was "just a little tot," and in turn she behaved like a "little tot," working in the protecting environment of physicians' homes selflessly looking after "little tots." A third patient assumed the inhibiting, rigid attitudes of his overprotective mother, but was overtly hostile toward her. A fourth internalized the strict, obsessive attitudes of her mother, but, following the latter's death, she attempted to emancipate herself by defying

Downloaded from www.brainlibrary.org

maternal injunctions, rearranging furniture, walking on the carefully polished floor, and taking a lively vacation. In this setting she developed asthma. A fifth patient developed asthma after the dramatic drowning of a sister who was regarded ambivalently and who played a maternal role for the patient. Where interviews with the mothers were possible, the patients' hostile distortions were often found to be of such proportions as to suggest projective mechanisms. Finally, there is the problem of explaining the association of the respiratory tract with the psychological mechanism of introjection. Fenichel[25] suggests that the physiological concomitant of "respiratory introjection" is smelling, in which a "particle" of the external world may be regarded "as taken into the body." This association is most meaningful in asthmatics with a predominantly anal-sadistic orientation.

Sadistic impulses directed against the deserting (hated and yet badly needed) mother, and feelings of guilt and of anxiety arising from them date back to early infancy. From this point of view it matters little whether the patient was, felt, or expected to be deserted. In this connection, reference may be made to F. Deutsch's suggestion[20] that the onset of asthma may be related to the concurrent disturbance in infancy of a somatic respiratory disorder and a major emotional conflict. In 8 of our patients, such a relationship seemed probable. Dekker and Groen[15] have demonstrated clearly, in an experimental setting, the reproducibility of "psychogenic" asthma in patients who are also sensitive to specific allergens. The role of conditioning in the production of "psychogenic" asthma is well-supported by the work of Dekker, Pelser, and Groen.[16]

### *Formulation and Speculation*

Available evidence is compatible with this formulation: The individual with constitutional autonomic and endocrine lability, possibly genetically determined, and with a respiratory tract prone to dysfunction on a genetic or acquired basis, who also possesses intense oral drives, either inherited or acquired, that bring him into conflict with an "unsatisfactory" mother to the extent that she is unable to satisfy normal demands or is a relatively "normal" mother unable to satisfy excessive demands, attempts to protect himself from separation anxiety by respiratory introjection and projection in psychodynamic terms and by ostentatious pseudo independence on a behavioral level.

Undue emphasis on any specific factor, such as constitutional, autonomic and endocrine lability, allergy, inherited or acquired proneness of the respiratory tract to dysfunction, or psychogenesis, fails to do justice to the complexity of the problem. There is good reason to believe that a combination of these factors, or more precisely, a constellation of these factors with varying preponderance of one or the other, accounts for the etiology of asthma. As far as the psychological parameter is concerned, the presence of deep-seated oral-respiratory conflicts arising from the child-mother relationship appears probable. In the deep layers of his mind, not infrequently hidden by defensive psychological structures, the asthmatic unduly longs for his mother's love. In view of his intense longings for the mother's love, the asthmatic responds to any situation which entails actual or potential loss of the mother, or which imperils the good relationship to the mother, with anxiety which is perceived and experienced as oppression and suffocation. The mother, her love, and her good will are essential to the asthmatic just as is air.

Oral surgery, respiratory infections, allergens, a traumatic water experience, actual separation or fear of being deserted may all activate the patient's unconscious conflicts and overdetermine the respiratory tract as the organ for the somatic expression of hypersensitivity to an expanding spectrum of stimuli. Once the final common pathway is established, it becomes the organ of expression for a wide variety of internal and external influences.

## ¶ Vasomotor Rhinitis

Seasonal allergic rhinitis (hay fever) is such a common complaint in contemporary North American society that one must look for caus-

Downloaded from www.psychosomaticmedicine.org

ative influences which are equally widespread. With respect to the allergenic factor, the pollens of ragweed grass and of trees are the most prominent offending agents in North America. Nonseasonal allergic rhinitis is frequently associated with dust, animal danders, drugs, cosmetics, and local foci of infection in the sinuses or teeth. The presence of psychologic factors is suggested in the findings of an early personality study of hay fever patients, whose dominant characteristics were noted to be self-absorption, dreaminess, and overweening ambition, in contrast to a control group of patients with fractures or appendectomies.[103] Although this study confirmed independently the findings of others, it probably represents an oversimplification of the problem on the level of personality. It is conceivable also that there are some cultural and social factors, with their emotional sequelae, which are sufficiently widespread to influence all of the many varieties of patients who develop this condition, but as yet these factors have not been identified. The precise role of psychologic factors has not been established as clearly as the role of allergens.

In perennial vasomotor rhinitis, as distinct from the first two entities, emotional factors probably play a dominant role. These patients develop nasal obstruction, rhinorrhea, and sneezing associated with the cellular changes described previously. Such changes, although possibly related to alterations in barometric pressure, humidity, and temperature, also frequently are related to emotional responses associated with conflict and stressful life situations. From a phylogenetic standpoint, the nose is a sexual organ, and anatomically the tissue around the nasal turbinates is erectile tissue innervated by cervical sympathetic fibers from the superior cervical and sphenoidal ganglia. Nasal hypersensitivity accompanies menstruation, pregnancy, and erotic activity to minor degrees but becomes magnified and produces symptoms when conflicts are associated with these functions.[70] Situations associated with feelings of humiliation, frustration, and resentment were found by Holmes and his colleagues[49] to produce marked swelling of the turbinates, mucus secretion, and obstruction. They further interpreted their data as suggesting that the nasal turbinates responded similarly to a variety of noxious or threatening "agents" (pollens, dusts, odors, persons, and situations) in attempts to "shut" them out defensively.

From evidence obtained during the analysis of 7 patients with hay fever, Wilson[100] suggested the importance of repressed olfactory sexual curiosity. He concluded:

> The interplay between these inner conflicts, attempts at their solution, and the external agents (specific pollen allergens) which precipitated the actual hay fever attack remains unknown. Either a specific constitutional hyperosmia leads to the sense of smell as a regressive solution to dangerous curiosity or the regression itself produced the hyperosmia and nasal sensitivity to pollen. The physiological principle relative to summation of external and internal stimuli may solve the problem of the interaction of physiological and allergic factors in hay fever. Patients who, as a result of their psychosexual development have substituted olfactory for visual sexual curiosity may, because of this, become more sensitive to pollens.

Wilson's formulation includes the possibility of cases of hay fever in which local sensitivity alone, in the absence of psychological stimuli, may precipitate an attack, and other instances in which emotional factors alone may produce an attack. Most cases probably involve varying proportions of both these elements as well as others, and in rhinitis of any form the importance of summation of stimuli should be recognized in the production of symptoms.

## The Common Cold

The widespread prevalence of the common cold and its social acceptability as an "organic" disease have tended to focus interest on the search for the specific disease agents involved to the exclusion of other environmental and host factors. Much progress has been made in isolating the one or more viruses believed to be associated with the common cold,[4] but the presence of a virus alone does not explain many of the epidemiologic observations, the variations in susceptibility of individuals to colds, or the precise temporal and environmen-

Downloaded from www.brainlibrary.org.in

tal circumstances attending the onset of a specific cold. For example, only about half the individuals "challenged" at any one time with infected nasal secretions develop symptoms, and this variation in susceptibility is apparently uninfluenced by the season of the year, length of time since the most recent cold, or by chilling of the environment, although changes in humidity may play some role in altering the permeability of the nasal mucosa.[87] It is probable that other environmental factors affect the virulence of the challenging dose, as well as the characteristics of the nasal and pharyngeal mucosa, but, as in the allergic disorders, particularly vasomotor rhinitis, it also seems probable that emotional stimuli, transmitted over autonomic pathways and perhaps conditioned by similarly activated humoral agents, can also alter the permeability of the mucosa or modify immune responses so that specific viral agents may invade the tissues.[90]

Data about emotional factors in relation to the common cold are scarce. Despert,[19] in a carefully documented study, observed 63 children in a nursery school during several school years. In a group of 8 of these children from broken homes, the mean total of absences for colds, calculated as a per cent of the possible days of school attendance, was 19 per cent, in contrast to 9 per cent for a group of 8 "well-adjusted" children from especially "happy" homes. When all 63 children were considered, the highest ratios of absences due to colds were found among the first group of 8 and among children with other obvious emotional stresses. There were also a few children free of such stresses in this group, and there were other children who had emotional problems but were relatively free from colds. The data do not prove that children from unhappy homes *have* colds more often than those from happy homes, only that the former are absent from school more.

In another study, Richter[79] reported emotional disturbances of rather severe degree following respiratory infections in children. He observed periods of apathy and depression which could not be attributed to any infectious process such as to the postinfluenzal depressive reactions which are believed to be associated with a transient encephalitis. The children all tended to show ready obedience, marked dependence, and subservience, were meticulous in their habits and dress, and carefully avoided quarrels or a display of anger. This behavior was interpreted as reflecting deep-seated conflicts related to aggression.

Menninger[68] reported psychoanalytic observations on a patient of forty who had had only four colds in her life and who, in the absence of an epidemic but while working out important conflicts in her analysis, developed a severe cold with an associated herpetic lesion. Similarly, Wilson[99] reported analytic data about a patient who expressed upwardly displaced anal-sadistic trends in speech and particularly in the form of obscene words. When passive homosexual tendencies were stirred up during analysis, the patient had to repress his impulse to "attack" back vocally and developed acute laryngitis with aphonia. Saul[84] reported psychoanalytical observations on 9 patients who, in situations resulting in frustration and strong, usually unconscious, receptive, dependent demands, and in varying degrees of repressed rage, developed colds, pharyngitis, and laryngitis. As he points out, this observation is by no means specific for the common cold, nor does it preclude the operation of the other important elements (infectious agents, allergens, and changes in temperature, humidity, and barometric pressure) alone or in combination. The data available suggest a fruitful area for more intensive investigation into the causes of this common though trivial disorder.

## Smoking, Chronic Smoker's Syndrome, and Emphysema

Social and cultural pressures to conform are probably important in initiating the smoking habit, and nicotine, by means of physiological addiction, perpetuates the habit once acquired.[29] Emotional factors probably determine the amount of smoking and many of the occasions for excessive smoking as well as certain forms of compulsive smoking. Bergler[7] reported 5 cases of compulsive smokers, all of whom showed similar neurotic substrates. He found them to be masochists who wanted

Downloaded from www.psychosomaticmedicine.org

constantly to be refused. "To offset this inner reproach which objected to the wish 'to be refused' they 'proved' that they wanted the opposite, i.e., 'to get'." In Bergler's view, the outward sign was an oral "pacifier"—a cigarette. "Psychological drives combine with the pharmacological to explain the addiction. When tobacco was forbidden these patients they appeared to behave in a predictable fashion. They tended to feel unjustly treated and reacted with pseudo-aggression, perhaps toward a wife, or later the environment, in a rather childish fashion."

The deleterious effects and even potentially self-destructive implications of long-term excessive smoking are now a matter of public knowledge. Apart from the possible causative role of excessive smoking in the pathogenesis of carcinoma of the lung, coronary artery disease, and peripheral vascular disease, it is associated frequently with a syndrome characterized by chronic cough, dyspnea, wheezing, chest pains, and a tendency to frequent respiratory infections.[97] In its earlier stages it is a reversible disorder associated with excessive smoking and the emotional tension underlying this. Still another concomitant of excessive smoking is emphysema which, unfortunately, is often irreversible when first seen by the physician. The well-documented association between emphysema and peptic ulcer is of more than passing interest.[63] Physiological factors such as increased secretion of hydrochloric acid and anoxia associated with the smoking and emphysema are undoubtedly important, but the strong probability remains that emotional factors related to unconscious conflicts may also be important in the association of these two pathological conditions.

## ¶ Bronchitis, Bronchiectasis, and Pneumonia

"Stress bronchitis" in children[66] has been described clinically but not studied systematically. Alteration in the size of the bronchial lumen in response to emotional stimuli has been observed at bronchoscopy,[22,23] and variations in the secretion of bronchial mucus during periods of life stress were reported by Stevenson and Wolff[92] and Stevenson.[91] In the authors' experience, pneumonia, both bacterial and viral, in adults, is frequently preceded by periods of emotional strain and accompanying depression which develop over a period of several weeks and reach maximal proportions several days before the acute pulmonary symptoms develop. Although the presence of an identifiable bacterial or viral pathogen makes this element certain among the causal factors in any infectious disease, its presence does not necessarily afford a complete explanation for the occurrence of a clinical disease at a particular time, nor does it explain the association it may have with a stressful life situation. The influence of emotional factors in the causation of pneumonia is supported by the careful studies of Tigyi and Lissak[93] in the production and prevention of "vagus pneumonia."

An ingenious study by Selye[88] suggests the possible role of adrenocortical hormones in the pathogenesis of pneumonia and other inflammatory diseases. Rats prepared with subcutaneous air pockets on their backs, into which an irritant—croton oil—was introduced, were "stressed" by immobilization at varying intervals before and after the introduction of the irritant. When the "stress" was applied between three and five days after the croton oil, but not at other times within a two-week period, there was a maximal inhibition of the inflammatory response as measured by the thickness of the granulomatous response in the walls of the pouch and the volume of exudate. This study and the observations of Loumos[62] suggest mechanisms by which emotional or physical stresses experienced by a host harboring specific pathogens could inhibit the normal inflammatory and immune responses and facilitate multiplication and invasion by pathogens.

## ¶ Pulmonary Tuberculosis

The time has long passed when the riddle of the etiology of pulmonary tuberculosis seemed to be solved by the discovery of the tubercle bacillus and when the treatment of tuberculous patients was solely concentrated

Downloaded from www.dbraulibrary.org.in

on the ravages which it causes in the pulmonary tissue. True enough, there cannot be tuberculosis without the tubercle bacillus, but it has been realized that there are many additional factors, including the psychological and the social factors, which determine the time of onset of the manifest illness, and which, for better or worse, influence the course of the illness.

Much work has been done regarding the psychosomatic, psychosocial, and somatopsychic aspects of tuberculosis. In fact, the literature is so extensive that it is impossible to review it adequately within the space allotted. Readers interested in specific problems may be referred to the surveys by Berle,[5] Barker, Wright and Gonick,[6] Korkes and Lewis,[59] and Merrill[69] and to the books by Antonelli and Seccia,[5] Derner,[18] Huebschmann,[51] Sparer,[89] and Wittkower.[102]

In this presentation we shall confine ourselves to a discussion of the personality of tuberculous individuals in relation to the natural history of their disease.

## *The Personality of Tuberculous Individuals*

Two approaches have been used—the psychosocial approach and the psychodynamic approach.

### Psychosocial Approach

The studies of Holmes and his co-workers[50] are based on examination of a random sample of patients representative of the tuberculous population in the metropolitan Seattle area. Free-association interviews, psychological tests, and sociological techniques were used.

The data of these authors indicate that cultural conflict contributes significantly to the natural history of tuberculosis. Striking features in the breakdown of the tuberculous population studied are the predominance of males, the high rate of first- and second-generation Americans, the frequency of broken homes in childhood, and the high rate of broken marriages, of residential mobility, of occupational transiency, and of consistent poor health.

Ecological studies revealed high rates of tuberculosis in Area I, including the city center and Seattle's skid-row population, and low rates in Area IV, including Seattle's well-to-do population. The authors conclude:

> These patients, when compared with the cultural norms, were in many ways marginal people at the time of onset of tuberculosis. They started life with an unfavorable social status and grew up in an environment that was for them crippling. They were, in essence, strangers attempting to find a place for themselves in the contemporary American scene. As perceived by the individuals with tuberculosis the poorly understood world in which they lived was a source of perennial danger, and the threat of being "walled off" and rendered "helpless" was always imminent. The nature of their attitudes and life experiences made it unusually difficult for them to decide what was expected of themselves. As a consequence, their attempts at adjustment were characterized by unrealistic striving, which was not only unrewarding but also productive of cumulative conflict, anxiety and depression.

### Psychodynamic Approach

As could hardly be expected, no uniform personality type covering all sufferers from tuberculosis could be delineated. Yet the frequency of certain personality features and a fairly constant psychodynamic pattern long antedating the onset of the illness have been reported.

Investigations by one of the authors, the results of which have since been confirmed by others,[41, 44, 57, 86] have shown that an inordinate need for affection is an outstanding common feature of the premorbid personality of tuberculous patients. This need for affection may be openly expressed, thinly disguised, well concealed, or flatly denied. Coupled with it are conflicts over dependency. At one end of the scale are individuals who adopt a receptive, parasitic, or leechlike acquisitive attitude toward members of their family, if not to the world in general; at the other end are individuals who, by ostentatious insistence on independence, reveal their inability to recognize and to admit their need for dependence. Between these two extremes lies the whole gamut of defenses against admission of need

Downloaded from www.dbraulibrary.org.in

for affection and dependence. A well-defined in-between group is one made up of rebellious individuals whose aggressive and sometimes antisocial behavior bears the characteristics of a defensive measure. Another group consists of individuals who usually fail to make use of acting out as a character defense—conflict-harassed individuals. Accordingly, the patients were classed as overtly insecure, rebellious, self-driving, and conflict-harassed types.

### *Life Situation at Onset*

Irrespective of whether the one approach is used or the other, there is agreement that emotionally disturbing events frequently precede the onset of the illness.

Holmes *et al.*[50] plotted, in a group of patients, the occurrence of stressful events for a decade preceding the onset of the illness and compared their frequency with that in a group of individuals free from tuberculosis. They found that (1) in the last few years preceding the illness the patients had suffered a much greater number of difficult and potentially distressing events and situations; (2) they were people who were less stable, less able to handle difficulties comfortably, than those who remained well; and (3) they did not recognize or could not admit this personality defect.

As regards the authors' studies, in four fifths of the individuals labeled overtly insecure, situations which rouse aggressiveness or endanger the delicately poised security system of the patients were found to precede the onset of tuberculosis. These individuals react disproportionately to rebuffs, to separation from, threat of losing, and actual loss of, a supporting figure. In individuals of a rebellious nature, resentment of imposed authority and imposed hardships often assumes a precipitating function. The emotional situation of self-drivers is different and yet similar in some respects. In them, external precipitating situations hardly ever precede the onset of tuberculosis. Their basic conflict consists in compliance with the demands of one driving parent (usually the father) under silent protest. They differ from the previous groups in so far as the authority against which the opposition is directed has become internalized. The emotional conflicts in the conflict-harassed group, in contrast to the others, have reached a preconscious level.

### *Formulation and Speculation*

Four conditions could be conceived under which, in adult life, florid symptoms of pulmonary tuberculosis may develop: (1) infection or reinfection by massive doses of tubercle bacilli; (2) reactivation of a dormant primary lesion (a) by an adverse environmental situation over which the individual has no control, (b) by a consciously or unconsciously self-engendered adverse environmental situation, and (c) by endopsychic processes. Some of these conditions are obviously not mutually exclusive. For instance, an individual may succumb to infection because he is susceptible to it owing to his disturbed emotional state.

Of these four conditions only the last may raise the eyebrows of some organically minded tuberculosis specialists. Most tuberculosis specialists, however, are familiar with the type of patient who, despite all efforts on the part of the physician, steadily goes downhill and who, on exploration, is found to have no will to live or, more precisely, in a state of severe depression, quite consciously wishes to die. Beyond this, psychiatric and psychoanalytic observations have indicated that tuberculous patients, in the deep layers of their minds, deflect aggressive impulses from objects in the external world to their own selves or to introjected objects.

Hartz[44] has suggested that in certain patients the disease process in the lung takes on a special symbolic significance, the character of which is determined by the nature of the patient's personality problem. "The lesion becomes personified and almost seems to be treated as if it had an existence of its own, separate from, but included in, the life of the patient." He reported the case of a patient who unconsciously identified the disease process with her mother—"it was her mother taken inside her who was symbolically being invaded and destroyed by this process." When psychological treatment enabled her to exteriorize the

Downloaded from www.dbraulibrary.org.in

hatred of her mother, the patient's whole attitude toward her pulmonary tuberculosis changed.

The question has been raised why tuberculous patients so rarely commit suicide. The answer has been given that if the tuberculous lesion is regarded and understood as an "organic" suicide[67] or as a "partial" suicide,[44] there is no necessity for the patients to take active steps to terminate their lives.

These views have been supported by Rebner,[78] who, using the Blacky picture test and the Rorschach test, subjected to a careful investigation the role of personality as one of the factors in relapse in pulmonary tuberculosis. His research population consisted of a group of 20 persons, whose tuberculosis had become arrested after a relapse, and of two matched control groups, one composed of individuals recovered without a relapse and the other composed of relapsed tuberculous patients. Although other factors related to immunity and reinfection undoubtedly played important roles in the relapses, statistical analysis of the results obtained showed (1) that both relapsed groups manifested a greater degree of oral aggression than did the unrelapsed group, and (2) that persons in the relapsed hospitalized group had a greater tendency to direct aggressive drives onto the self than did persons in the relapsed arrested group.

Finally, the question may be justifiably posed: How can emotional conflict and disturbance on purely physiological grounds affect the organism in such a way as to precipitate the onset of illness and to influence its course? In this respect, once again, reference may be made to the work of Holmes *et al.*,[50] who studied the relationship of life stress and adrenocortical function in tuberculous patients and found that the level of 17-ketosteroid excretion was related to the emotional state of the subjects and to the type of tuberculous lesion. Rapid changes in 17-ketosteroid excretion accompanied changes in emotional states resulting from acute or chronic stress situations arising during the course of hospitalization. These alterations in adrenal cortical function persisted for the duration of the emotional experience. From their own work as well as that of others, Holmes and his co-workers conclude: "From these observations it is suggested that adrenocortical activity plays a role in resistance to tuberculosis and that the effects of life stress upon the course of tuberculosis, in part, may be mediated via the adrenal gland."

CHAPTER 36

# SEXUAL DYSFUNCTIONS IN MEN

Emil A. Gutheil

Downloaded from www.dbraulibrary.org.in

THE SEXUAL FUNCTION of the man is dependent on a set of partly psychic, partly physiologic stimuli which are links in a chain of interrelated conditioned reflexes. Any disturbance of this chain—in its somatic or psychic parts—may lead to a disturbance of the sexual function.

In evaluating a disturbance of this sort in a patient, four main factors must be taken into consideration—the initial sexual charge (libido), the erection, the ejaculation, and the orgasm. The performance of a normal sexual intercourse is possible (1) if the individual shows a sufficiently high degree of initial libidinous charge; (2) if this libidinous charge is strong enough to stimulate his erective centers sufficiently to produce an erection; (3) if the erection is sufficiently strong and lasting to permit an insertion of the organ* (through subsequent friction, achieved by voluntary thrusts, that is, by summation of stimuli, the male must be able to reach a level of excitation high enough to flood with it the ejaculatory centers so that an ejaculation can ensue);* and (4) if this ejaculation occurs at the peak of excitement, by involuntary spasms of the pelvic floor musculature, and is accompanied by a distinct climactic pleasure (orgasm), experienced psychosomatically.

* The erective reflex leads to two synchronized nervous reactions: (1) There is a dilation of the arteries of the penis, with subsequent engorgement of the corpora cavernosa. (2) Simultaneously, there is a tonic spasm of the muscles of the urogenital triangle (bulbocavernosus and ischiocavernosus), with the result that no blood escapes the cavernous bodies through the venous system. These reactions are effected by the inhibition of the sympathetic (vasoconstrictor) centers, located in $L_{1-2}$, and by the excitement of the parasympathetic (vasodilator) centers in $S_{1-3}$. Both spinal centers are in communication with cortical, subcortical, and medulla oblongata (vasomotor) centers.

* The ejaculatory reflex is triggered off by impulses which originate in the genital epithelium. They are carried via the dorsal nerves of the penis to the common pudendal nerves and enter the posterior spinal roots at $S_{3-4}$. These impulses then reach $L_{1-2}$, causing (1) peristalsis in the ampulla of the deferent duct, the seminal vesicles, and the ejaculatory ducts which bring the semen toward the membranaceous part of the urethra, and (2) clonic spasms in the muscles of the urogenital floor (pudendal nerve, perineal branch) which cause ejaculation.

## ¶ Diagnosis of Sexual Dysfunction

The diagnosis of a psychogenic sexual dysfunction can be made only after a thorough somatic and psychic examination of the patient. Such an examination will have to exclude the physical forms of dysfunction. Among the most frequently encountered physical causes of impotence are diseases which affect the central and/or peripheral parts of the neurone, thus disrupting the function of the reflex chain. They are (1) infections and intoxications (for example, syphilis, multiple sclerosis, transversal myelitis, diabetes, saturnism, and others); (2) central and peripheral malformations which mechanically obstruct the conduction of stimuli (such as tumors) and peripheral pain-producing obstructions (such as phimosis or the like); and (3) hormonal hypoplasias, aplasias, and other hypofunctions.

The vast majority of sexual dysfunctions leading to impotence, however, are of psychogenic character. Some of them are symptoms of an underlying sexual deviation (paraphilia) or of a psychoneurosis connected with an immature sexual pattern (psychosexual infantilism).

The psychologic exploration needed to establish the nature of the disorder includes (1) the patient's family background, (2) details of his sexual development, (3) his moral training and education (as potential sources of sexual inhibition), (4) if married, the history of his marriage and the current state of the marital relationship, and (5) his own theory regarding his disorder. The answers to a number of special questions must then be determined.

## ¶ Special Information Required

### *Duration of the Dysfunction*

We inquire whether the potency was lost after a relatively normal sexual period or whether the patient was unable to perform intercourse from his very first attempt.

In the first case, our interest must concentrate on the factors which may have contributed to the patient's current loss of potency. Inhibitions, fears, acute conflicts between conscious and unconscious desires, etc., will come into focus here. The analysis does not have to go far back beyond the onset of the disturbance. Only occasionally does the necessity arise for making farther-reaching forays into the patient's past in order to reconstruct some of his pathogenic patterns which had remained latent until they were set off with the acute outbreak of the disturbance.

In the second case, the pertinent inhibitions have apparently been carried into the sexual relationship from the patient's very early childhood. A thorough investigation of the past is, therefore, mandatory. The relevant causative factors may lie anywhere between infancy and the current phase.

### *"Absolute" or "Relative" Dysfunction*

I should like to begin by expressing a pessimistic axiom[3] which may be formulated as follows:

Because of the existing "cultural neurosis," the man of today is no longer capable of having sexual intercourse with *any* partner, at *any* time, and under *any* circumstances. Given a proper partner, a suitable time, and propitious external and internal circumstances, he can have a satisfactory and thoroughly enjoyable sexual intercourse. Not that the ever-potent and "ideal" type does not exist any more; however, our selective affinities and specific idiosyncrasies in human relations play a greater part today than they used to centuries ago, when the psychic organization of the individual was simpler, the tempo of living less stressful, the personality and social status of the woman less complicated, and thus also the sexual intercourse closer to the purely biological, physical level.

Many sexologists[2, 4, 5] have pointed out that even the so-called normal individuals may have certain specific love conditions under which sexual stimulation may reach a higher degree—conditions involving position, type of partner, the partner's conduct during intercourse, etc.

Downloaded from www.dbaumbooks.co.in

For example, there are men who, without being conspicuously neurotic, are more stimulated when their partner is in the inverse position; or who are especially aroused when their partner has voluminous breasts or buttocks, is aggressive and active in the sexual act, or passive and even motionless. There is no doubt that a deeper analysis of these specific sexual predilections, relying heavily on the patient's dream material, may reveal not only the deeper meaning of these preferences but also their origin and the conditions under which they have come to existence. However, this does not preclude that in evaluating a sexual disorder, we must draw a relatively wide margin of normality.

Although the moral code in some countries, including our own, has declared some commonly practiced variations of sexual relations as taboo, the modern psychiatrist will be inclined to favor the formula that what two mature people do in the privacy of their bedroom, to enhance their mutual enjoyment, without offending the sensitivities of any third party, does not represent a psychiatric problem.

We must not forget that man long ago abandoned the natural sexual rhythm of rut, or heat, which regulates the sexual life of animals. Man has extended his capacity to enjoy sexual relations and his need to mate beyond the regular mating seasons of the year. This capacity is dependent, to a high degree, on psychosexual stimulation from outside. A shortcoming of this universalization of the sexual rhythm is that, at times, the male may be ready to mate while the female may still be sexually uninspired, and vice versa. It may, therefore, be necessary for either partner to make an effort to increase the initial sexual charge by deliberate efforts to synchronize the sexual rhythm.

One of our queries at the initial interview is whether impotence was encountered in marital sexual attempts as well as in extramarital ones, if any. In some cases, owing to an overstrong super-ego reaction, extramarital intercourse may be impossible, while connubial relations may remain undisturbed. One of my patients, a traveling salesman, showed this form of "relative" impotence. His extramarital impotence proved to be the guardian of his marital fidelity.

On the other hand, there are individuals who are potent only in their extramarital relations, with harlot types of women, while their marital relations are entirely unstimulating. A forty-year-old musician had intercourse with his wife only on rare occasions. His usual way of obtaining sexual gratification was to visit bars, get semidrunk, pick up one of the female bar customers, and have intercourse with her. When he developed a stomach ulcer and alcohol was prohibited by his physician, he was automatically deprived also of his sexual outlet.

This patient, an inwardly religious person, could not perform sexually unless he had dulled the voice of his conscience by alcohol. In addition, his latent homosexuality and the general hostility toward women connected with it made women who were promiscuous, that is, "men-women," more attractive to him (the "triangle of latent homosexuality"). His guilt feelings toward women led him to self-punishment by self-degradation, which the alcohol daze helped him to tolerate.

### *Details of the First Failure*

Various factors may have been responsible for a patient's failure in the first intercourse: (1) The first encounter may have been fraught with anxiety, to begin with, an anxiety carried over from old masturbation fears or from unresolved castration complexes. (2) The patient may have been subjected to an acute upsurge of unconscious hostility toward his partner. (3) He may have had another experience which had led to an intrapsychic shift of the sexual interests. (4) The external circumstances of the intercourse may not have been propitious.

In one of my cases, the patient's mother-in-law was sleeping in the adjoining room during the wedding night, and only a curtain separated the two rooms from each other. Inhibitions involving her, as well as some oedipal factors, conspired to make the sensitive patient unable to perform.

Another patient, a married dentist, who wanted to have intercourse with his office

Downloaded from www.dbraulibrary.org.in

assistant in his main-floor office, was acutely impotent when he heard the rhythmic step of the policeman walking up and down in front of the windows of his office. It was impossible for him to perform the immoral act of infidelity "under the eyes of the law," representing, of course, also his super-ego.* In his unconscious, this fear fused with his oedipal anxieties† and evoked symbolic self-castration.

### *Traumatic Impotence*

Under traumatic circumstances we occasionally observe impotence with or without loss of libido. It is not sufficiently known that impotence can represent also an unspecific symptom, as the result of an upheaval within the dynamic forces of the ego. Under conditions of prolonged stress, sexual energies may be included in the ego's attempt to maintain or regain its adaptive capacity and may have to be withdrawn from their specific contrectative goals.

### *Frequency of Intercourse*

The next question to be asked at the initial interview is, how frequently, on the average, intercourse takes place. Many superstitions are encountered at this occasion. Some men are afraid that too frequent intercourse may be harmful, that it might lead to the exhaustion of the potency.‡ They may make every effort to cut down the frequency of intercourse and to increase the intervals, with the result that their performance steadily declines. Infrequent intercourse increases the inner sexual pressures and often leads to premature emissions, owing to a chronic engorgement and overstimulation of the genital system by many frustrative excitations.

Often it is the woman who prevents her husband from indulging frequently in intercourse. She may use all sorts of rationalization to dissuade him from approaching her, because she is frigid and hates sexual relations. Some women tolerate sex if they must, but they gladly grasp any pseudoscientific explanation to avoid their marital obligations. Intercourse in this type of marriage may then become the object of a struggle for power between both partners, with the man having to "deserve" it as a special favor, or having to forgo it as punishment. As time goes on, physical relations may lose much of their desirability for the male partner also.

The unbiased student of sexology cannot concur with the idea that physiologic glandular secretions of any kind should be harmful or could be exhausted. The opposite is true with most of our glands, as the phenomenon of "disuse atrophy" indicates.

### *Initial Sexual Urge*

Attention should also be paid to the question of the strength of the initial sexual urge. Has it always been sufficiently strong? Does the patient still consider it adequate at the time of the current interview?

Analytic investigation reveals that hyposexuality and asexuality—with the exception of organic disorders—are products of transformation within the dynamic forces of the patient's ego. In cases of this type, the patient's libido moves along underground pathways, because it is not directed toward the mature sexual union with a woman but has either remained on a pregenital level or assumed homosexual character.

One of my patients, aged thirty-four, stated that he was not surprised at being impotent; he was not interested in sex to begin with (libidinal impotence). He went out with girls because this was expected of him, and because he frequently felt bored and lonesome; but he did not care for

* In his *New Introductory Lectures on Psychoanalysis* (Norton & Co., New York, 1933) Freud states as follows: " . . . the function which I am beginning to distinguish within the ego is the conscience; but it is more prudent to keep that function as a separate entity and assume that conscience is one of its activities, and that the self-observation which is necessary as a preliminary to the judicial aspect of conscience is another. . . . I will henceforth call this function in the ego the 'super-ego'" (page 86). [For a further definition of super-ego, see Greenson, Chap. 69—EDITOR.]

† [See Greenson, Chap. 69—EDITOR.]

‡ Old-fashioned sex-hygiene manuals (and, unfortunately, some more recent ones, such as of The United States Public Health Service, 1937, and the *Boy Scout Manual*, 1945, and others) exhort the youth to avoid "wasting" the vital fluids.

Downloaded from www.dtic.mil/dtic/index.html

women sexually, and the sexual interest he often noticed in women left him cold. He would have preferred to spend his time in a stimulating conversation with women. Homosexuality repulsed him, however.

The marriage of the patient's parents was very unhappy. His mother was a domineering woman, who, according to the patient, was the most despised person in town. She not only showed no affection for her children but also, by constantly demanding their services, discouraged any warm feeling for her. The children preferred to stay away from her rather than be constantly forced to respond to her whims. The patient's father was a taciturn person who was completely dominated by his wife. He knew nothing and cared nothing about anything but business, from which he had amassed considerable wealth. The patient often heard his mother say that women were "gold diggers," and that if they should ever show interest in the patient, it would only be for his money. The patient thus had learned in his early youth to suspect women's motives and was constantly on guard against any attempt on the part of women to "rope him in."

Gradually, the patient developed an asexual attitude toward women. When, in his adolescence, he failed in his first attempt at intercourse with a prostitute, his resistance toward sex obtained a realistic basis. He was, however, able, in his late twenties, to perform intercourse repeatedly with a neighbor girl, until the relationship led to pregnancy. This unexpected event not only represented the end of the relationship but also reinforced the patient's sexual inhibitions. In the course of a few years, the patient's sexual interest reached the zero point.

Some patients of this type use all sorts of artificial stimulation to get into the proper mood, for instance, by viewing some sexual pictures. Some of these pictures may reveal the repressed source of the specific stimulation, for instance, homosexuality, sadomasochism, pluralism, or other abnormal traits. Other patients behave as though their sexual urge had evaporated completely, and as if nothing were able to stimulate their sexual interest. It should be stated at this point that even if sex seems to have been banned from the patient's consciousness completely, this in itself does not represent any important indication regarding the prognosis of the case.

## *Erection*

Our next questions are: Has the patient had any erections at all? Has he morning erections? Is he aware of having erections when he does not "need" them, while they fail him when he contemplates intercourse (erective impotence)?

In general, we may say that the presence of erections is a favorable sign, regardless of the context in which they appear, a fact which should be stressed by the therapist. Through a successful therapeutic intervention, it should be possible to synchronize the erective reflex and the sexual act.

The phenomenon of morning erections has received a great deal of attention from sexologists. Some experts consider them insignificant and only a response to the increased filling of the urinary bladder. Stekel[5] proved, however, that sexual dreams, and fantasies produced on awakening, are primarily responsible for the appearance of morning erections. In many cases the patient is unable to reconstruct them, but careful analysis can elicit the sexual images accompanying the dreams.

It is also valuable to investigate whether the erections are spontaneous or have to be stimulated by the woman, and whether the patient has the desire to insert his penis or waits for his wife to take the initiative. The patient's basic attitude toward women and sex is revealed in this manner. The erection of a normal man is a "penetrative" one; it creates an almost unpleasant state of tension which can be relieved only by penetration and the subsequent phases of intercourse. The feminine, passive, neurotic man has to be "taken," "milked," or "given" pleasure, instead of generating it actively.

## *Ejaculation*

Is the patient's ejaculation adequate, premature, retarded, or absent? Does it occur with or without an erection?

Although in most animals ejaculation fol-

Downloaded from www.dbraulibrary.org.in

lows soon after penetration, and the anthropoid apes ejaculate in a matter of seconds,[2,4] the average human male is capable of engaging in intercourse for several minutes and longer before the seminal emission takes place.

Nevertheless, premature emission (ejaculative impotence) is a very common disturbance in man. While many men make conscious attempts to delay the ejaculation in order to extend the enjoyment of the act or to synchronize it with the partner's orgasm, the duration of the intercourse is often so deficient as to leave the female partner unsatisfied. It is interesting to observe how the fear of being inadequate leads to the delaying tactics and how the delaying, in a vicious circle, gradually leads to a shortening of the act. It seems that along with the reduced sexual endurance of the average man goes the modern woman's lowered capacity for responding to the stimulation. As a result, a woman who needs a prolonged intercourse to obtain an orgasm is often faced with a man whose ejaculation occurs too soon. The male's attempts to reduce the mounting sexual tension, in order to avoid a premature climactic discharge—by physical means (such as, slowing down or interrupting the thrusts of the intercourse, or the like) or by mental efforts (such as, deliberately distracting his mind)—lead to hyperirritability and, as a consequence, to premature emission.

It is, therefore, preferable to increase the frequency of intercourse and to let the reflex chain take its normal course, even if, at first, it should lead to the usual premature ejaculation. The best way to reduce the speed of the act is by frequent regular intercourse. Some patients use the leisure time of a holiday or a vacation to increase the sexual relations to daily or even more frequent acts. As a rule, they notice, after some time, that the second intercourse is more successful than the first, and gradually they can delay the moment of ejaculation to a more satisfactory point. Concurrently, psychotherapy is being used to eliminate the effects of unconscious anxiety.

Ejaculation may occur without erections and thus combine two phases of the disturbance. The ejaculation, in many of these cases, is obtained by manipulation of the penis so that, diagnostically, the erective impotence still remains the presenting symptom.

In extreme cases, ejaculation is so rapid as to occur before introduction of the penis into the vagina (ejaculatio ante portas).

Analytic investigation of premature emission has attempted to cast some light on the nature of the inhibition underlying this condition. In the opinion of analysts, we are dealing here with the patient's unconscious pregenital trends, which show either urethral or oral predominance within his generally feminine orientation toward sex. In urethro-erotic cases the patient may have a highly erogenous zone in the prostatic part of his urethra, at the root of the penis, acquired at an early phase of his development, and he may experience his orgasm in that area. He may also show a history of enuresis (an infantile form of emission), and his unconscious attitude toward semen may prove identical to that toward urine. In the ejaculatory act, he may be spilling semen on the female genital (as though it were urine) instead of penetrating it. The oral trends within this generally feminine orientation include the identification of the penis with the maternal breast. In cases of this type, seminal emission on the unconscious level equals the discharge of milk; intercourse on this level may thus represent an act of nursing.

Premature emission may, at times, be misinterpreted by the patient. Some patients have to be enlightened that mucorrhea, which may accompany the initial sexual excitement and represent a physiologic lubrication of the organ, is not premature emission. Misinformation in this respect often leads to unnecessary hypochondriacal ideas and anxieties. Mucorrhea is even sometimes misinterpreted as spermatorrhea and thought to be of ominous import, although it only indicates that the patient is hyperirritable and inadequately satiated sexually. Frustrating excitations caused by so-called "necking" or "petting," without adequate outlet (at one time called "bridegroom neurasthenia" because it was found so often in young people about to be married) are usually the cause of this hypersecretion. The mucus in these cases is supplied by the urethral

Downloaded from www.PsychiatryOnline.org

glands of Littre along with some prostatic secretion. There is rarely any semen in it.

Retarded ejaculation is usually a sign of a deep-seated disturbance of the sexual instinct and requires careful analysis. Resistance to ejaculation usually develops if dangers appear to be connected with it. In many cases, repressed sadomasochistic impulses play a role in the development of this symptom, but we also find anal (retentive) and oral (rejective) features in special cases.

One of my patients, a twenty-five-year-old man who suffered from a retarded ejaculation was once slapped on his buttocks during intercourse by an angry and impatient prostitute. This was enough to bring about a prompt and powerful ejaculation in this unconsciously masochistic man.

Ejaculation may be absent altogether; the orgasm then occurs without seminal emission. As an acute phenomenon, it may be due to a temporary exhaustion of the ejaculatory reflex as a result of repeated intercourses with too short intervals of rest in between. As a chronic condition, it bespeaks deep-seated sexual anxiety which has to be investigated analytically.

A twenty-eight-year-old fireman complained that he was lacking emission. He had been married for two years and desired a child. Because of religious reasons, he had had but little intercourse before his marriage. Once, at the age of twenty-two, he had intercourse with a girl of his acquaintance and, despite continuing the intercourse to exhaustion, achieved no ejaculation.

He had been brought up with the idea of a "clean" life, and his parents as well as his clergyman friend, who used to visit with his family, emphasized the blessings of chastity. When, at the age of fourteen, he noticed that he had an erection, he was sure that he was degenerate and that he had completely lost his soul.

In his childhood he had often witnessed acts of extreme brutality toward women. His father often shocked him by cruelly ill-treating his mother. The patient was, in general, shy toward girls. In addition, he read many books on sexual hygiene, supplied by his clergyman friend, which portrayed "self-abuse" in most dramatic colors and described it as a step toward physical and mental perdition. At the age of fifteen, the patient developed a strong yearning for girls but, because of his shyness, was unable to establish any personal relationships with them. The town's burlesque show represented the boy's only sexual distraction.

Because of his "sinful" behavior, he suffered from deep feelings of guilt and looked forward to his future sexual life with great apprehension. At the age of eighteen he was convinced that, should he ever have an opportunity to be with a girl, he would be impotent.

At the age of nineteen he was a witness of a family tragedy. After a violent quarrel, his uncle killed his wife by choking her to death. About this same time the patient also read Bram Stoker's *Dracula*, in which a human vampire attempts to kill a woman he sexually desires. The patient was deeply impressed by these experiences and made up his mind that he would rather give up sex forever than expose himself to such terrifying potentialities.

The next few years found the patient in the throes of a deep asceticism. He avoided all contact with women until, at the age of twenty-one, he followed the invitation of a streetwalker and had intercourse with her. He had no ejaculation on this occasion and had none after that.

The analysis of this case brought out the patient's strong sadistic component. His early and adolescent impressions of violence toward women triggered off latent lust-murder tendencies, against which the patient protected himself by blocking orgasm and ejaculation. The idea of lust murder by strangulation clearly filtered out of the dream material. The patient's attempt at asceticism was another form of ego defense.

An interesting detail of this case was that the patient had a phimosis which had not been discovered until he was twenty. An operation was performed at the age of twenty-four to set his glans penis free. According to some analysts,[5] such protracted cases of phimosis often form a physical matrix for the development of sadomasochistic sexual deviations. The prepuce, which squeezes and generally interferes with the function of the penis, forms a compulsive force which is set in motion in connection with sexual excitement, causing feelings of strangulation of the penis, physical pain,

Downloaded from www.dbraintherapy.org.ru

and discomfort. Thus pain and pleasure coincide, forming a somatic substratum for a sadomasochistic paraphilia. The patient's lust-murder idea characteristically involved strangulation of the type that the patient had seen performed by his uncle and that he himself had endured through phimosis.

### *Orgasm*

Ejaculation is not identical with orgasm. There are people who ejaculate without feeling any significant pleasure (orgastic impotence). If this is not a symptom of a general anhedonic attitude which is to be found in some psychoses (schizophrenia), it bespeaks a severe conflict between the id and the super-ego. It is found in people who cannot love and whose psychosexual development has not reached the stage of genital primacy. It is also seen in people for whom pleasure, for some specific reasons, represents a threat. The type of threat varies—from oedipal castration fears to the fear of repressed sadistic impulses—but the result is always that the drive has to be renounced by the ego, together with the sensation of pleasure attached to it. In this way the ego is able to comply with the demands of the super-ego and to maintain the normal integration of the patient's personality.

### *Contraception*

Among the questions to be asked at the preliminary examination, we consider it important that inquiry be made concerning contraceptive methods used and the patient's attitude toward them, not only because the fear of causing pregnancy may play a part in the inhibitory reactions responsible for the sexual dysfunction but also because the mechanical details involved may prove to represent unwelcome, annoying, or repulsive factors, capable of interfering with the normal course of the physiologic event.

If coitus interruptus is practiced as a contraceptive measure, we must explore the man's attitude toward it. He may be inclined to anticipate that it will bring him harm. Early psychiatrists (including Freud) believed that coitus interruptus — like masturbation — was harmful, and that it led to a so-called "actual neurosis." Today, this concept is no longer considered valid.

### *Accompanying Fantasies*

One of our questions will be whether the patient has ever used any accompanying fantasies to stimulate his deficient sexual excitation during the act. Among these are fantasies of other women (who may fulfill the patient's specific sexual needs better than the available one), pluralistic scenes (more than one partner), and other deviations. Although the patient may, at first, hesitate to reveal these guarded secrets, knowledge of these fantasies is essential for the understanding of the dynamics of the dysfunction.

### *The Act*

We stated above that the margin of normality in sexual relations must be drawn quite generously, yet it is of importance for us to know the type, amount, and scope of variations of the act which the patient had been practicing in the past. While an inverse position can be considered normal as a variation within a normal relationship, it may, by its exclusive character, bespeak the patient's unconscious desire to play the feminine part and thus may require further study. It is equally important to investigate any attempt by the patient at cross-dressing (man in woman's attire) or any attempt by him to demand from his partner ill-treatment, calling him abusive names, etc.

A forty-two-year-old musician had a peculiar condition of his potency—to have intercourse with the wife of one of his friends. Since the patient was only rarely able to fulfill this condition, he masturbated with the fantasy of being watched by the husband of his sexual partner during intercourse (triangle of latent homosexuality). He was once able to have intercourse with the wife of one of his friends, a dentist, in a room adjoining the dentist's operating room. The proximity and the danger of being discovered were the unconscious homosexual-masochistic stimuli he needed to se-

Downloaded from www.dbraunbrary.org

cure his potency. It was as though he secretly wished to be discovered.

As in all paraphilias, this deviation had an infantile root. It was based on experiences from the patient's childhood, when he overheard parental intercourse and masturbated simultaneously.

### *Postcoital Reactions*

Where intercourse is technically possible, reactions following it are of diagnostic importance. Although we know today that the old Roman proverb, *post coitum omne animal triste*, does not necessarily apply to humans, there are men who do show all sorts of negative reactions following intercourse, reactions which must be studied in detail. Some men become depressed, others have the feeling of repulsion, some drink excessively.

One of my patients, a handsome man of twenty-nine, regularly developed a severe antagonism toward his sexual partner, a feeling which began during the act and increased toward the end of it, so that he had difficulty in bringing the act to a close. It was torture for him to stay in bed with the woman for any length of time after the intercourse. Yet, a short time following the ejaculation, his mind would begin to wander, and he would contemplate intercourse with another woman. Its fate, in reality, would then be analogous to the previous one. Once the woman's cooperation was assured and intercourse undertaken, the same gamut of emotions would ensue, culminating in complete disappointment and disgust.

Analysis of this case revealed a strong hostility toward women in general, based on a repressed hate toward the patient's mother whom he suspected of having caused his father's untimely death. As a consequence, the patient had strong homosexual tendencies, an outgrowth of his repressed hate-fear of women. His "Don Juan complex" was an attempt by the patient to prove to himself that he was a man, and that women were desirable and not potential killers of their partners (like his mother).

### *Nocturnal Emissions and Masturbation*

Nocturnal emissions occur in people who either have no sexual outlet (abstinence) or are, for some reason, flooded with sexual excitation. If a patient has no sexual intercourse and does not masturbate, nocturnal emissions are likely to occur. They play the part of safety valves by which surplus energy (like steam in an overheated engine) is automatically discharged. Through this discharge, the level of sexual pressure is lowered, and the sexual equilibrium is restored. Emissions of this type are usually connected with sexual dreams, although not all sexual dreams necessarily end with emission. For the psychiatrist, emission dreams are especially valuable because, in most cases, they carry traces of the so-called "specific sexual fantasy" of the patient.

Of special interest are nocturnal emissions which occur despite the fact that the patient has normal sexual relations and/or masturbates, that is, although no increased pressure of the sexual drive seems to exist. Such is the case, for example, if a nocturnal emission occurs the night following intercourse. Closer examination of the accompanying dreams will help explain this phenomenon in the specific case. We may find that the patient's "specific sexual fantasy" is not concerned with normal intercourse, and that parts of the sexual drive remain frustrated, to be gratified surreptitiously by way of the emission dream.

Persisting masturbation must be similarly explored. If the patient has a chance to perform normal intercourse and yet prefers to masturbate, then we assume that parts of his libido remain unsatisfied in the normal act. What the specific situation is that has to be invoked in the masturbation fantasy to fill the gap, is a subject which can be answered only by analysis. The specific masturbation fantasy is either conscious or it represents a part of the unconscious material to be elicited by dream interpretation. The details of this masturbation fantasy and the patient's specific disturbance may have a causal connection. This is particularly true in cases of paraphilia (sado-

Downloaded from www.dbraulibrary.org.in

masochistic deviation, homosexualism, fetishism, transvestitic fantasies, etc.).

A forty-two-year-old chemist complained that he could not get an erection when in bed with a woman. He had been married twice before; his impotence was the cause of the breakdown of both his marriages, which ended with divorces. The patient had erections occasionally, especially in the morning. He had not had any contacts with women until he was twenty-seven. The reason for this was his fear of being impotent. His first physician encouraged him to get married, so he did, hoping that marriage would solve automatically his sexual problem. He had been in love several times prior to his first marriage, and was also in love with his wives. When the impotence persisted, he consulted several physicians, first a general practitioner, then a urologist, and finally a psychiatrist.

The inquiry about his masturbation fantasy (to which the patient replied under great resistance) cast a sudden light upon the case. The patient had masturbated since the age of thirteen, with a fantasy of a crippled woman. The fantasy woman had one leg shorter, or amputated, or one arm amputated, which made her movements laborious and clumsy. Whenever he saw such a woman, he had an emission, without having to touch his penis or having any contact with his object. In masturbation, erections were normal.

While it became clear that this disturbance was not a case of impotence but of a sexual deviation in which intercourse was not the goal, it was necessary to investigate analytically the psychology of the paraphilia. It was evident that what the patient characterized as "love," which he supposedly felt toward women, was a brother-sister type of relation and was apparently separated from the patient's sex life. All he felt for these women was a tender reaction of comradeship which did not go beyond that point.

The patient's paraphilia started with himself identifying with a crippled woman. He began tying his own leg, flexed at the knee, with a rope, and walking about in this clumsy fashion. This process was sexually stimulating and was accompanied by erections. The patient identified himself with wounded horses and even with the devil, who is described by some poets as limping. He wanted to have absolute power over women, and, since he knew that his self-consciousness would prevent him from having any outstanding success, he, like Faustus, sold his soul to the devil in exchange for that power. In his fantasy he was Mephistopheles. In one of his sessions he quoted the sentence which Freud used as the motto to his dream book—*"Flectere si nequeo superos, Acheronta movebo"* (If I don't succeed to influence the gods above, I shall try to move the gods of the underworld)—as being pertinent also to his case.

His first dream revealed that this patient harbored unconscious sadistic tendencies. It ran as follows:

*"I borrowed a truck to use it over the week end. I was worried it might get damaged while I had it in use . . . ."*

The analysis of the dream revealed the patient's fear of injuring his partner (truck) during intercourse (while in use). The further analysis showed that the patient's disorder had the purpose of protecting him against his own antisocial impulses, and that his marriages had twice rekindled his fears of violence toward his partner. The paraphilic fantasy which contained the picture of the woman on whom crippling violence had been committed before was one of the patient's own ways to neutralize and inactivate his "devilish" impulses. The crippled woman was a composite symbol. In his fantasy it was an end product of a sadistic assault, and, at the same time, it represented, as a warning image, a memento not to overstep the moral boundaries, the picture of castration. As stated above, the problem in this case was not impotence but a disturbed attitude of the patient toward the opposite sex.

## *The Partner*

The personality of the partner and the patient's relation toward the opposite sex are the next questions to be discussed. Is the patient in love? Was he ever in love with his partner? How was their first sexual encounter? If the first intercourse happened to be a failure while the next ones were successful, what, in his opinion, were the inhibiting factors? How did his partner (wife) react to his initial diffi-

Downloaded from www.dbraulibrary.org.in

culty? Was she patient and encouraging, or openly disappointed and/or derisive?

A woman can, under certain circumstances, make a man impotent. Expressions of reproach, derogatory remarks, indications of disinterest, or expressions of exaggerated anxiety may have a castrative effect on a sensitive man and lead to a lasting disturbance.

One of my patients, who was criticized by his sexually more experienced wife on their wedding night, lost his erection before the act and never was able to have it again—with this woman. He always felt toward her like a schoolboy who has been censored by the teacher.

Impotence of this type shows elements of revenge; it deprives the castrating woman of what she seems to value (or to need) and indirectly opens the way for an ultimate separation from an unacceptable marital partner.

Phallic women, especially those who have had previous sexual experience, often take over the conduct of the intercourse. They comment on the man's every move, tell him how to recline, how to regulate his motions—they wield his penis, as it were. The man, in the eyes of such women, is an unimportant appendix to his penis which these women use because they lack one of their own. They don't realize that most normal men want to feel that their partners appreciate their sexual approach as a "love offering" and want to feel that they are contributing to their partner's enjoyment. Any decrease of the man's feeling of masculinity may lead to a decrease of his performance.

A twenty-nine-year-old lawyer, who was sexually inexperienced, married an equally inexperienced woman. Her mother supplied her with the premarital instruction, one point of which was that the first intercourse was very painful and caused a severe hemorrhage. The girl was, nevertheless, ready to fulfill her marital obligations, no matter what the price. Before retiring for her wedding night, the woman placed all sorts of first-aid materials at her bedside—gauze, bandages, iodine tincture, and a washbasin with hot water. At the sight of these preparations, her husband lost all his sexual feelings. Because of the aroused castration fears, neither this nor subsequent attempts were successful.

### *The Patient's Own Theory*

At this point we wish to know what the patient himself thinks about the cause of his dysfunction. We learn a great deal from the patient's answer to this question. Hypochondriacal ideas, fears of the consequences of past "sins" and "abuses," and all sorts of misconceptions regarding the current disorder may be elicited in this way.

### *Prognosis*

The last question to be clarified concerns the circumstances under which the patient hopes to have intercourse after therapy. It is clear that the patient cannot consider himself cured "theoretically." Before the patient is discharged, he and his therapist may wish to have proof that the potency has been restored.

There are patients who have experienced their impotence in a premarital attempt and wish to be rehabilitated before they make their decision to get married. The situation in these cases may not be simple at all. Marriage will be rejected by such patients until they have regained the necessary self-confidence. However, they may be disinclined to risk "experimental" intercourse (with prostitutes or otherwise) for moral reasons. On the other hand, for the psychiatrist to declare after therapy that the patient "now can get married because the inhibitions have been removed analytically," entails a certain amount of risk and a moral (perhaps even legal) responsibility, which should not be underestimated.

## ¶ Two Types of Psychogenic Impotence

### *Anxiety Type*

Patients themselves rarely know the cause of their disorder. Many rationalize it. They lay the blame to fatigue, business worries, etc. Others claim that they have "ruined them-

Downloaded from www.pbh.library.org.in

selves" by "abuse" in their youth, and that "now it may be too late." The real reasons for this disorder lie deeper, however. Only few have the intuition of a Johann Wolfgang Goethe who once (about 200 years ago) himself experienced an acute case of impotence and was able to recognize its immanent psychogenesis.

Goethe described this event in his diary (*Tagebuch*) as follows: He was returning home from the city, when a wheel of his carriage broke. As the damage required prolonged repairs, the poet was forced to spend the night at a nearby inn. A young, attractive waitress caught his attention, and, on an impulse, he wanted to kiss her. She withdrew from his arms, however, and said that while she could not stay with him at that moment, she would visit him in his room at midnight. Goethe was full of pleasant anticipations when at midnight the young girl appeared at his bedside. Before she joined him, however, she made an astounding confession: She told him that she was a virgin, but that she was so impressed by his personality, that she had decided to give her first love to him.

At that point, Goethe experienced a peculiar and new, to him, sensation—he felt no sexual excitement. No matter how much he wanted it consciously and deplored his inability to enjoy something that was offered to him so freely, his situation did not improve.

Meanwhile, the tired girl fell asleep. Goethe was baffled. In his predicament he began to think of the success he had always had with his wife as his sexual partner. And while he tried, in his thoughts, to recapture the early spirit of his marriage, he became aware of the appearance of a strong erection. His sexual arousement disappeared promptly, however, when he attempted to approach the girl again.

Goethe jumped out of his bed and wrote in his diary the following words for the benefit of his wife:

> I was approaching my home, when the last hours threatened to move me away from you, my beloved. But then, on a peculiar place, and under peculiar circumstances, I have found back my faithful heart. You may not understand this and the following inference, beloved; but note the mysterious final verse: Often it is illness that helps to preserve our health.

The genius of Goethe made him realize that his impotence was purely psychogenic. Intuitively, he grasped the fact that the stimulus which suddenly rekindled his faded sexual desire had come from the thought of his wife. He recognized that the double challenge—infidelity and the defloration of a virgin—was too much for his sensitive conscience to bear. His super-ego was indeed a guardian of his virtue. Goethe pays tribute to this intrinsic moral force, when he says in the same diary, ". . . if a demon approaches us and tempts us —something happens and the virtue is preserved. . . ."

Impotence is a symptom of a common disease in our civilization. It affects men incomparably more severely than its equivalent (frigidity) affects women. While suicides are known to have been committed for this reason, especially in young men about to be married, suicides of women because of frigidity have hardly ever occurred. A few generations ago, women were often proud to be "above the animal level" of desiring sex.

Psychologically, we can consider every case of impotence as an expression of resistance against the performance of the act. As all neurotic symptoms, it has not only a cause but also a purpose. Stekel spoke of a "will to impotence" and considered it the last-minute effort to make intercourse impossible. The "will to impotence" stands in the service of antisexual, antifeminine tendencies. It is a precipitate of many fears, among which we find (1) fear of losing independence, (2) castration anxiety, and (3) fear of death.

1. Fear of losing independence is an outgrowth of our present civilization. It follows the association: intercourse, marriage, loss of freedom. Although some analysts consider this fear as another form of castration anxiety, it could also be viewed as a cultural factor, reflecting the modern man's fear of the responsibilities of marriage. In the deeper layers of the patient's mind, fear of losing independence through intercourse is based on the idea that

Downloaded from www.cbtlibrary.org.in

the woman (more exactly her organ) bears hidden dangers, but these dangers do not necessarily represent a threat of castration. Man may consider his independence threatened by the fact that the woman exerts irresistible sexual influence on him.

2. Conscious and unconscious fear of venereal disease stands closer to the castration complex. Venereal disease is actually a damage to the male organ emanating from the female organ. However, even conscious castration fears may sometimes dominate the picture. They comprise fears of losing the penis in the act, or suffering direct damage to the organ. Fairy tales about cases of a *penis captivus* (a prolonged form of vaginismus which immobilizes the inserted penis in the female) that are supposed to have occurred in the past, have an almost global circulation.

Usually, the story has it that two people engaged in illicit intercourse are surprised by the sudden entrance of a third person, are shocked and, to their greatest embarrassment, are caught by a spasm of the woman's genital which prevents them from separating from each other. The phenomenon observed in dogs may be the basis for this story and also may be material for all sorts of anticipatory fears.

In reality, no such case has ever been reported in a bona fide scientific publication. No such case has ever been observed or treated by any reputable sexologist of the world. This story shows only the ubiquitous character of the latent castration fear in men, and of the fear of punishment for illicit sexual acts. Vaginismus hardly ever occurs after complete insertion. Its purpose is to protect a threatened organ (*défense musculaire*) and to prevent anticipated injury. We can elicit similar reactions of muscle spasm on McBurney's point (in appendicitis), on the shoulder part of the rhomboid muscle (in apicitis), and in many other regions in which a muscle group overlays inflamed and sensitive tissues. The defense loses its biologic purpose once a penetration has taken place. The specific structural and functional conditions in the dog's organ make it possible for dogs to be joined temporarily, after the ejaculation, by the spasm of the female's constrictor cunni, but this mechanism does not apply to man.

In some men, castration fears are easily aroused by phallic, that is, too-active, female partners. A woman who is too manipulative, too coarse, or lacking in feminine qualities may render some self-conscious men acutely impotent by arousing their homosexual and castrative fears. The impotence in such cases protects the man from imagined harm and/or from retaliatory aggression.

3. Fear of death may cause temporary impotence in individuals suffering from cardiac or pulmonary disorders. Such individuals are afraid lest sexual excitement bring about a fatal attack. Unconscious feelings of guilt usually play a part here, too. Having considered themselves as "marked" by fate, such patients unconsciously live in the expectation that, at some critical moment, punitive forces will take their toll. Intercourse mobilizes these guilt feelings together with fears of retaliation.

One of my patients, who was suffering from pulmonary tuberculosis, once experienced a severe coughing attack with hemoptysis following a petting session. When, some time later, he attempted intercourse, he was impotent. In analysis he admitted that he had never really overcome the fear that sexual excitement might bring about another pulmonary hemorrhage and even death.

This and similar—partly realistic, partly hypochondriacal—fears may account for the neutralization or paralysis of the sexual drive. The conscious thought, "I want," meets head-on with the unconscious command "I mustn't," and the result is "I can't."

The symptom of impotence can protect the individual against antimoral and antisocial id acts (Goethe) as well as against dangers to the ego (castration complex or fear of death).

The finding of a castration complex as a concomitant of oedipal strivings is too ubiquitous and too general to be accepted as a valid etiologic factor. We must be able to determine what gives this complex specific significance in an individual case. The patient's history and dream material, as a rule, offer the necessary clues.

Downloaded from www.dbraulibrary.org.in

Some urologic operations, especially those connected with the use of sounds introduced into the man's urethra, and similar manipulations, may lead to a temporary increase of passive (feminine) tendencies, homosexual fantasies, etc., with the possible result that acute impotence ensues. (The urologic operation in man has been known to be an affect-charged experience, with repercussions often reaching farther than its topical character warrants.)

Of importance also are some of the patient's occasional hypochondriacal ideas concerning his physical appearance, which may lead to feelings of inadequacy. Foremost among them is the patient's idea that his penis is too small, or that the amount of his seminal fluid in ejaculation is insufficient. Examination may disprove the patient's complaints, without effecting any change in his outlook. Closer analysis then may disclose that the patient's feeling of inadequacy has sources other than his poor physical endowment. Lack of masculinity, latent homosexual trends, or fear of women are usually found behind this symptom. In reality, the length of the organ, especially in its flaccid state, is unimportant, for several reasons: (1) Many organs, while appearing undersized in the unerected state, reach normal proportions when erected. (And this is the only condition that counts.) (2) It is not the relative length of the penis that makes the difference in intercourse, but the relative degree of its engorgement, that is, the erection. (3) The length of the organ would be of importance if the woman's erogenous tissues, to be aroused in intercourse, were located in the back of the vagina, in its fornix rather than, as they are in reality, in its frontal part around the introitus. Anatomy teaches that the corpus cavernosum of the vagina straddles, as it were, the front part of the vaginal tube. (4) Barring a conspicuous disproportion between the male and female physiques, a gentle friction by the penis shaft should be sufficient to elicit an orgasm in a woman, even if the penis is of slender shape (small circumference). Under normal circumstances, the woman does not require a violent friction of the vaginal walls to be satisfied. (5) The capacity for orgasm in the woman is as much a function of her brain as it is in the man. It is the woman's psychic attitude toward the act that decides what kind and whose organ is satisfactory.

The fear of being sexually inadequate is often found in men who have an exceptionally good physique and are very popular with women. Their passive, narcissistic overvaluation of their appearance may lead them to a fear that in the sexual embrace they may not live up to the woman's expectations. As a consequence, they may develop fears of a sexual encounter or even outright impotence. Sexually, women, to them, appear as potential creditors who demand their due. Many men of this type develop unconscious feelings of hostility toward all women, an attitude which prevents them from displaying their normal sexual capacity.

Hostility toward women and various manifestations of the so-called "war between the sexes" account for many of the sexual dysfunctions in modern men. In the minds of such men, women may appear to be exploiting (gold diggers), dominating, faultfinding figures of whom they are secretly afraid. Much of this reaction stems from real life situations, from oedipal taboos, and from traumatic experiences, but much depends also on the cultural interrelations between the sexes. The man is most potent if he is most relaxed and least suspicious. Man's potency is lowest if he suspects entrapment, or if he is made to feel that, by yielding to his sexual desires, the woman has granted him a favor he does not really deserve. If a man has married this type of woman, then it still remains for the analyst to explore why he has made this choice.

One of my patients, a forty-eight-year-old man, complained that his wife demanded of him a "romantic behavior" from the early morning on, if he was to approach her at night. She claimed that otherwise she did not get into the proper mood for intimacies. The man was so anxious to be romantic all day that by night he was pretty tired and disgusted with his enforced part of a Romeo; he was then hardly in a condition to have relations.

A few words now about the so-called old-age

Downloaded from www.dbraulibrary.org

impotence. Statistical data in this respect must be taken with a grain of salt. Theoretically, the limits for sexual potency cannot be established with validity. Much depends here on circumstances, the state of health, and autosuggestion. Although we may assume that a certain degree of decline in sexual interest normally takes place between marital partners who have been living together for many years, this factor alone is rarely the cause of a complete sexual insufficiency in man. Many men who are in their late fifties begin to show the inclination to "save" their sexual power, as though it were an irreplaceable material with which they have to economize. They develop typical symptoms of a hypochondriacal neurosis. They lengthen the intervals between the acts, increase the emotional distance from the opposite sex, and, with the declining degree of physical and mental attraction, gradually lose their potency. When Kinsey speaks of the fact that, at seventy, 30 per cent of men are sexually completely inactive, this may be statistically correct, but it is subject to changes. Psychiatrists with adequate experience in sexology know that the best way to preserve normal function to a relatively old age is to retain a healthy attitude toward sex in general, to practice sexual relations regularly, and to keep the intervals between episodes relatively short.

## *Compulsive Type*

### CHASTITY CLAUSE

Among the unconscious causes of impotence, none is more baffling than the secret chastity clauses by which some individuals attempt to render their sexual life less complicated. Unless a chastity clause is brought to light and worked out analytically, cases of this type may remain incurable. Religious people may, in hours of grave mental anguish, make vows of chastity, to which they then adhere, even though these vows meanwhile have lost their meaning and have disappeared from their consciousness.

Strong incestuous fixations, particularly those based on actual incestuous relations, are often behind this readiness to sacrifice sex. They may tie a man inseparably to the incest object, with the result that no other woman can attract enough of his interest to herself to replace the original object fixation. This is especially true with cases where the self-punitive element is one of the psychodynamic motives of impotence.

Some of the chastity clauses go back to the youthful struggle against masturbation. They may retain their inhibitory force in the patient's unconscious even after the conscious struggle is over. Anxieties may then go underground, may assume the character of hypochondriacal anticipations, or the like, but they will affect the patient's relation to the opposite sex.

### DEATH CLAUSE

The second of the compulsive types of impotence is that based on the secret death clause: "If you have successful sexual relations, you (or someone else) will die." We have touched upon this subject in our discussion of the castration complex. On the unconscious level the intercourse may be considered as a challenge to the super-ego, inviting extreme retaliation. This is the case primarily if the underlying sexual object is a tabooed one; but even if this is not the case, early religious, puritanic influences may lead the patient (in his unconscious) to consider intercourse as an unpardonable sin and to mobilize self-punitive tendencies or fears of divine retaliation.

One of my patients kept himself in the condition of chastity by means of impotence in order to preserve magically the chastity of his sister. The analysis proved the existence of a magic "junction" between the patient and his sister; in their fantasy, they were like husband and wife. Neither was able to get married—she by choice, and he because of his impotence.

Only through analysis can one elicit such ideas which act from the patient's unconscious to obstruct his sexual function. In the case mentioned, it was the sister's death which ultimately made it possible for the patient to break the magic lock—one of the more fortunate coincidences of analytic practice.

## ¶ Therapy

Psychic impotence requires dynamic and rather active forms of psychotherapy. The prognosis is, on the whole, good, and suggestion, which plays a great part in the origin of the disorder, plays its role also in the results of therapy. The task of the therapist is to recognize the nature of the inhibition, that is, the reflex-obstructing, affect-charged ideas underlying the dysfunction, and to help the patient overcome the inhibition. Anxiety, hostility, and guilt feelings are among the affects involved.

From what was said before, we can see that the therapist cannot add much to the patient's sexual strength; what he must do is to remove something that inhibits the patient's performance as a pebble between the cogs of a cogwheel interferes with the normal revolutions of the wheel.

### *The Partner*

Therapy is limited by two factors—the partner and age.

As mentioned above, the woman, through the way she participates in the act and through her general demeanor, can decisively contribute to the man's success or failure in intercourse. If the woman is inaccessible to medical counsel, the man's chances of recovery—with this woman—may be seriously affected. Since intercourse is a matter of two people, we should have a chance to obtain a deposition by the other side and to get an independent idea of their mutual relationship. However, this may prove not feasible. The lack of cooperation on the part of the patient's partner can be so thorough that a direct invitation by the therapist to see him in his office may be flatly rejected.

The wife of one of my patients refused to accept my invitation with the statement that she did not need any "additional sexual enlightenment," and, since her husband was the one who was ill and in treatment, I would do well to concentrate on him. From this reaction as well as from the patient's description of his marital relationship, it was clear that the woman had no interest in her husband's recovery. She was glad that he was impotent, because she was not only free from his (annoying to her) sexual approach but she also had a welcome weapon with which she could humiliate and insult him. She was a frigid woman who, in conversations with her husband, was always complaining about the "exaggerated" sexual needs of men ("all men are beasts") and who liked to bask in her idea that she herself was above these base instincts.

I have been more successful by inviting the patient's partners to "help me understand better the patient's condition," to "make his case history more complete by adding to it her views," or by using similar phrases to stimulate the woman's interest in cooperating with therapy. (In general, a partner feels flattered if she has the opportunity to contribute something to the doctor's understanding of the mate's case. Once the woman is in our office, all pertinent problems can be discussed.) The woman's feelings of guilt, of inferiority ("with another woman he is potent; I am not attractive enough to him"), and similar reactions, may at first prevent her from exposing herself to the doctor's scrutiny. Her ego is bolstered, however, if he approaches her with a tactful request for assistance.

If the psychiatrist recognizes that the partner also requires therapy, then another therapist has to intervene in her behalf. Both therapists then proceed with their respective tasks, and they need not worry that they may not proceed synchronously. Conferences and consultations, in most cases, either will be unnecessary or can be reduced to a minimum. If they do take place, both therapists must be aware of the fact that they are treating not the marriage but two separate individuals, whose individual problems may be completely different. Greatest care must be taken not to yield to the pressures of the two marriage partners who would like to see the therapist in the role of an umpire, coordinator, and adjuster of their marriage. If the same therapist is handling

Downloaded from www.dbraum.com

both partners, attempts to influence the other partner through the analyst will invariably be made—at the expense of a systematic and effective personal analysis. The two patients should, therefore, be treated independently, and the two therapists will do well to concentrate on their own respective cases, with the hope that they can succeed in removing the essential personal conflicts which are impeding the normal development of the marital relationship. The problems in question may lie on different levels and require a different length of time and different approaches. It is only in the therapeutic goal that the therapy of both coincides.

A forty-year-old woman, in analysis with a reputable psychiatrist for a complicated personality disorder, complained that her husband did not satisfy her sexually, because he suffered from a premature emission. He was referred to me for therapy. His difficulty was removed in less than one year of treatment, but his wife's sexual response was not much improved. There was no indication for a termination of her treatment at that time. As years passed and the marital conflicts did not abate, she accused her husband of being at fault because he was not in therapy. She demanded several consultations with leading psychiatrists to prove that he needed additional treatment and kept on calling me with various complaints about her husband. I invited the man repeatedly to visit me in order to evaluate whether any traces of pathologic behavior could be found in the patient's relation to his wife, but I was unable to detect any. On the contrary, I was more and more convinced that the patient's wife, a severely sick person, in her extraordinary narcissism, considered as a major personal defeat the fact that her husband was finished with his treatment while she was still in therapy. Rivalry between husband and wife characterized this marriage from the very beginning. She was the daughter of a wealthy industrialist and could not accept the fact that her husband, who was once a "poor boy," had found a "soft spot" in her father's business. It was hard for her analyst to restrain her from incessant attempts to prove that the difficulties in her marriage were entirely his fault.

### *Age*

Another limitation in the treatment of impotence is age. This does not mean the absolute chronologic point at which the prognosis begins to be unfavorable; it is governed, rather, by the relative state of health and the social circumstances which accompany the advancing years in a man's life. An elderly man may be sexually less attractive, may be suffering from all sorts of intercurrent discomforts of his age, such as greater fatigability, more apprehensiveness, more self-consciousness, discouragement, or even functional difficulties due to vascular or prostatic changes, but, as stated above, he may not show a distinctly lowered potency.

Psychotherapy of elderly patients, as a rule, is less promising—regardless of the neurosis involved—because they are not as flexible, not as ready to change their habits and traits as are younger individuals. The same applies to the chances of psychotherapy of the so-called "old-age impotence," although remarkable results of dynamic psychotherapy can be seen in some cases of this type.

Old-age impotence must be considered as unfavorable prognostically if it has existed for many years. While in younger individuals even a prolonged duration of impotence may come to an abrupt end, in older people, prolonged insufficiency creates, as a rule, so many secondary characterological changes and becomes so fixed as to be irreversible.

A fifty-nine-year-old physician had suffered from ejaculatio praecox since his early manhood. In addition, he showed various personality changes of a compulsive-obsessive character, and he was unable to establish a regular relationship either in his sex life or in therapy. He was married but had been separated from his wife for years, and even when he joined her geographically, he did not consider himself bound sexually to her. In his continuous promiscuous relations the pattern of premature emission remained unchanged. He failed to profit from psychotherapy, in which he did not believe, but he adhered to all sorts of faddist dietary regimes.

The experienced therapist does not promise

Downloaded from www.dbraulibrary.org.in

cure, despite the value of such suggestive influence. However, the therapist must be firm and persistent in the face of the patient's discouragement, and must pursue the search for the unconscious pathogenic elements of the patient's neurosis.

While this is done, the therapist must gradually eliminate any individual fallacies concerning sex that the patient may harbor. It is not only indicated but is of definite value to make sure that the patient has correct ideas concerning sexual hygiene, masturbation, female anatomy and psychology, contraception, and all the problems involved in mature sexual relations, with all due consideration paid to the specific cultural, religious, and personal conditions existing.

It is regrettable that, despite analytic penetration and working through the individual problems of the patient, some cases of impotence remain unchanged. It is as though the impotence in these cases had become a habit, a fixed experience, a "pattern of defeat." To prevent such reactions and to counteract the patient's autosuggestion of failure ("I cannot"), at the beginning of therapy it is desirable to discourage intercourse attempts. (The patient must inform his partner about this.) One advantage is obvious: The patient spares himself additional disappointments, which previously reinforced his autosuggestion of failure. The other advantage lies in the fact that the fixed idea "I cannot" shifts—by doctor's orders—to "I mustn't." The experience teaches that it is easier to break the bond of a prohibition than that of a fixed idea. In many cases the artificial taboo is soon broken, the patient performs a normal intercourse, and the analytic work can proceed more auspiciously.

This method does not apply to cases of ejaculatio praecox or those where chastity or other clauses guard the patient's sexual activity. In the first case, we do not profit from expanding the patient's abstinence; in the second, sexual inactivity is the patient's unconscious goal anyway.

The chances are better when both partners are available for counsel or therapy. It is a poor policy to treat a sexual dysfunction "in a vacuum," as it were. To declare the analysis as finished and the patient as "ready" to go ahead and start looking for a suitable partner is a risky proposition. Even after a thorough analysis, many complications may still develop on the road to practical adjustment, and these must be dealt with as they occur.

An organic therapy of the psychogenic impotence is inadvisable for many reasons:

1. An endocrinologic treatment is justified only if proof has been established that a glandular deficiency exists. This expensive treatment remains otherwise unsuccessful. In some cases it may be harmful (carcinogenic). In cases where impotence serves as protection against antisocial tendencies, a sexual stimulant—even if it were effective—would be undesirable.

2. Drugs (introduced orally or parenterally), diathermy, prostate massage, instillations, sounds, etc., are contraindicated, except in cases in which psychotherapy is not feasible. They draw attention to an already overcathected organ; they cause the patient to expect help from mechanical devices without making an effort to effect changes by himself; they foster passive, feminine, and receptive, rather than active, masculine, penetrative tendencies.

We must not forget that psychogenic impotence is not a disease of the genital apparatus. Huhner and others, who pointed out that in many cases of impotence "chronic congestion" existed in the verumontanum, did not take into consideration that congestion, even if diagnosed, might have been a product of overstimulation of a functionally inactive organ, and that it would disappear without local therapy once normal intercourse had been resumed. The same can be said about the so-called Huhner operation (ligation of the dorsal vein). Its occasional success can be considered as purely suggestive.

Aycock[1] suggested cocainization of the glans penis, prepuce, and adjacent shaft to combat premature ejaculation. Intercourse with an anesthetized penis, even if possible, is not to every man's liking.

Psychotherapeutic methods such as sugges-

Downloaded from www.dbraulibrary.org.in

tion (hypnosis), if effective at all, prove to be short-lived. As a rule, they do not reach the level of the patient's personality on which the pathogenic forces operate.

For similar reasons, a combined organic and psychic therapy must be rejected. The organic therapy appears to confirm that an organic disturbance is responsible for the dysfunction. Such ideas cannot be accepted without jeopardizing the psychogenic concept. Therefore, a combined therapy cannot but weaken the impact of psychotherapy.

After the patient has had his first successful intercourse, the psychotherapist should not express too much surprise. It is advisable to say casually: "You have now seen that your conviction of being impotent was wrong. Any man may fail under adverse circumstances."

However, this is not a point at which we can discharge the patient. The analyst must make sure that the success has a chance to be rooted, that all potential pitfalls have been discussed and worked through, and that the patient's self-confidence has been strengthened sufficiently to permit him to navigate on his own.

## ¶ Impotence and Marriage

We consider it a rule that the man's disorder must be treated before marriage can be contemplated. Marriage should never become a therapy. Only in exceptional cases can marriage be encouraged before the disorder has been eliminated, namely, if the moral and social circumstances make premarital ("test") intercourse impossible. But even then, the therapist will do well not to suggest marriage directly or to take any responsibility for its outcome. A good way to handle this special situation is to remark that, according to the analytic findings, the best possible condition for the man's potency lies in a marital union. Of course, such a statement can be made only after an extensive study of the case and after a thorough evaluation of all pertinent factors.

CHAPTER 37

# SEXUAL FUNCTIONS IN WOMEN AND THEIR DISTURBANCE

Therese F. Benedek

Downloaded from www.dbraulibrary.org.in

THE AIM OF THIS CHAPTER is to present the interaction of physiologic and psychologic factors in the sexual functions in women and to demonstrate the dynamic principles of the psychopathology related to the female reproductive functions.

## ¶ Introduction

Psychoanalytic theory is based on the axiom that motivational forces originate in organic sources. The spectacular experiments, around the turn of the century, regarding the sexual glands seemed to confirm Freud's early assumption that the sexual drive and its concomitant psychic energy (libido) originate in a specific "sexual chemism." Freud[28] established his concept of the role which sexual energy plays in the development and integration of the personality. He limited his formulations to the observations obtained by psychoanalytic method and expressed the hope that endocrinology would hold the answers to the problems of normal and abnormal sexual behavior. In the same publication he formulated a sequence of psychosexual development from infancy on. Freud's thesis of infantile sexuality, a basic tenet of psychoanalysis, was at variance with both the general medical and the psychiatric thinking as well as with the results of endocrinology.

After isolation and synthesis of the steroid hormones, experiments on lower mammals seemed to confirm the thesis that sexual behavior is under simple chemical control. It was established that in lower mammals the cyclical function of the ovaries governs sexual behavior. Mating occurs at the height of the periodically recurring estrus (heat), which is recognizable in the animals' activities leading to copulation. Observations in primates, how-

ever, reveal discrepancies in the proportional relationship of gonadal function and mating behavior. Primates can be stimulated to sexual activity by a variety of factors independent of estrus. In man the complex and variable stimuli which motivate sexual behavior may almost completely conceal the physiological cycle. Further investigations regarding the function of gonadal hormones revealed that sexual behavior cannot be explained simply in terms of gonadal function. It is known that gonadal hormones are absolutely necessary for the completion of the maturational processes which lead to procreation. One assumes that the physiological role of the gonadal hormones is defined by a genetically determined responsiveness of the nervous mechanisms, and that hormones are merely facilitating agents which increase the reactivity of the specific neuromuscular system to stimulation; thus, they influence the thresholds of response patterns.[5] In man the primary reactivity of the nervous system to internal and external stimuli becomes highly complicated by environmental factors which modify the stimuli interacting with the organism, causing variations in the personality organization. These, in turn, account for individual variations in the responses to stimuli.

It is the specifically human quality of the psychic apparatus that allows for the variability of behavior patterns in response to hormonal stimulation. Psychoanalytic theories which bear upon these phenomena are usually presented from two viewpoints: one refers to the theory of instincts, the other to the theory of personality development. In Chap. 3, which deals with the theory of instincts, such processes as repression, displacement, symbolization, etc., are discussed. These processes, functioning unconsciously, make human instincts appear plastic and adaptable. Chapter 69 describes the development through which each individual, in the process of attaining sexual maturity, incorporates in his psychic apparatus the controlling functions of his ego and super-ego. As the super-ego develops in each individual, as a result of the interaction of the organism with its environment, it also participates in the organization of the sexual drive toward its mature function. In the transactional processes between sexual maturation and personality development, the physiologic substratum of the sexual drive may become disguised; the pattern of its organization and response may seem to be motivated by psychic processes so far remote from its physiological substratum as to appear independent from it. Another science—ethology—revived the interest of psychoanalysts in the theory of instincts. While there is a trend to emphasize what differentiates man from other mammals, it is to be hoped that careful studies of the psychologic and hormonal processes will elucidate the hierarchical organization in the chains of motivation of human behavior.

## ¶ Developmental Factors

The sex of the individual is determined at the time of fertilization of the egg through the chromosomal make-up of the gametes (the egg and the sperm nucleus). Through this, the embryo is endowed with a potentiality to develop toward one sex. All the necessary rudimentary tissues for the development of both the male and female sex organs are present in every embryo. Embryonic hormones (estrogens and androgens) and embryonic organizers[16] direct the maturation of the sex patterns toward the sex which, after the ninth week of gestation, begins to be recognizable to the embryologist as the sex of the individual determined at conception. There is evidence, however, that this development is not completely safe and secure. Experiments show that sex patterns can be reversed by inundation of the embryo with hormones given to the mother during pregnancy.[10] Thus, "sex intergrades" develop not on the basis of gene-determined heredity but by "external" hormonal conditions. This accounts for various degrees of bisexuality at birth.[33] In the neuromuscular and psychic structures of both sexes remain rudimentary patterns of response and activity characteristic for the other sex. (The significance of the clitoris for the psychosexual

Downloaded from www.dbraulibrary.org.in

development and experience of women indicates that this may be more true for the female than for the male.) In our further discussion the term "bisexuality" refers, however, not to any physical form of sex intergrade, but to a specific predisposition for certain psychologic reactions to environmental influences which exert control over the further development of the personality.

The environment of the newborn is defined in a significant way by the still-existing symbiosis between mother and infant. Through lactation the mother transmits some of her hormones to the infant. But more significant is the fact that, through lactation and other activities of mothering, there exists a reciprocal interaction between mother and infant which determines the meaning of the primary identifications with the mother and the primary ego-structures which result from them.[10] When the infant integrates the memory trace, needs are gratified; with his developing confidence in his mother, he establishes confidence in his own well-being, in his thriving, "good self." With memory traces of frustrating experiences, he integrates the image of the frustrating mother as "bad mother" and himself as a crying, frustrated "bad self." These primary ego-structures, originating in the rudimentary emotional experiences of early infancy, are significant for the infants of either sex. Since the development of the male does not interest us here, it suffices to say that in the girl the primary ego-structures determine the emotional content of later identifications with the mother. The innate femaleness of the girl directs her development in step-by-step identification with her mother. The positive psychologic balance of the early alimentary phase, which accounts for confidence, facilitates a relatively conflict-free development toward the female reproductive goal. The incorporated reaction to frustration (ambivalence), on the other hand, charges the mother-identification with hostile tendencies which interfere with the development toward femininity. It brings about a development in which, because of the wish to reject femininity, the bisexual tendency becomes preponderant. Such an outcome of the girl's identification with her mother demonstrates the psychologic factors in bisexuality.

As far as our present knowledge goes, hormones play no discernible role in the psychic manifestations of pregenital development. Children of both sexes excrete in their urine both androgenic and estrogenic hormones. These remain on a low oscillating level until the age of six to seven years, when there is a fairly sharp increase in the hormone production in both sexes.[19] There is no evidence of an increase in hormone production in correlation with the oedipal phase of development.* The marked upward trend at the age of six to seven coincides with the beginning of the latency period. Both hormones show a slow and steady rise until the age of ten to eleven. However, neither the testes in boys nor the secondary sex structures in either sex show any acceleration in growth until after that time. This indicates that the hormone production during the latency period is extragonadal, originating in the adrenal cortex rather than in the gonad.†

The latency period slowly evolves into the period which Helene Deutsch[18] defined as prepuberty and characterized as the girl's "last stand" against femininity, which, in turn,

* There are investigations which report on the excretion of estrogenic and androgenic hormones as beginning at the age of two to three years.

The oedipal phase is referred to here only because of its significance for the intensification of bisexual tendencies. The prephallic development may determine the girl's tendency to identify with the opposite sex as a defense against heterosexual impulses. Through the intense wish to have a penis, the clitoris becomes highly cathected. In consequence, the psychosexual development remains fixated in the phallic (pregenital) level of organization. This interferes with an undisturbed development toward reproductive maturity.

† We may speculate whether the extragonadal steroid hormones have other than sexual functions. The study of the sexual cycle reveals that, corresponding to increased estrogen production, the ego appears to be supplied with more energy, which is manifested in an increased strength of the ego. The positive response of the integrative capacity of the ego to estrogenic hormones (androgenic hormones have the same effect in both sexes) is an impressive corroboration of Freud's concept that libido is a psychic energy aiming at greater integration. During the latency period the personality enlarges its field of action externally and stabilizes its organization internally. It is not impossible that in these processes the extragonadal steroid hormones (in synergy with the corticosteroids, etc.) have some function.

Digitized for www.sharmajyoti.in

gradually gives ground as the physiological maturation proceeds. From puberty (the appearance of the physiological signs of sexual maturation) until full functional maturity is attained, several years pass. Puberty is induced by the function of the anterior lobe of the pituitary gland which secretes a gonadotrophic hormone. This stimulates the ovaries to produce estrogenic hormones and to promote the growth of the ovarian follicles. At about the age of ten to eleven years girls show a marked rise in estrogen production but not in androgenic substances. Estrogenic hormone is the hormone of preparation. Produced from childhood on, at the time of early puberty its function is to stimulate the growth of the secondary sex characteristics and the genital organs. Estrogenic hormone levels continue to increase and later assume a cyclic variation as a consequence of the rhythmic ovarian activity, which is brought about by ovulation. Estrogens thus prepare the uterus and maintain it ready for the changes that will be imposed upon it by the corpus luteum.*[15]

## *Menstruation*

Menarche—the first menstruation—may occur at any time from the beginning of puberty through adolescence. The onset of menstruation takes the central place among all events of the girl's puberty. As if menarche were a puberty rite cast upon women by nature itself, it is expected to be accompanied by intense emotional reactions. However, the anticipation of menstruation, as well as conscious response to it, are influenced by cultural factors. In our present civilization, education and hygiene prepare the girl for the menarche in a sympathetic way. This seems not only to diminish the manifest rebellion against menstruation but makes the girl expect it with eagerness. Yet the bleeding and the discomfort may stir up latent anxiety (originating in the bisexual aspect of development). It was one of the early psychoanalytic observations that women connect menstruation with the idea of mutilation. Even mature women may dream about bloody acts which they commit or which are committed upon them about the time of menstruation. This type of anxiety dream indicates that menstruation represents injury to the woman. But whether the injury necessarily means castration in the sense of penis envy remains to be investigated in each case. Menstruation forecasts the pain of defloration, and even more significant injuries connected with childbearing. It enforces the awareness of the uterus through more or less pain and discomfort. At the same time, it activates the process of integration of the latent partial identifications with the mother toward the future task of childbearing. Fliess[23] recently formulated this theory by calling attention to the womb (*Gebär-mutter*) as a symbol of the mother. When menstruation stimulates the awareness of the uterus as an integral part of the body, "mother enters the body" (*ibid.*, p. 216). The next step in the girl's development is to accept "mother = womb" as a part of the self, and with it to accept herself as a future mother and motherhood as a goal of her femininity. The maturation toward the female reproductive goal depends upon the previous developmental identifications with the mother. If these identifications are not charged with hostility, the girl is able to accept her heterosexual desires without anxiety and motherhood as a desired goal. This, in turn, determines the girl's reaction to menstruation. If the feminine sexual function is desired, the girl accepts menstruation without undue protest. In contrast, if the phallic (bisexual) fixation dominates the psychosexual development, the hostility toward the mother continues as a protest against menstruation, and also against other aspects of femininity.

The onset of menstruation used to be taken as a sign of sexual maturity. It is now accepted that menstruation begins in most girls before their ovaries are capable of producing mature ova, and ovulation may take place before the

* It should be emphasized that the sex and psychosexual development are not the function of estrogenic hormones alone. In cases of ovarian atresia, the woman may remain underdeveloped physically and emotionally, and certainly she does not menstruate or bear children, but she is neither a male nor a neutral individual but still a woman.

Downloaded from www.pdfbooksinfo.blogspot.in

uterus is mature enough to support normal gestation. This brings about a period of adolescent sterility* (Pratt,[41] p. 1277).

Knowing the adolescent's struggle for achieving psychosexual maturity in our society, one is inclined to assume that the processes which lead to super-ego development, that is, to the incorporation of parental and cultural inhibitions, necessarily lead to a delay of the physiological maturation of the reproductive functions. Yet the correlation is not a simple one. While arrestation of physiological maturation may occur on the basis of inhibiting emotional factors, one cannot make the generalization that the stronger the prohibitions, and the related anxiety and guilt, the longer will sexual maturation be delayed. In this regard, constitutional, genetic, and intrauterine influences may determine the effectiveness of the emotional factors. If all variations were to be arranged in a continuous series, at one end would be those cases in which the stability of the physiological processes is such that normal reproductive maturation is not influenced by emotions, and at the other end would be those in which emotional factors can permanently arrest maturation. The greatest number will lie between the extremes and present a variety of disturbances in sequence and coordination of the various phases of the sexual functions. Correct psychosomatic diagnosis tends to evaluate the proportionate relation and interaction of organic and psychologic factors in each symptom. This general principle of psychosomatic pathology is pointed out here in connection with menstruation, since we look upon menstruation as a cornerstone of female development, a focal point where physiologic and psychologic factors meet and reveal whether the adaptation to the sexual function will succeed or fail. Here again, it should be emphasized that the great majority of cases lie in the middle range and succeed in overcoming initial symptoms and intermittent difficulties.

* Young and Yerkes[46] collected data on chimpanzees indicating adolescent sterility. There appear to be differences in the timing and coordination of the physiologic processes of the reproductive function, even if maturation is not complicated by psychological factors imposed upon the individual by sexual restrictions. Concerning human development, adolescent sterility was detected at first in civilizations where there is free sexual play and copulation between adolescent males and females.[28]

## ¶ The Sexual Cycle

In woman, the ebb and flow of the gonadal hormone production renders the interaction between endocrine functions and psychodynamic processes accessible to study. The first such investigation was published by the author in collaboration with B. B. Rubenstein.[12] In spite of the complex and variable superstructure of human personality, it was demonstrated that the emotional manifestations of the sexual drive evolve in correspondence with the ovarian hormone production; the gonadal cycle and the psychodynamic response pattern represent a psychosomatic unit—the sexual cycle.

The cycle begins with the gradual production of estrogen; parallel with this the emotions are motivated by an active object-directed heterosexual tendency. Its biological aim is to bring about copulation. The estrogenic phase is usually accompanied by a sense of well-being and alertness. The normal manifestations of the heterosexual tendency are easily recognizable in dreams and fantasies, in conscious emotional attitudes as well as in behavior. If the desire is not satisfied, the emotional tension may increase; restlessness and irritability are often signs of thwarted sexual urge in adult women. For the psychologist it is important to recognize the heterosexual tendency in its disguises as it appears in immature or inhibited individuals. In these persons, parallel to the increasing hormonal production, the characteristic defense against sexuality can be observed; anxiety and hostility toward men may express heterosexual tendencies by covering them up.

About the time of ovulation the active sexual energy fuses with the passive receptive tendency and creates the highest level of psychosexual integration, that is, the biological and emotional readiness for conception. If frustration is anticipated, the increased physio-

Downloaded from www.pbookshop.com

logical tension stirs up suppressed conflicts; these may be expressed through dreams and fantasies and may bring about exacerbation of symptoms. In the enhanced libidinal readiness, or if this is thwarted, in the increased emotional tension, the preovulative phase can be recognized.

After ovulation the tension is suddenly relieved, and a period of relaxation follows. Ovulation is a unique physiological event, since it is accompanied by systemic reactions. Of the physiologic signs of the systemic reactions, the best known is heightened basal body temperature. On the psychological side, a sense of relaxation and well-being seems to flood the woman with libido. As if the psychic apparatus has registered the somatic preparations for pregnancy, the emotional concern shifts to the body and its welfare. This is a high-hormone phase, since both estrogen and progesterone are produced. Yet the active heterosexual tendencies appear to be masked by psychological expression of the preparation for motherhood. Parallel with the preparation of the uterine mucosa for nidation, the emotional manifestations of intensified receptive-retentive tendencies represent the psychological preparation for pregnancy. Correspondingly, the overt behavior, as well as dreams and fantasies, reveal the wish to receive and retain. The manifestations of the emotional preparation depend on many factors such as age, the level of emotional maturity, and external conditions such as marital status. (Economic insecurity may turn the wish for pregnancy into fear.) In neurotic individuals and in growing girls, the tendency toward childbearing is often expressed as a wish to be a child and be taken care of by the mother, or it may appear in conflicts, complaints, and frustrations about inadequate love and care. Generally, the psychologic material of the progesterone phase in adolescents is characterized by the repetition of conflicts related to the mother in various phases of development. Mood changes, overeating, and/or anorexia may occur during this phase of the cycle. As the physiologic and emotional maturation progresses, the progesterone phase reflects the "reconciliation" with the mother, the resolution of the conflicting tendencies toward motherhood. The psychological material reflects the mature woman's wish for childbearing and her tendency to give and to take care of children.

Upon the decline of progesterone production, the premenstrual phase follows. Parallel with the diminishing hormone production, a regression of the psychosexual integration takes place; pregenital manifestations of urethral, anal, and genital eliminative tendencies motivate the psychodynamic trends. Very few women are completely free from mood changes and from discomfort during this part of the cycle. The symptom manifestations show great variation. Apprehension of what will happen to one's body, fear of mutilation, and recurrence of other infantile sexual fantasies may give rise to anxiety, excitability, and anger. In other cases, fatigue, crankiness, sensitiveness to being hurt, or weeping spells indicate a calmer but not much more agreeable condition. The psychodynamic regression and the generally increased irritability of the sympathetic nervous system are manifestations of "the moderate degree of ovarian deficiency of the premenstrual phase" (Hoskins,[38] p. 295). These factors are responsible for the fact that at this time all needs and desires appear imperative, all frustrations seem unbearable; the emotions are less controlled than at any other time during the cycle. While this explains the "recurrent neuroses of women,"[14] it is significant also for the manifestations of sexual behavior. The heterosexual desire which is stimulated by the estrogenic production of the premenstrual phase often appears more intense and demanding than the sexual desire at the peak of the cycle (ovulation).*

The end of the sexual cycle is marked by menstrual flow which, ushered in by a sudden decrease of hormone production, continues for several days. Soon after the flow is established, the tense and fearful mood relaxes, the excitability decreases. It seems that adult women accept the menstrual flow with emotional

* Comparative analyses of the heterosexual drive in the different phases of the cycle show that during the ovulative phase the sexual desire is modified by passive receptive tendencies, and during the late premenstrual phase by eliminative tendencies which may account for the urgency of the sexual wish.

Downloaded from www.psychosomaticmedicine.org

relief. The depressive mood usually lasts longer than the premenstrual excitability, and continues during the first days of the flow. Women then recall sad experiences and talk about death and abortions. The mood and the content reveal a regret over failure in achieving pregnancy. In other cases, or in other cycles, the mood is dominated by inferiority feelings; the women depreciate themselves and the female genitals which they feel are worthless, and complain about menstruation which is regarded as superfluous, senseless, dirty. This depressive mood usually continues until the new estrogen phase re-establishes itself. After a few days, normally during the flow, the estrogen development begins, and parallel to it the state of well-being recurs. This, with the increasing sexual desire, suggests the beginning of the new cycle.

This schematic outline of the sexual cycle suffices to demonstrate that the gonadal hormones force the emotional processes of the adult woman into regulated channels. On the other side of the ledger is the influence which emotions exert upon the hormonal cycle. A comparative study of a series of cycles in the same woman reveals the effects which stimulating and inhibiting emotional factors have upon the course of the gonadal cycle. It is well known that emotions may precipitate or delay the menstrual flow; less known is the fact that the time of ovulation also may vary under emotional influence. For example, gratifying or exciting heterosexual intercourse may facilitate ovulation, while sexual frustration or fear of childbearing may inhibit it. The variation in the time of ovulation is such that probably no immutable period of infertility exists in the human species (although this condition is approximately reached in the last week preceding menstruation). Besides such direct and immediate effects of emotions upon the hormonal cycle, psychic factors exert a long-term (developmental) influence on the gonads. The comparative study of the sexual cycle of several individuals reveals that the pattern of the cycle unfolds in interaction with the constitutional and environmental factors which determine the developmental organization of the personality. In the evolution of the gonadal cycle, estrogen production is necessary for the completion of ovulation and for the ensuing progesterone phase. Similarly, in the integration of psychosexual maturity, the capacity for heterosexual love prepares the woman for acceptance of the feminine sexual role, and, with it, not only for the physiological processes of childbearing but also for its emotional manifestations in motherliness. Just as the psychosexual maturation is an interrelated sequence of physiological processes, so the phases of the sexual cycle represent a transactional sequence, one phase determining the course of the other. Thus, the gonadal cycle shows individual patterns. The length of the cycle, the time of ovulation, the frequency of anovulatory cycles, menstrual symptoms, etc. appear to be peculiar to the individual. The most obvious characteristic of the cycle is the interval between menstruations. The average length is twenty-eight days. But the normal range extends from twenty-one to thirty-five days. Careful investigations, however, show that there are always slight variations in the length of the cycle even in those women who seem to be certain of their regular twenty-eight-day cycle. Most revealing for the pattern of the hormonal cycle is the intricate relationship between the estrogen and progesterone phases of the cycle.

Progesterone is the hormone of maturity.[15] While estrogen—the hormone of preparation—is produced in varying degrees from infancy on, progesterone appears only after puberty as a function of the ovum. It is understandable that its relation to estrogen production, its relative deficiency or its preponderance, determines the variations of the cycle. If the individual reaches normal sexual maturity without fixating traumata in the pregenital phases, the hormone cycles, that is, the relationship between the estrogen and progesterone phases of the cycle, will be normal; this implies practically normal ovulation and normal length of the cycle. If—because of organic disposition or crippling traumata, or on account of the interaction of both—fixation occurs on a pregenital level, the disturbance of the psychosexual maturation is reflected in the cycle. For example, in puerile bisexual individuals, the prog-

Downloaded from www.vidyanidhi.org.in

gesterone phase does not develop fully; they usually have short cycles. Women whose infantile fixation causes a prevalence of receptive-retentive tendencies (as in cases of bulimia or obesity) usually have long progesterone phases and long cycles. If the psychosexual development is even more inhibited, long low-hormone periods characterize the cycle; menstrual flow may occur with irregularities still within the normal range.

## *The Organization of the Reproductive Drive*

Study of the sexual cycle reveals that the sexual drive is organized differently in male and female in order to serve specific functions in procreation. The propagative function of the male under the control of one hormone group (androgens) is discharged in one act; the male sexual drive is organized to motivate this act. Corresponding to the two phases of the female propagative function, the female sexual drive evolves consecutively (1) to motivate the heterosexual act, and (2) to supply the psychodynamic correlates of pregnancy and lactation. The psychoanalytic concepts of sexual maturity are based on the organization of male sexuality. The term "genital primacy" refers to a drive organization which is consummated in heterosexual coitus climaxing in orgasm. Female sexuality cannot fit into this model, since heterosexual intercourse is, from the point of view of reproduction, only a preparatory act. Pregnancy and lactation constitute the completion of psychosexual and reproductive maturity in women. Yet the drive organization which motivates pregnancy and lactation is not genital in the same sense as is mating behavior. Helene Deutsch, in an early publication,[17] assumed that the female sexual drive achieves its orgastic discharge by reaching its reproductive goal in parturition. Parturition, however, is not orgasm, in spite of the immensity of discharge and detumescence. Lactation and the activities of mothering are complex behavior patterns; in spite of their oral drive-organization, these functions necessitate a higher level of cortical and psychologic integration than the heterosexual act requires.[5] Freud assumed that psychosexual maturity in women is connected with genital primacy which, parallel to male orgasm, culminates in vaginal orgasm.

## *Orgasm*

The meaning of orgasm in women is obscured by the concept that sensations localized in the clitoris should be transferred, with genital maturity, to the vagina and the clitoris should lose its significance for orgasm. Thus, it is assumed that vaginal orgasm is analogous to male orgasm and, as such, is the badge of genital maturity. Recent histological investigations have shown that the sensory cells known as "genital corpuscles," which are end organs for the perception of orgasm, are confined predominantly to the glans clitoridis in women, just as in men they are localized in the homologous glans penis. They can be found also in the labia minora and in the muscles of the lower vagina. In general, the vagina has no sensory nerves; embryologically, it is homologous to the shaft of the penis. The mechanism of female orgasm and the interplay between clitoral and vaginal orgastic experience become understandable if one approaches the problem from its central neurological innervation. It is accepted that in man there is an orgastic spinal center in the sacral segment of the spinal cord; this receives stimuli from higher cortical sensory receptors. The normal male orgasm is a result of a combination of cortical and spinal mechanisms. The assumption of similar interaction in women clarifies several baffling problems of orgasm.[38] Since the spinal center responds with a reflex to mechanical stimulation, clitoral orgasm can be elicited in each instance, unless cortical inhibition is so severe that it suppresses the reflex. Cortical influences, sexual attraction, love, fantasy, and willingness to accept the sexual role, etc., not only stimulate the spinal center but permit the woman to relax and experience the pleasurable sensations, which, beginning in the clitoris, spread through the vaginal walls and finally encompass her whole body in orgasm. Since the physical stimulation in vaginal intercourse does not occur primarily

Downloaded from www.edupsy.org

in the vaginal wall and mucosa, and since some clitoral stimulation is an important factor leading to orgasm, "The difference between so-called clitoral and vaginal orgasm is explicable not in terms of the different origin or location of the orgastic response, but in the different intensity of it and in the degree to which cortical factors are contributory"[38] (p. 243).

## ¶ Dysfunctions of Heterosexuality

The processes of psychosexual development predispose women to pathology originating either in the heterosexual or in the childbearing aspect of the drive organization. However, because of the reciprocal interaction between the phases of the sexual cycle on the one hand, and between these and the emotional processes on the other, the manifest symptoms may represent disturbance of either or both phases of the reproductive function. Most of the psychosomatic symptoms discussed under this heading originate in heterosexual conflicts and in inhibitions of heterosexual development.

### *Frigidity*

Frigidity is the most frequent psychosexual dysfunction and can be related to the ovarian function only in rare cases of severe hypogonadism. In all other instances, women may have any form and degree of frigidity and at the same time normal gonadal function. Sexual intercourse is a physiologic and emotional transaction of the partners; their mutual excitation facilitates the processes which lead to orgasm. In women, more so than in men, the quality of sexual experience depends upon the mate, upon his potency, skill, and ability to overcome her sexual fear. The complexity of sexual maturation in women is apt to create defenses against sexuality. Fear of being injured by the penis, fear of pregnancy, envy and hostility to men often bring about inhibitions in the woman's capacity for orgasm. Since the social and emotional significance of frigidity is different from that of impotence, women can use the suppression of their own sexual needs as a weapon against their husbands. This was especially true in times past when orgasm, or the desire for it, was considered unwomanly. Since most women now freely admit their sexual desire, they often respond to the lack of complete orgasm with a sense of inferiority. This increases the anticipation of frustration. Because of this, such women often anxiously watch the sexual act and control it with hostile impatience; thus they interfere with what they seemingly are eager to achieve. Underlying such behavior is a narcissistic defense originating in penis envy.[25] This may become increased by the modern woman's concept of sexuality, by the expectation or demand that she *has to* reach vaginal orgasm and suppress clitoral sensations. Women who are able to assume the role of passive cooperation, who are less anxious and more giving in their receptiveness, gain a greater emotional gratification even by partial orgastic discharge. Dyspareunia (painful sexual intercourse) may be caused by local traumata, by pathologic and inflammatory lesions due to mechanical and anatomic anomalies of the urogenital structures. Dyspareunia is psychogenic when psychogenic pain, or fear of pain, is utilized to render intercourse unbearable or highly unpleasant. Vaginismus is an involuntary spasm of the vaginal muscles, always psychogenic in origin. While it protects the woman from the pain she fears, she suffers a pain which is brought about unconsciously. This is a conversion symptom. Above and beyond the sexual fantasies which the symptom may express, vaginismus achieves its unconscious goal by excluding the penis, by expelling it, or by painfully enclosing it. Sadistic and masochistic tendencies fuse in this symptom with urethral and anal eliminative and retentive tendencies. Thus, vaginismus can be compared to ejaculatio praecox or ejaculatio retardata. Since the vagina is a receptive organ, vaginismus can be considered as an expression of powerful incorporative tendencies; it seems to be the realization of the idea of "vagina dentata," the hurtful female genital. Vaginismus occurs usually in young women whose psychosexual make-up reveals,

Downloaded from www.brainbrary.com

beside pregenital fixations, a general sexual infantilism. This is expressed not only in their emotional life but also in the incompleteness of their sexual cycles. At present we can consider this as a corresponding manifestation of psychosexual immaturity. It is, however, justifiable to assume that the factors which cause frigidity suppress the ovarian function through the emotional media of anger, fear, and frustration.

Psychogenic frigidity is considered a causative factor in organic conditions, such as vulvitis, leukorrhea, vaginitis, some forms of endometritis, and even of tumors of the uterus.[37] The mechanisms by which the unreleased genital tension leads to organic and psychiatric symptoms are manifold and depend on the total personality. Freud assumed that, in cases of chronic frustration, the dammed-up libido brings about the symptoms of actual neurosis,[28] such as anxiety, hypochondriasis, pelvic pains, etc. These again might bring about more organic symptoms through the involvement of autonomic innervation, causing vasodilatation of pelvic and sexual tissues. Since the psychologic factors which lead to frigidity may suppress the ovarian function, these symptoms are not caused by dammed-up libido but rather by lack of libido because of faulty sexual chemism. Better knowledge of the metabolism of the ovarian hormones may throw light upon these processes.

## *Menstrual Disorders*

The bulk of psychosomatic gynecology deals with disturbances of menstruation. In general, psychic factors play a role in all forms of menstrual disorders. Menstruation itself may be considered as a precipitating factor: it mobilizes unconscious conflicts related to female sexual function.

The term "dysmenorrhea" designates various forms of painful menstruation. Each individual has essentially the same symptoms with each dysmenorrheal state. This suggests some organic predisposing factors, such as immaturity of the pelvic organs, faulty response to gonadal hormones, or circulatory and autonomic imbalance. Four clinical forms of dysmenorrhea are distinguished: (1) pains resembling those of labor with discharge of blood clots; (2) pain from hyperemia and distention occurring shortly before the onset of menstruation and subsiding after the flow is established; (3) membranous dysmenorrhea; and (4) menstrual colic. Menstrual colic is the most frequent form of dysmenorrhea; its symptoms include abdominal distress, nausea, and vomiting. Migraine, tachycardia, bradycardia, anxiety states, and fainting spells may develop with any of these conditions.

Investigations indicate that women who suffer from dysmenorrhea have a relatively low pain threshold.[31] Whether this can be attributed to an infantile personality organization, to a "weak ego," or to other factors, the low tolerance to pain increases the anxious anticipation of the menstruation, and thus stimulates the emotional defenses against it. While most women adjust to menstruation, and by this diminish the experience of pain, the expectation of the cyclical pain renders the hypersensitive woman either sick, helpless, or rebellious against her fate.*

It seems clinically useful to differentiate between the commonly occurring premenstrual distress (as described in the course of the normal sexual cycle) and the more severe premenstrual tension and depression. While they are not necessarily precursors of dysmenorrheal states, the latter may be often accompanied by a feeling of helpless wrath. The syndrome may imitate an agitated depression; a sense of frustration, anger, and restlessness fills with activity the unloving "arid" woman. The other type of premenstrual depression is characterized by sadness, withdrawal, increased sensitivity, and hypochondriacal anxiety. Migraine and other forms of severe headaches often occur. The pathogenesis of the syndrome is complex. In a nutshell: hormonal imbalance is responsible for electrolyte and fluid changes in tissues and for reactions of the autonomic nervous system.[32] These, in turn, interact with

* In investigating the psychologic factors which may motivate a symptom, we now consider not only the developmental conflicts which cause psychic tension but also the ego's ways and means of dealing with that tension.

Downloaded from www.dbraulibrary.org.in

psychic factors originating in the development of the personality. Just as there is a hypersensitivity to pain which predisposes to dysmenorrhea, so is there also an initially diminished capacity of the ego to maintain its integrating and controlling function under stress. This weakness of the ego accounts for mobilization of otherwise latent conflicts at the time of menstruation. It is a clinical observation of long standing that behavior disorders exacerbate during the premenstrual and menstrual phase. Overeating or alcoholism often become uncontrolled. Kleptomania and other psychopathic kinds of behavior occur more often during this phase than at any other time. There is a large literature on the conspicuous, although not completely clarified, relationship between various forms of psychosis and menstrual disorders.[20]

Oligomenorrhea refers to scanty menstruation at long intervals. It may be a sign of retarded sexual maturation on the basis of hypogonadism; usually, however, it is a defense against sexuality. Oligomenorrhea is often associated with obesity. Overeating occurs in adolescent girls who, as a defense against sexuality, regress to the oral level of development and become more or less depressed. The metabolic processes of obesity and depression lead to manifestations of hyposexuality. Obese women are often sterile on the basis of anovulatory cycles. The scanty menstruation occurs without pain and distress; dysmenorrhea may occur in the same women when, after weight loss, the normal gonadal function is established.

Under emotional influence, menstruation may be suppressed for several months, even for years. Among the psychogenic cases of amenorrhea, two main groups may be differentiated. One can be related to the repression of heterosexual impulses. Young women, even after menstruation has been established, may suppress the ovarian cycle more or less completely as a defense against mature sexuality. Without having anything to do with the "painful," "dirty," "dangerous" part of sexuality, they may go on with their adolescent fantasies of a life rich in sexual experiences. When these girls become able to accept sexuality, the amenorrhea usually disappears. The investigation of wartime amenorrheas has demonstrated that amenorrhea can be the result of long-lasting sexual deprivation and is not primarily the result (as it was assumed) of nutritional deprivation. After heterosexual relationship was re-established, the menstrual cycle recurred, in many instances, without a change in nutrition.

The other form of amenorrhea occurs as a part of the syndrome of pseudocyesis. It often happens that, under the influence of the wish for and the fear of pregnancy, menstruation is suppressed for a number of weeks, even for several months. While women begin to fantasy about pregnancy—with pleasure or with anxiety—as soon as menstruation is delayed, this alone does not account for pseudocyesis. The amenorrheas of long duration, with abdominal distention, breast changes, and weight increase imitating pregnancy, are complex psychosomatic symptoms which occur in women of hysterical character structure, or may be a sign of (incipient) schizophrenia. Pseudocyesis expresses on many levels the conflict regarding childbearing. These women are usually infertile. Being unconsciously afraid of pregnancy and guilty because of hostile wishes (toward mother and children), they clamor for motherhood, and, during the period of pseudocyesis, they enjoy gratifications which only pregnancy justifies. The opposite also can happen, as for example, when unmarried women, sometimes advanced in pregnancy, convinced that "what should not be cannot be," remain unaware of pregnancy. Often they can cite the fact that they menstruated several times during pregnancy. Such cases illustrate that physiological functions may become disassociated under the influence of contradictory motivations and needs.

Menorrhagia, noncyclic uterine bleeding, occurs occasionally under unusual emotional tension connected with anticipation of feared and/or desired intercourse. It often complicates matters between husband and wife after long separation; it is often cited as a symptom of brides. Each of these instances demonstrates the emotional control of menstruation. Yet its physiologic mechanism is unknown. The occasional untimely menstruation after which the

Downloaded from www.ebrahimray.com.in

cycle is re-established most probably is not a result of an imbalance of the ovarian hormones. Menorrhagia occurs often in young individuals before the ovarian cycle is definitely established. Suppression of the gonadal hormones may occur in adult women after many years of normal menstruation; it may be the result of frigidity, sexual deprivation, or of exhaustion after frequent pregnancies and accompanying depression. Menorrhagia is often a symptom of the imbalance of the ovarian hormones heralding the menopause. Thus, the symptom has different meaning in the psychosexual life of the woman, depending on her age and on the conditions which brought about the symptom. It is especially significant in young girls. The bleeding which seems to be always impending interferes with the normal life of the girl. Even if it does not cause anemia, it brings about an exaggerated preoccupation with the "unfortunate fate" of womanhood. In spite of more or less severe depression, these cases respond very well to psychotherapy.

## ¶ Childbearing

It is a physiological characteristic of woman that her reproductive function requires an increase of metabolic processes. Each phase of the reproductive function—the progesterone phase, pregnancy, and lactation—goes hand in hand with an increase of receptive and retentive tendencies; they are the psychic representations of the need for fuel to supply energy for growth.*

### *Pregnancy*

When conception occurs, the cyclic function of the ovaries is interrupted and is not re-established with regularity until after lactation is finished. Because of the uninterrupted and enhanced function of the corpus luteum, the psychology of pregnancy is best understood as an immense intensification of the progesterone phase. The heightened hormonal and general metabolic processes, which are necessary to maintain the normal growth of the fetus, augment the vital energies of the mother. It is a manifestation of the symbiosis (the reciprocal interaction between mother and fetus) that the pregnant woman's body abounds in libidinous feelings. While some women enjoy this narcissistic state in vegetative calmness, others, especially in the second trimester of pregnancy, find outlet for their physical well-being by enlarging their activities. As the metabolic and emotional processes of pregnancy replenish the primary narcissism* of the woman, this becomes the wellspring of her motherliness. It increases her pleasure in bearing her child, stimulates her hopeful fantasies, and diminishes her anxieties. While the mother feels her growing capacity to love and to care for the child, she actually experiences a general improvement in her emotional state. Many neurotic women who had suffered from severe anxiety are free from it during pregnancy; others, despite the discomforts of nausea or morning sickness, feel emotionally stable, and have the "best time" during pregnancy. Thus, healthy women demonstrate during pregnancy, as during the high-hormone phases of the cycle, an increased integrative capacity of the ego. Indeed, the devoted patience "in the service of the species," which women of uncounted generations have proved, has its roots not in the necessities of woman's sociological dependence on man but in the drive organization of the reproductive function. This accounts for the gratifications as well as the inherent dangers of motherhood.[8]

Though pregnancy is biologically normal, still it is an exceptional condition which tests the physiological and psychologic reserves of women. There are many attitudes, realistic fears, and neurotic anxieties which disturb the woman's desire for pregnancy. Some of these may be motivated by realistic situations. Bad

* At the time of ovulation and during the progesterone phase, the actual increase in metabolic need must be minimal. Yet the physiologic and psychic responses are intense. This signifies that in the presence of signal stimulation the psychic apparatus sets in motion an innate pattern of responses, which, if actually not needed, affords learning by repetition.

* Primary narcissism is the libidinal state resulting from a positive metabolic balance, with its attendant "surplus energy."[2]

Downloaded from www.brainline.org

marriages, economic worries, or conception out of wedlock may cause the pregnancy to be unwanted and the infant to be rejected before it is born. Usually, even such pregnancies have a more or less normal course. Only if the psychosexual organization is laden with conflicts toward motherhood do actual conditions stir up the deeper conflicts and disturb the psychophysiologic balance of pregnancy.

Since the complex steps toward maturity, motherhood, and motherliness begin in the mother's own oral phase of development, it is easy to describe the psychodynamic process of normal and pathologic pregnancy in terms of the oral-dependent phase. Passive-dependent needs revived, the pregnant woman thrives on the solicitude of her environment. If her needs are unfulfilled, the frustration of her oral-dependent wishes may motivate well-known symptoms such as perverse appetite, nausea, or morning sickness. These symptoms seem to diminish in frequency and intensity under cultural influence. The changing relationship between the sexes brings about a change in the conscious attitude of women toward pregnancy. The subjective symptoms of pregnancy are minimal in women who, becoming pregnant by mutual consent, can count on their husband's care and loving participation in their great experience. Mood swings, however, occur in every pregnancy, especially during the first trimester, when the endocrinologic and metabolic adjustment may cause fatigue, sleepiness, headaches, vertigo, and even vomiting. These symptoms are usually alleviated as the pregnancy progresses. During the last months again, the increasing bodily discomfort, disturbances of sleep, and fears connected with parturition interfere with the contented mood of pregnancy.

Self-centered and dominated by receptive-retentive tendencies, the pregnant woman is in a vulnerable ego-state. The physiological increase in receptive-retentive needs, the libidinal regression, brings about a regression of the ego. In evaluating the psychodynamic meaning of this regression, one should consider that the integrative task of pregnancy and motherhood—biologically, psychologically, and realistically—is much greater than a woman has ever faced before. In some cases the adaptive task appears greater with the first child, when the woman experiences something completely new. The physiologic and emotional maturation of the first pregnancy makes motherhood generally easier with the second and third child. Yet it may happen that women, fatigued by the never-ceasing labor of motherhood, experience pathogenic regression during later pregnancies.

Normally, the biologic regression of pregnancy and lactation serves as a source for growth and development. The same processes, however, harbor dangers for those who cannot withstand the regressive processes inherent in the reproductive function. External circumstances, such as a lack of love from or for the husband, may stir up the deep-seated conflicts of motherhood. In such cases any change inherent in pregnancy may become a source of irritation and may cause frustration instead of gratification. Then the pregnant woman, like an angry frustrated infant, cannot find gratification within herself. The symbiosis evolves then as a vicious circle. The frustrated, hostile pregnant woman becomes anxious, since she feels her inability to satisfy her child. The hostility toward the child and the rejection of the pregnancy, go hand in hand with the hostility toward the self, the rejection of the self. Anorexia, toxic vomiting, and consequent severe metabolic disturbance such as eclampsia may express the woman's destructive tendencies.*

It is a well-established concept of psychoanalysis that regression to the oral phase of development is the psychodynamic condition of depression. Since such regression is inherent in pregnancy and lactation—even in the progesterone phase of the cycle—depressions of varying severity and psychosomatic conditions of oral structure are the basic manifestations of the psychopathology of the female propagative function.[8] The further elaboration of

* These symptoms appear often in women who, as infants, had anorexia and psychosomatic illnesses of the gastrointestinal tract. As the psychodynamic processes inherent in pregnancy mobilize the ambivalence toward mother and motherhood, they reactivate the anxieties, frustrations, and pains referable to the oral phase of development.

Downloaded from www.libadium.org

this primary pathology depends on the total personality of the woman. If the hostility is concentrated on the embryo, women have fantasies of harboring a "monster," a gnawing animal, a cancerous growth. This gives rise to panic and hypochondriasis. The aggressive impulses toward the embryo may be experienced as inadequacy in taking care of the child. Phobic reactions; even suicidal impulses, may represent defenses against the hostility toward the contents of the womb.

The contents of the womb has many meanings in the unconscious emotional life of the woman. Freud assumed that the frustration caused by the lack of a penis is the central motivating factor in the development of woman; he concluded that woman's wish for the child is motivated by the tendency to retain the penis (in the sense of the oedipus complex, the penis of the father). According to this, the male child represents the fulfillment of the originally repressed wish.[29] Freud's hypotheses, however incomplete from the point of view of psychobiology, demonstrated in many instances the motivational power of infantile fantasies. There are many common infantile fantasies. One or the other of these fantasies has a greater significance in the development of the personality. During pregnancy the individually significant fantasy may become recathected and may influence the emotional course of pregnancy. (Such an influence may be beneficial or may be anxiety-producing.)

The fetus is a part of the mother's body. What aspect of the body image does the fetus represent? It may be the missing penis in some cases; in others, it is the admired beauty, or the envied pregnancy, of the woman's own mother; most frequently the fetus is the token of the loved self. Normally, the fetus is cathected with narcissistic libido.[27] This, however, does not always mean pleasurable emotional sensations. There are many ambivalent, hostile manifestations of the feelings concentrated upon the self. Thus, the fetus can represent the "bad, aggressive, devouring self," engendering fear of having a "monster." Many women identify the fetus with feces and relive during the pregnancy the ambivalent feelings and mysteries of the infantile sexual fantasy of the anal child. There are many cases in which the anal or other regressive fantasies do not interfere with the pleasure of pregnancy. The mother's object-relationship to her unborn child becomes ambivalent or strongly hostile when the fantasy which is projected onto the fetus is highly charged with ambivalence. The fetus, then, becomes the representation of a hated and/or feared person, and motherhood becames an overwhelming menace (Deutsch,[18] Vol. II).

The anxiety and depression caused by such motivations may remain on the level of neurosis. In many instances, depending on the predisposition of the personality, the anxiety may activate a true psychosis, with hallucinations, paranoid defenses, and schizophrenic reactions endangering the woman and her fetus.[20]

### *Parturition*

It is generally assumed that the fear of labor is universal and, in some instances, represents the immediate fear of death. Even in those cases where there is no fear of labor during pregnancy, such fear may rise suddenly to cataclysmic intensity during critical phases of labor. Modern obstetrics is very much aware of the significance which sudden and violent emotions have on the course of labor, just as psychiatrists are aware of the influence of obstetrical traumata upon the personality of the mother; it may alienate her from her child or activate serious postpartum reactions. For several decades general anesthesia was considered the method of choice to protect the mother and the child against the effects of labor pain. General anesthesia, however, deprived the mother of the deep gratification of experiencing the delivery, of hearing the first cry of the baby. Many women who were delivered under anesthesia complain that the lack of memory of the delivery made it difficult for them to relate to the baby and feel motherly. A better understanding of the psychodynamic processes involved in labor has resulted today in the use of general anesthesia often only as a last resort, or in surgical procedures.

Downloaded from www.dbraulibrary.org.in

Pain is a subjective experience. Even if it is caused by organic processes, the experience of pain depends, in a particular way, on the experiencing ego (Chap. 49). Since G. D. Read described the fear-tension-pain syndrome in labor,[43] many obstetricians utilize the "mental hygiene" of pregnancy. This aims at diminishing the fear of delivery and, by this, reducing the tension-pain response. Read believes that a person adequately conditioned to minimize the discomforts of labor may have a delivery free from observable discomfort ("natural childbirth"). Kartchner[35] and others observe that women emotionally well oriented to childbirth benefit from training and education; those, however, who have serious emotional conflicts hardly ever will be influenced by indoctrination.

The exaggerated expectations of the effect of mental hygiene on parturition harbor psychiatric hazards. There are many unexpected obstetrical conditions which may interfere with the course of delivery. There are also many psychologic complications of labor. One of them is the woman's disappointment in herself if she cannot "behave" during labor as her self-respect demands. The sense of failure may then activate inferiority feelings hidden under the cover of a perfectionistic ego-ideal. The resulting shame brings about the condition which one wished to avoid, namely, the woman may "give up." Since the "natural childbirth" permits the woman to feel responsible for what she has to endure, the obstetrical trauma may become complicated by a narcissistic blow. The psychopathologic effect of this varies according to the personality of the mother and upon the maturity of her motherliness.

## *The Postpartum Period*

The trauma of birth interrupts the biological symbiosis between mother and infant. The hormonal changes which induce and control parturition, the labor pains, and the excitement of delivery interrupt the emotional continuity of the mother-child unity. Under the influence of excruciating pain, the mother is concentrated upon her own survival. After delivery the love for the newborn wells up in her as she first hears the cry of the baby. This sensation reassures the mother about the continuity of the oneness with her child. There are, however, many mothers, especially primiparas, who, after delivery, experience an emotional lag. They are surprised by a lack of feeling for the child, by a sense of loss and emptiness. Disappointed in themselves, such mothers feel guilty and become insecure in their behavior toward the child. Such incipient postpartum depressions are not infrequent. The postpartum woman, for many reasons but primarily because of her physiological condition, has a regressive tendency and therefore a need to be mothered. Through the love which she passively receives, she may overcome her tendency to withdraw from the child. Whether the mother, through the feeling of love, is able to maintain the sense of unity with her child, or whether she has to miss this most significant gratification, the organism of the mother is not ready to give up the symbiosis after parturition: biologically and psychologically she prepares to continue the symbiosis through lactation.[9]

Lactation is stimulated and maintained by prolactin, a hormone of the anterior lobe of the pituitary. This usually suppresses the gonadal function and induces an emotional attitude which is similar to that of the progesterone phase of the cycle.

During lactation, just as during the progesterone phase and pregnancy, receptive tendencies gain in intensity, they become the axis around which the activities of motherliness center. The woman's desire to nurse the baby, to be close to it bodily, represents the continuation of the original symbiosis, not only for the infant but for the mother as well. While the infant incorporates the breast, the mother feels united with the baby. The identification with the baby permits the mother to "regress," to repeat and satisfy (on the unconscious level) her own receptive incorporating wishes.[8]

Lactation thus permits a slow, step-by-step integration of motherliness.

In spite of hormonal control, lactation is influenced by emotions. Galactorrhea, a free flow of the breasts during pregnancy or after

Downloaded from www.freepsychotherapybooks.org

weaning, occurs often under the influence of emotions, for example, if the mother sees a woman lactating. Suppression of milk production by a conscious attitude against lactation leads to such a statement as, "Ability to nurse is equivalent to the will to nurse" (Kroger and Freed,[37] p. 182). This is, of course, an oversimplification of the variety of processes through which emotions affect physiologic processes.

In regard to the postpartum period, it may be that the mother-child symbiosis can be best maintained by maximum physiological participation, such as in breast feeding; however, in many instances, permitting the mother to omit this physiological activity lessens the potentially disturbing maternal ambivalence and thus improves the mother-child interaction. Motherliness in women is not a simple response to hormonal stimulation brought about by pregnancy and the ensuing necessity of caring for the young. Instead, motherliness in humans develops through the cyclic repetition of hormonal stimulation, which, interacting with other aspirations of the personality, reaches functional maturity through a complex process of personality development.

In each phase of motherhood, even in each act of mothering, we might differentiate two levels of motivation as well as action. One is dominated by the emotional manifestations of the passive-receptive-retentive tendencies; the other, more accessible to consciousness, mobilizes the loving, succoring activities of mothering. In simple societies the biological and ego-aspirations of the woman are easily integrated in her ego-ideal. Our culture, however, conveys to the woman an active, extraverted, "masculine" ego-ideal. This may conflict with the passive tendencies inherent in the propagative function. Consequently, women may respond with guilt reactions to the biological regression inherent in motherhood. If they cannot permit themselves to be passive, to enjoy lactation, to breast feed the infant, they deplete their source of motherliness. Such women respond with anxiety and guilt, with a sense of frustration to their inability to live up to the biological functions of mothering. Yet, given time and reassurance, these women learn to relax, and their interaction with their infant becomes pleasurable and emotionally productive without lactation.[7, 13]

Not only the masculine-protest attitude complicates mothering. There are women for whom the physiologic gratification of mothering remains an everlasting temptation, who enjoy pregnancy and lactation and caring for the infant as long as he is completely dependent. As if the procreative function of these women were completely under physiologic controls, they are unable to develop an object-relationship to the child beyond infancy. Psychologically, such women do not mature through motherhood. They neglect each child as they become pregnant with the next, often abandoning their children, since they cannot cope with the responsibilities of motherhood toward growing individuals.

A discussion of the psychopathology of the postpartum period will be omitted here, since these problems are similar to those of development toward motherhood and to those of pregnancy. A less known manifestation of postpartum pathology is one which untowardly affects the transactional processes between mother and child, and thus becomes a source of pathology for the child. In recent years several observations have been published demonstrating that the infant, by some not clearly defined psychic process, incorporates the emotional attitudes of the mother, embodies her anxiety, and develops symptoms which are similar to or identical with those of the mother. Beata Rank[42] observed psychic transmission of conflict constellations to children who become feeding problems; René Spitz[46] demonstrated the infant's reaction to the mother's depression. Escalona[22] deals with the larger concept of "contagion." The present author interpreted these processes in terms of the postpartum symbiosis, "which is oral, alimentary for both infant and mother" (Benedek,[10] p. 398).

The oral-dependent needs of the child as a motivating factor in the child's responsiveness to the mother, to her security and smiling love as well as to her anxiety and insecurity, have been well studied. The mother's receptive needs toward the child, however, are not so easily recognized. From the time of conception, the offspring has stimulated the receptive tendencies of the mother; after parturition the

Downloaded from www.dbraulibrary.org.in

newborn remains the object of these instinctual needs. Normally, the infant, by the very fact of his existence, represents the most significant fulfillment of the mother's receptive needs. With her baby the mother feels whole, complete, but not so without him. Many young mothers feel an "emptiness" when they leave the child, become anxious or depressed, and may feel compelled to eat. This indicates an increased tension of their receptive needs. The affect hunger of the mother, her need for love and affection, her wish to reunite with her baby, to overprotect and overpossess him, are all exaggerated manifestations of the very emotions which originate in the psychobiological processes of motherhood. The intensity of these emotions indicates the meaning of the separation trauma of parturition for the mother. As if the separation could be undone, mothering and each manifestation of love for the child are fused with an urgent need to "incorporate the child," to hold on to him. As the mother clings to the child, he becomes for her psychic economy (at least partially) the needed, loved, and hated object of her own past. Reciprocally, the child affected by the incorporative need of the mother, which does not allow self-differentiation, responds to any attempt toward independence as if it would mean separation and deprivation of love and protection. Such a hypersensitive reaction to emotional separation is a manifestation of the primary ego-structure which originates in the ambivalent charge of the symbiotic relationship between mother and infant. Recent investigations of psychosomatic illnesses in children demonstrate the significance of this pathology in the mother-child relationship for the psychosomatic illnesses of children.[21, 29]

Infertility, if not caused by organic pathology, can be considered as a defense against the dangers inherent in the procreative function. All those conflicts which interfere with the normal evolution of the procreative function may lead to infertility if the individual is constitutionally predisposed to it. The same conflicts which cause hypochondriacal panic in one woman and postpartum depression in another may be elicited as a causative factor of infertility in still another. The women who "suffer" from functional sterility are saved from the awareness of their conflicts, anxieties, and hostilities regarding childbearing; they may go on asserting their unambivalent attitude toward motherhood. Functional infertility is relative. It may be temporary and disappear with the maturation of the physiologic and emotional processes involved in motherhood. Infertility may be a conjugal phenomenon[11] caused by deep dissatisfaction with the marital partner and by sexual maladjustment. Chronic sexual frustration may lead to infertility. It happens frequently that women, after having practiced birth control for a long time, may not become pregnant easily or at all. Relative infertility may be the result of the inhibition of the heterosexual drive. Women who are afraid of men or of marriage are not considered "infertile" from a diagnostic point of view, yet analysis of unmarried women often reveals that fear of childbearing is the primary motivation for their sexual inhibition. Women may appear sterile if the desire for intercourse is suppressed during the fertile period and coitus takes place only during the infertile period. Such birth control is also practiced voluntarily. There is more organic compliance in instances where relative infertility is caused by a shift in the cycle so that ovulation occurs during menstruation, when coitus usually does not take place;[44] this is even more pronounced in those cases where the conflicts lead to a suppression of the gonadal function so that ovulation does not occur at all.

The unconscious conflicts which may lead to infertility can operate through interaction of psychic, neurologic, and hormonal processes, but they may act also through reflexes which have their origin in primitive sensations of fear and rage. Reflex action may play a role in infertility caused by spasm of the fallopian tubes, so that the ovum cannot reach the uterus. The spasm may be transitory or persistent; that is, it may be the result of a response to acute fear of pregnancy, or it may be a conversion symptom. This form of infertility occurs in anxious, hysterical women. Without outlining profiles of infertile women, it seems justified to differentiate between the dynamics of infertility in these women and in those active, adaptable women who, except for the functional infertility, are well integrated,

Downloaded from www.dbraincloud.org.in

healthy individuals. Infertility, in these instances, develops as a somatic counterpart of the characterological defenses.[6]

During the progesterone phase of each cycle, the woman responds more or less unconsciously to the tasks of motherhood. Normally, through the monthly repetition, she overcomes the anxieties and absorbs the conflicts of childbearing. It is different in those women who, perceiving the stimulation of the progesterone phase, recoil from the task, repress the conflict, and with it suppress the gonadal function which otherwise would charge the conflict with energy and would make repression impossible. Thus, along with the psychologic defense (repression), an organic defense develops; the gonadal function is suppressed, and infertility is attained. In comparing the women who become infertile to those who develop psychiatric symptoms, we may assume that infertile women have a stronger ego than those who become mentally ill as a result of motherhood. Indeed, among the infertile women there are many who have ego-aspirations which are in conflict with propagative function.

Under the influence of a variety of experiences, functional sterility can prove to be a transitory, curable condition. It is assumed that adoption often "works miracles" and facilitates successful childbearing. It would be easy to theorize that direct contact with a child relieves the woman's anxiety of childbearing. Psychoanalytic explorations of such couples reveal that the conditions which facilitate conception, the sexual and emotional relationship between husband and wife, improve before the adoption occurred. Indeed, the very idea of adoption is probably an indication of the diminishing intensity of the conflict about motherhood. The study of a large number of cases conducted by Hanson and Rock[30] shows that not more than a fortuitous correlation exists between adoption and ensuing pregnancy.

### *Miscarriage*

There are many miscarriages which are not caused by emotional conflicts regarding childbearing in general, or regarding the particular pregnancy. Therefore, it seems justified to talk about psychosomatic miscarriages only in those cases where miscarriage becomes a "habit." Habitual abortion can be considered a variety of relative infertility. The same conflicts which produce the psychiatric pathology of childbearing also may cause spontaneous abortion. The symptom may be mediated by autonomic disharmony, causing uterine irritability; this, in turn, may be secondary to a balance in endocrine function insufficient to maintain the pregnancy. Abortion may occur as a result of a reflex in extreme rage. The psychologic meaning of repeated abortions is often revealed if one analyzes the motivations for therapeutic abortion.[36] The wish for therapeutic abortion is often motivated by social, ethical, and economic factors, but also by unconscious fears, which, in women of lesser fertility, may cause sterility or spontaneous abortion.

## ¶ Menopause

The reproductive period in women lasts on the average thirty-five years. Its decline approaches gradually; its end is marked by the cessation of the menstrual flow. This occurs in some cases abruptly, but usually there is a period during which the cycles become irregular and the menstrual flow scanty. Since ovulation usually ceases before menstruation, there is a lack of balance in the ovarian hormones even before menopause. There are few women unaware of the transition; most have some, others seem to have all, the well-known signs and symptoms of menopause. Increased irritability, mood swings, hyperesthesias, paresthesias, vertigo, and a multitude of other symptoms indicate a lowered tolerance to emotional tension. Many symptoms are related to an increased irritability of the vegetative nervous system, especially involving the vascular apparatus, giving rise to hot flashes, chills, palpitation, cardiac arrhythmias, etc. Since the same symptoms arise after surgical removal of the ovaries, and they can be controlled by substitution therapy, one is led to assume that the failure of the ovaries is the main cause of the symptoms. Yet, in natural menopause, the symptoms show great individual variations in intensity as well as in duration; since these

Downloaded from www.dbraulibrary.org.in

symptoms are, in any event, only temporary, it seems that they are due rather to an imbalance of hormones than to simple deprivation. One indication of this is overproduction of *pituitary gonadotrophin*. "This characteristic feature of the climacteric may be one factor in prolonging, if not initiating, the disturbances" (Hoskins,[33] p. 310).

There is evidence of a difference in the process of tissue degeneration of the ovaries in women who have not borne children as compared to those who have had several pregnancies. The menopause sets in earlier and with more intense reaction in the former group than in the latter. This is in harmony with psychoanalytic observations, namely, that with complete sexual maturation and function, the regressive emotional manifestations (which characterize the low ebb of the premenstrual hormone phase) become absorbed by the adaptive processes of development. Thus, when the gonadal stimulation subsides permanently, the healthy woman is not severely threatened by this loss. The accomplishments of the reproductive period—not only the propagative function but also the total developmental achievement of the personality, its lasting sublimations, its capacity to love and to do for others—will sustain the personality when the gonadal stimulation abates and the woman faces the change of life.[8]

The anticipation of the climacterium—just as in the anticipation of a previous change, the menstruation—influences the symptoms and the woman's emotional response to them. As long as women considered the climacterium not alone as cessation of the reproductive period but also as cessation of their sexual attractiveness and ability for sexual experience, the mental stress of the climacterium was complicated by a deep narcissistic blow; it also implied the necessity for repressing sexual desires or being ashamed of them. This often brought about regressive and less mature sexual behavior and threatened the woman and her environment by breaking the previous moral code of the personality.

It is different in most women of today. Following the menopause, healthy women respond to the gradual desexualization of their emotional household with an influx of extraverted energy. Their still-flexible personalities, relieved from the responsibilities of child raising, seek and find new aims for their psychic energy. As in childhood the repression of sexual impulses led to super-ego formation and socialization, so in climacterium, the cessation of the gonadal function releases new impetus for socialization and learning. (See footnote on p. 729.) The manifold interests and production of women after climacterium, as well as their improvement in general physical and emotional health, serve as evidence that woman's climacterium may be regarded in a psychological sense as a developmental phase (Benedek,[8] pp. 352–372). In any event, it is a challenge for the reorganization of the personality. Many of the interpersonal attitudes of the woman change. She does not love with youthful ardor, but much of her ambivalence, jealousy, and insecurity have been overcome. Her love becomes more tolerant, and shows certain "post-ambivalent" qualities.[1] These evolve effortlessly toward grandchildren. Identification with her pregnant daughter or daughter-in-law permits the aging woman to be a mother again. One step removed, she is now less involved; her love toward her grandchildren is freer from the conflicts which, as a mother, she had toward her own children. Through the manifold gratifications within and without the family, healthy women approach unobtrusively—and many years after climacterium—the physical and mental involution of senescence.

In spite of all the positive aspects of climacterium, many women suffer from neurotic, psychotic, and psychosomatic manifestations of varied severity. Because these symptoms occur during climacterium, they are usually attributed to the stresses of the menopause. Yet the psychoanalytic study of such cases reveals that the symptoms which are aggravated during this period have existed before, or had been preformed in the precarious integration of the personality. The role of the endocrinological aspect of the menopause as a trigger for psychiatric disturbances can best be understood in terms of the psychodynamics of the premenstrual phase of the sexual cycle. As the

Downloaded from www.dbraulibrary.org.in

premenstrual hormone levels decline, the libido regresses from the level of genital integration to the infantile level. Together with this, the ego's integrative capacity diminishes, bringing to the fore the premenstrual symptoms. Their persistence, severity, and character have a prognostic significance for the climacterium. Those women who were unable to adapt to the premenstrual hormone decline and suffered from premenstrual depressions and dysmenorrhea usually suffer severely with the permanent cessation of gonadal activity.

The general irritability, lack of emotional stability, and diminished integrative capacity, which accompany the decline of hormone production, interact with the developmentally determined psychic factors and thus determine the experience of internal frustration of climacterium. In psychoanalysis the term "frustration" indicates that a drive is thwarted in attaining its goal. Thus, frustration may be the result of external prohibitions or of internal prohibitions of the super-ego which exclude the instinctual need from gratification. Here, however, the term "internal frustration" refers to the patient's inability to feel gratified. In correlating the sense of internal frustration with the inefficient ovarian function, we assume that it expresses the lack of libidinous emotions, rather than dammed-up libido. Describing it from the point of view of the affective experience, it appears as if the ego, aware of its diminished integrative capacity, responds to the inability to feel, to act, to love as before, with anger and hostility toward the self. The internal frustration is in the center of the emotional experience of climacteric women.

The symptoms which develop as a result of internal frustration depend on the total personality of the individual. This determines the intensity of the sense of frustration as well as its further pathologic elaboration. The study of the personality structure and life experience of women who manifest severe psychiatric disturbances in climacterium reveals that in these cases: (1) the bisexual component played a dominant role; (2) the psychic economy was dominated by narcissistic ego-strivings; and (3) both these factors interfered with the primary emotional gratifications of the female sexual functions. Such individuals gratify the usually strict demands of their super-ego with perfectionistic performance. Such ego-gratification may protect the woman from awareness of her basic lack of fulfillment as long as "everything goes well"; however, she is often unable to tolerate the disappointment which comes when the ego loses the power to perform as usual. As long as the woman is able to relate her difficulties to actual situations, and to respond to them in the degree and manner that she did during her adult life, she is safe. In many instances, however, the external, interpersonal situations activate responses which the woman cannot reconcile with her accustomed behavior or with her ego-ideal. Whether it is a physical symptom which she cannot accept, or her emotions, fantasies, or hostile impulses, she collects her ego-strength; "this cannot happen to me" is an often-heard defense of the climacteric person. Yet just this activates a "defensive tail spin." As the patient perceives her failure in maintaining the usual level of ego-mastery, inferiority feelings and self-accusations mount, causing depression and anxiety. The anxiety brings to the fore the previously compensated pathological potentials of the personality organization. Oversensitivity, paranoid projections, phobic, compulsive, and paranoid reactions may develop in the course of the struggle to retain the old self. The process may continue on to full-blown psychosis. Psychoanalysis of menopausal women reveals that severe psychiatric conditions occur in individuals whose adaptation to internal and external stress occurred throughout their life at a cost of an increase in narcissistic defenses. It can be expected that the narcissistic armor will crack when it becomes overtaxed by the internal and external frustrations which the woman faces at this phase of her life.

In evaluating the factors which enter into the psychopathology of menopause, we have to assume at present that the endocrine imbalance and the accompanying autonomic symptoms are precipitating agents; the causes of the psychiatric symptoms are deeply embedded in the psychic organization. This is indicated by the fact that endocrine therapy affects primarily the autonomic-nervous-system

Downloaded from www.dbraunlibrary.org.in

reactions and not the psychiatric symptoms.

Many women go through climacterium without any psychiatric disturbance and develop depression later when physical or psychologic manifestations of aging bring about dissatisfaction with their functioning capacity. The perception of any sign of aging, especially in the area which is most significant for the individual, can bring about similar intensification of defensive processes, as described above, even without acute endocrine imbalance. Every single phase of life involves a shifting and reorganization of psychic structures in accordance with the supply of vital energies. As they decline, the vector of psychic and somatic processes changes. The giving and expansive attitudes needed for the reproductive period become outweighed, step by step, by the restricting, self-centered tendencies characteristic of old age. Yet, this, too, is the result of the adaptive function of the ego, which tends to maintain the individual as he knew himself, as he used to be—to the last.

CHAPTER 38

# DISTURBANCES OF THE BODY-IMAGE

Lawrence C. Kolb

Downloaded from www.dbraulibrary.org.in

BODY-IMAGE DISTURBANCES are receiving wider recognition, particularly in psychiatric and neurologic practice and in their consultive services to medicine and surgery in general hospitals and clinics. The psychiatrist is frequently called upon to assess the unusual problem of the patient with such a disturbance and to provide an opinion as to the nature of the clinical phenomenon and the treatment. In the general field of psychiatry, knowledge of the body-image concept has been applied in furthering understanding of the bodily sensations in the schizophrenias, involutional psychoses, hypochondriasis, neurasthenias, and the multitude of phenomena that occur with acute and chronic brain disease or result from various toxic, metabolic, and degenerative states. Sound data on the specific developmental factors which predispose or determine disturbances of the body-image in the major psychoses and psychoneuroses are sparse.

Body-image phenomena, as observed in the general clinic, may represent either a healthy psychophysiologic reaction or be evidence of psychological and emotional maladaptation. The differences between expected and healthy presentations of body-image phenomena and their pathological variants are not widely recognized and hence not generally diagnosed. The distinctions between health, disease, and the rationale of much of the clinical phenomenology may only be understood in the context of the developmental process of the personality and by consideration of the detailed accounts of phantom phenomena.

The material presented in this chapter deals mainly with the general principles and phenomenology underlying body-image disturbances, discussion of disturbances which follow dismemberment or disfigurement of the body or body surface, and considerations for prognosis and treatment. The concept of the body-image is discussed in the following section.

## Historical Perspective

The first written account of body-image disturbance was that of Ambroise Paré,[66] a six-

teenth-century surgeon. Noting the frequent occurrence of the phantom limb following amputation, Paré advised surgeons that this disturbance should not prevent their proceeding with additional amputation if such were indicated. It is most unlikely, however, that Paré's report was man's first awareness of this overt expression of his body-image. Recognition probably dates back to the earliest days of man, with the phenomenon providing him with an experience as impressive and of as great psychological import as his dreams and other reactions to death.

Following Paré, Weir Mitchell[64] provided one of the better descriptions of the phantom, observations which were noted a few years later by Charcot. Head[38] was responsible for the description and development of the first basic concepts of the body schema or body-image, as well as for the interpretation of its significance for the perception of body functioning in relation to motility, localization of tactile stimuli, and the phantom phenomenon. The broader concept of body-image presently utilized in psychiatry was developed largely by Schilder.[78]

The concept of disturbances in body-image derives from observations of the affected individual's failure to perceive his body and its parts and adapt to them as they actually exist. The outstanding examples of acute disturbances occur as a result of traumatic or surgical dismemberment, where the basic body-image persists, despite the visible or apparent loss of a body part. The phantom limb is one of the most dramatic and convincing expressions of the phenomenology. Similar disturbances are seen following radical excision of tumors or masses of the face, head, and neck; thoracoplasty; paralysis of extremities following poliomyelitis; sudden paraplegias or hemiplegias; and distortions of the body resulting from hyperadrenalism or other endocrine dysfunctioning.

At the present time, body-image disturbances may be classified as consequent to the following categories of illness: (1) disorders following neurologic diseases and affecting any part of the sensory or motor system connected with movement and posture, whether involving the peripheral or the central nervous system; (2) disorders occurring with changes in the body structure as an expression of acquired or induced toxic or metabolic disorder; (3) disorders consequent to progressive deformities, occurring either late or early in life and caused by other somatic diseases; (4) disorders after acute dismemberment; and (5) disorders of personality development, including the psychoses, psychoneuroses, and psychopathic states.

Head, the neurologist, visualized the body schema not simply as the integrated resultant of past sensory experiences but more as a unity deriving from past experiences and current sensations organized in the sensory cortex. These postural schemata, often functioning outside central consciousness, were considered to be modifying impressions of incoming sensory impulses for their localization on the body surface. Also, they made possible the intricate and delicate motor activities through the constant relationship of the body to other objects. Thus Head conceptualized an area of sensorimotor functioning, a postural model of the body, which brings about the possibility of projecting the recognition of posture, movement, and locality beyond the limits of the body to the ends of instruments held in the hand, or operated by the body. Anything which participates in movement of the body was seen as added to the postural model and as becoming a part of the body schema. The postural model of the body, as described by Head, is of major importance in understanding many phenomena which occur in the area of practice shared by the fields of neurology and psychiatry or the levels of functioning of the central nervous system.

In contrast to Head, Schilder[78] extended the body-image concept to include not only an individual's personal or psychological investment in his body and its parts but also a sociological meaning for both the individual and society. To Schilder, the image of the human body is that picture or scheme of our own body which we form in our minds as a tridimensional unity involving interpersonal, environmental, and temporal factors. He also related the body-image concept to curiosity, expression of emo-

Downloaded from www.psychiatryonline.org

tions, social relations, duty, and even ethics. In his considerations, the borderline between body-image and the psychoanalytic concept of the ego is obscure. He specifically suggests that one go beyond the purely perceptive side of the body-image development to that of the expressive. Schilder conceived of the ego as constant and underlying throughout life, something which takes or views the body as an object toward which it has percepts, thoughts, and feelings.

Federn,[81] in discussing the individual's consciousness of himself, differentiated the ego from the body-image. He writes of the mental and bodily ego as felt separately; the mental ego is identified alone in the sleeping state, but it is experienced as inside the bodily ego when awake. According to Federn, ego is not body-image except when the body-image is invested completely with ego-feeling. Similarly, the ego, in contrast to the body-image, is considered to be capable of complete dissolution yet to have a capacity for preservation of the somatic organization which allows for proper use of the body and its perceptions. (Federn equates ego-feeling with unity, in continuity, of contiguity and causality of the experiences of the individual: "The body scheme represents the constant mental knowledge of one's body; the body image is the changing presentation of the body in one's mind. Throughout the changes, the bodily ego is the continuous awareness of one's body. Image, scheme, ego all three are themselves not somatic but mental phenomena.")

Szasz[88] has recently reviewed the thinking of Schilder and other psychoanalysts relative to the relation of the body-image and ego. He proposes that the ego relates not only to other people as objects but also to the body (of the self) as an object, with mutual interaction between the ego and the body as an object. His discussion of his position versus that of Schilder is in terms of modern theories regarding the ego. His effort to synthesize disparate viewpoints poses an interrelation between the ego and the developing bodily functions. This interrelation could be considered theoretically as "a process of progressive mastery of the ego over the body (as an object), or, to put it more generally, as the evolution of a progressively more complex ego-body integration."

As indicated in this brief historical account, the phantom phenomenon, as representative of body-image phenomena, was studied by surgeons and neurologists. The first theoretical explanations for the changes in modifications in the limb phantoms were derived from neurology, namely in the context of Hughlings Jackson's laws of dissolution and restitution of function consequent to lesions within the nervous system. These data have never been contradicted, and the theoretical explanations advanced suffice to describe the modifications of the body's postural image organized in the sensorimotor cerebral center under ordinary conditions.

The second primary source of information on body-image has come from psychoanalysis. The observations of psychiatrists and psychoanalysts are based on studies of percepts, thoughts, and feelings toward the body, as well as personality reactions to disruptions of the body-image. Since these data represent an organization of information which occurs in the central nervous system at the highest integrative level, they may be best understood in terms of the theoretical constructs of modern psychology. Within the later framework it is possible to predicate current unusual modifications, perceptions, attitudes, or reactions to the body as consequent to the individual's previous life experiences which determine conflict between the body-image as perceived and that maintained by the ego as ideal.

For the purposes of this chapter, the term "body-image" includes both the postural model of the body as defined by Head and also the perceptions, attitudes, emotions, and personality reactions of the individual in relation to his own body.

The descriptions of the consequences of dismemberment are now sufficiently extensive to allow discrimination between healthy and pathological psychological adaptations to modification of the body-image resulting from trauma, surgical procedures, or disturbances of the central integrating mechanism. Where the consequence of disturbance of the body-image does not follow the general expectations of the

Downloaded from http://www.dbraulibrary.org.in

recognized healthy adaptation, the influence of neurotic or psychotic personality development or social factors will be found operative.

The discussions appearing in the succeeding portions of this chapter are arranged to help the reader gain a clear picture of the factors influencing the development of the body-image and some of the known consequences of the expression of the body-image in healthy persons in the face of the acute stress procedures. From this information, the variations which constitute pathology and pathological psychodynamics in an individual case may be inferred.

## ¶ Development of the Body-Image

Over the years, the individual organizes his body-image through the integration of multiple perceptions, a process beginning with the earliest stages of development. The embryonic and infantile nervous system is exposed to proprioceptive sensory impressions from the vestibular apparatus and the receptors in muscles and joints. (The hand-to-mouth movements appearing initially *in utero* are the precursors of the complex and significant face-hand relationship.)

With the progressive acquisition of motility, the newborn acquires knowledge of his body from tactile impressions. In the sucking and feeding process, the mouth is the first area to be stimulated, regardless of whether hand, breast, or both are presented. Tactile impressions arising from the regions of the cheeks and oral cavity become closely linked with the increasingly prominent role of the hand sucking. From approximately the twelfth week following birth, the structuring of the hand-to-mouth relationship is accelerated.[35, 41, 57] The child begins to use both hands and arms to grasp and knead the mother's breast. From this movement, he then proceeds to use his hands to explore his own body surface and to contact others. Concomitantly, he finds that the hand can also substitute for the nipple as a pleasure mechanism and thereby can relieve tension.

The infant's exploratory movements of the hands over his own body, the hands in contact with the mother, and their use in projecting into and grasping objects in space provide the primary kinesthetic and tactile sensations underlying the definition of the postural model. These are the processes upon which are founded the beginnings of self-awareness, of individuality, and the sense of the ego. Important perceptions also develop in the early period from exposure to sensations which arouse varying degrees of pleasure and displeasure; stimulation by self and others, thermal stimuli, and, occasionally, direct painful contact.

In every instance, however, those sensations subserving optic, olfactory, auditory, thermal, and pain stimuli are of secondary importance to the kinesthetic and tactile exploration and perception of the body to form the postural model. This is in keeping with our knowledge of the embryological development of the nervous system in humans. As Langworthy[53] found many years ago, those sensory paths subserving kinesthetic and tactile activities are the first to complete myelinization.

Even the influence of visual percepts of the body must be considered as subsidiary to the kinesthetic and tactile. The fact that the congenitally blind develop the capacity for adult patterns of response to Bender's[12] test of double simultaneous cutaneous stimuli demonstrates the fundamental importance of the processes of kinesthetic and tactile sensation in structuring the postural model to subserve location of touch on the body surface. The significance of early sensory experience for the development of the body-image is further strengthened by the observations of Pick[68] and Riese and Bruck[76] that infants and young children who sustain an amputation before the age of five do not develop a phantom extremity. Similarly, Souques and Poisot[85] and Simmel[83] have reported that children born without limbs (congenital aplasias) do not experience a phantom limb.

With growth of the individual in size and shape and with evolving capacities for intricate motor activities, the body-image is continuously modified. The progressively developed images of the body and the body parts remain as memory traces within the nervous system and reappear in states of neurological dissolution or psychological regression, as clinical

Downloaded from www.dbaulibrary.com

observations have demonstrated time after time.

In addition to the modifications resulting from developmental and sensory influences, the character or quality of the body-image is also a function of the socialization experiences of the individual. The socially determined qualities commence to appear with the earliest experiences of the individual in relation to the significant person in his family or home environment. Toward his body and its various parts, the child acquires social percepts, attitudes, and affects culminating from his interaction with his parents and members of his family as they represent the molding forces of the culture. The attitudes of parents impart an indelible impression on the child's concept of himself, his body, and its function. Depending on the experience with the parents, the body and body parts may be conceived as good or bad, pleasing or repulsive, clean or dirty, loved or disliked.

Among some families as well as some cultures, certain aspects of body development tend to be prized, while others are derogated. In general, these attitudes are related to the sex of the individual. Strength and prowess may be emphasized in boys and men, with a major investment in the development of strong limbs and muscles. In a similar manner, the parents and the culture may emphasize the aspects of the body-image which are regarded as qualities of beauty for girls. Apart from these sexually defined values, there are also specific body parts which may be de-emphasized for both sexes. This de-emphasis can manifest itself in concealment by clothing; denial through prohibitions of exposure, touch, or examination; absence of verbal communication (except in jokes); and outspoken derogation of certain body features.

Attitudes toward the body also derive from the individual's perceptions, comparisons, and identifications with the bodies of other persons. Usually, children who are accepted by and conform to their family and cultural expectations for them neither over- or undervaluate their body. Derogatory attitudes with overcompensatory mechanisms frequently develop to obscure either actual or fantasied body defects when the child feels, or is made to feel, that his body fails to meet the expectations of those about him. Where families tend to exploit the significance of body functioning and appearance, overevaluation and reliance upon security through bodily beauty or activity inevitably follow. Should there be a disruption of the body-image, persons with such security reliance are less able to adapt and are thus more susceptible to emotional disturbances.

In so far as knowledge of the surface of the body and its parts is concerned, the individual has many sources upon which to draw. Early, and relatively easily and quickly, he gains a concept of the orifices, including the mouth, the nose, the ears, anus, and urethra. In contrast, knowledge of the internal organs is gained from sensations of discomfort. These sensations may be displaced to the contiguous body surface, referred over related surface segmental impressions, or transferred to the surface through the mechanism of segmental pain. The incorporation of internal organs into the body-image is customarily vague except when a sense of pain or discomfort is referred to the surface. The influence of body knowledge and awareness on language and usage of words referring to the body is shown in such studies as that of Wright,[87] who analyzed the names of parts of the body that occur most in literature. The most frequently used by referents are linguistically the oldest and are found to conform with our accepted personal body-image.

Szasz has recently suggested an extension of the concept of the body-image or, as he calls it, the ego-body integration, to include not only the percepts, affects, and attitudes experienced historically in the life of the individual but also body parts which occur in fantasy as wish-fulfillment in defensive operations of the ego. Thus, Szasz, in broadening the concept of the perceptive ego to the expressive, would include penis-envy in females, castration in men, fetishism, and transvestism. In the case of the transvestite, he is seen as creating, with the aid of garments, a materialization of female phantom parts and an image of the body to which the ego clings.

In evaluating Szasz's concept from the standpoint of human experience, the writer holds that the expression of a phantom part

Downloaded from www.dbebibliotecavirtual.it

is of a different quality and order than that expressed in a wished-for and envied missing body part that has never been experienced in reality. Persons who have not experienced the existence of a limb do not have the capacity for consciously experiencing the existence of a phantom, even though they may wish for a limb. There is a basic physiologic substratum imposed upon the cerebral cortex as the result of perceptual experience which allows development of quality of experience over and beyond that observed in the case of ego-adaptive wish-fulfillments. In line with this rationale, the writer has considered in this discussion only those disturbances of the body-image which are derived from actually perceived body parts. Disturbances representative of partial ego-adaptive mechanisms are discussed by other contributors.

## ¶ Physiology of the Body-Image

From a neurophysiologic standpoint, the postural model of the body is maintained through integrations of spinal neural activity and those of higher cerebral levels. That modification of peripheral sensory activity may influence the subjective appreciation of the body-image is shown by the following observations. Souques and Poisot found that cocainization of the peripheral nerves leads to temporary disappearance of a phantom extremity. Schilder states that Gallinek and Forster had success in removing a phantom by peripheral changes, and also that Adler and Hoff noted diminished perception of the phantom with application of ethlyl chloride to the stump. Head has described the disappearance of the phantom limb following a cerebral operation. De Gutierrez-Mahoney[23] and Echols[27] reported abolition of a painful phantom by surgical excision of the posterior central gyrus. De Gutierrez-Mahoney found, on follow-up studies, that the original impression of abolition of the pain or phantom did not hold. Kolb[45] observed three patients after removal of the somatosensory cerebral cortex done in an attempt to eradicate a painful phantom extremity. The phantom was not lost, but it became less vivid. Also he[49] has observed that there are no significant modifications in phantom percepts following explorations of the stump with removal of terminal neuromata, or with rhizotomies, sympathectomies, cordotomies, injections of alcohol into neuromata, paravertebral anesthetic blocks of the sympathetic ganglia, spinal anesthesias, and prefrontal lobotomy.

The body-image is, as Schilder so properly inferred, integrated in the parietotemporal areas of the cerebral cortex. Pool and Bridges[72] have reported that unilateral surgical ablation or cortical undercutting of the parietal lobe does not destroy phantom percepts. From his study of patients with hemiplegic anosognosia, allachesthesia, and various aphasias, Anastasopoulos concludes that the right parietal lobe is the major cortical area for corporeal representation. However, it would seem that imperception of the body occurs only in those with bilateral cerebral vascular lesions that have led to extensive cortical damage. Cook and Druckemiller[21] have suggested that the body-image is represented in the cortex as the function of a widespread neural network in the postrolandic area. This network, they postulate, may be activated by stimuli from the periphery or centrally from other areas of the brain when the individual turns attention on problems of body functioning or is actively motile.

## ¶ Family and Cultural Attitudes Affecting the Body-Image

Genetic and intrauterine processes and those later accidents of life in the form of traumatic or surgical experiences determine the bodily structure adapted to and perceived by the ego. From this ongoing interaction between perceived body and perceiving ego, consciously and unconsciously, there arise percepts, attitudes, and affects leading to adaptations of the body-image. Gross deformities such as aplasias lend themselves to the development of body-image concepts at both the physiological and psychological levels of integration, which differs from that where there have been less

Downloaded from www.psychosomaticmedicine.org

serious disturbances of the body structure. The body-image of the blind, the deaf, and persons with other dysplasias has been less well studied than that of individuals who have acquired deformities as a consequence of illness, trauma, and surgical procedures.

For the most part, the influence of family attitudes on the development of disturbed body-images has been neglected in study and practice. In point of fact, however, the capacity for a satisfactory social adaptation among those with bodily defects depends more upon the family and cultural attitudes toward body structures than upon the presence of defect. When the family or social attitude toward serious body defect is constructive and supportive, there is greater possibility for successful compensatory development without personality disorder. In the family with healthy attitudes, the defect is accepted, and personality development is directed by the parents along lines where other assets can be developed and strengthened. By these means the afflicted can obtain a kind of satisfaction which, to a degree, compensates for the effects of the inadequacy of the body-image. MacGregor *et al.*[59] have well summarized much of the existing knowledge concerning family patterns that contribute to a healthy and satisfying body-image concept.

The attitude of society toward physical disfigurement is generally that of disapproval, repulsion, and rejection. The deformed child is rejected on grounds that his deformities are due to "sins of the fathers," "punishment for wrongdoing," "incestuous parentage," etc. These myths and conceptions exist not only among the ignorant or uneducated but also among the well-educated and highly intelligent. Large adoption agencies report that it is difficult to place children with deformities. For this reason, it is not an uncommon practice for agencies to offer disfigured children to people who would otherwise not be considered suitable as foster parents. But even under these circumstances, the agencies report that they have difficulty in finding foster parents for children with physical disfigurement.

The use and misuse of superstitious rationalizations regarding deformity have a psychological value in that they provide a means for expressing and projecting an individual's own conflict and fear about deformity in his own body. In the case of the parents, the acceptance of these unsound and unrealistic values provides a means or an excuse to project the blame for the deformity onto another source, to strengthen their existing guilt feelings, or to support hostile or rejecting attitudes toward those whose appearance is different.

Despite evidence of social, vocational, and intellectual competency, the deformed are exposed to a kind of stereotyping which is socially disadvantageous. Pervasive as these attitudes are, there is a reality basis for the high concern manifested by patients with physical deformities. As a rule, the type rather than the severity of the deviation evokes the stereotyped responses. A receding chin is often associated with weakness or effeminacy. A large nose may assign its possessor to a minority group. Persons with protuberant ears, knock-knees, or pigeon toes are frequently ridiculed or become the butt of jokes and hostile humor. Some facial configurations precipitate immediate typing as a moron, gangster, drug addict, or sufferer of some serious disease. On the other hand, certain physical deformities carry a degree of social prestige, as the broken nose of a prize fighter or the scar resulting from a war injury.

With the birth of a deformed child, the mother usually responds with mixed feelings of humiliation, sadness, guilt, or depression. A small group of mothers consciously fail to see the defect as being as serious as other family members and the physician do. While this minority of mothers will have feelings of protectiveness toward their deformed children, they will also feel jealous toward other mothers with healthy babies. Comments about her baby's defect tend to increase the mother's sensitivity.

MacGregor *et al.*, in their study of persons with facial deformities, point out that the attitude of the mother varies according to the sex of the child with the defect. These investigators noted that overemphasis on physical beauty by mothers led to maladjustment in daughters. The facial defect of the female

Downloaded from www.obeslibrary.com

child was seen as producing feelings of rejection, hostility, or guilt in the mothers. As pointed out in this study, boys born with facial deformities were less likely to suffer from such maternal attitudes. It appears that the mothers and the culture as a whole did not make a strong connection between the idea of beauty and the equally desirable idea of "masculinity."

The attitude of the mother toward the defective body of the child is strongly influenced by her perception of the attitude of the husband-father. As a rule, if his response is sympathetic and positive, she finds it easier to accept the disfigurement. However, in some cases, mothers are less anxious about the child if the husbands show more distress than they do. In other cases, the guilt feelings of the mother may become magnified when the father blames her for the defect and when she has reason to believe that there is a basis for the accusation.

If the mother has a realistic awareness of the importance of physical appearance but does not exaggerate this value to the exclusion of all other assets, it is possible for her to accept the disfigured child. In such instances, and with the help of teachers and friends, the mother can be instrumental in helping the child to compensate through good manners, gracefulness, careful grooming, and attractive clothing. The usefulness of encouraging compensating personality traits depends, however, on the genuine acceptance of the child by both parents. Otherwise, parental urgings of compensatory behavior can aggravate or increase feelings of inadequacy in the deformed.

In a study of children with excessive body sensitivity but without particular deformity, Levy[54] found that the specially conducive factors were parental oversolicitude, histories of significant illnesses and injuries in the past, exposure to sick persons or frequent discussions of illness, bodily variations differing significantly from that of peers, and special bodily values of the group subculture. Parental solicitude leading to excessive bodily concern in the child was secondary to a variety of conditions in the life of the parents. For the mother particularly, marital conflict, death of the father, difficulty with the spouse's parents or family, absence of neighbors, and narrow emotional outlets tended to cause them to focus their interests on the child. To compound this difficulty, the interest carried with it displaced hostility and also destructive drives and the reaction-formation of protection. In sum, parental exploitation of the child to resolve emotional conflicts or satisfy ambitions, parental ignorance or immaturity linked with vacillatory overprotection, the death or deformity of siblings, miscarriage and stillbirths, and other special concerns resulting from personal experience served to sensitize the protective parent.

Observations of family life indicate that the deformed child does not receive the same treatment as the other children of the family. The afflicted child is usually treated either with greater consideration or with less approval and warmth, and sometimes even with outright hostility. The responses of the siblings are not necessarily the same as those of the mother to the child. In families where mothers reject the deformed child, the siblings may compensate by providing friendship and help to the child with a defective body. In some other families, the siblings will treat the defective child with outspoken impatience and resentment. Observations suggest that mothers and siblings have less pathogenic attitudes toward children who are accidentally deformed than to children born with a congenital defect; there also appears to be less likelihood of guilt reaction, resentment, and hostility on the part of the mothers.

Emulating the rejecting attitudes of their families and society, most patients with body defects manifest unhealthy attitudes and behavior in relation to their bodies. The majority of children are unwilling to look into mirrors, dread making trips away from home, and try to slip into corners and hide their faces from public view. Contacts at school with other children, who may jeer or ridicule them, often result in the deformed child's returning home in tears or sulking. In small children the ridicule may not at first be understood, but, once it is within the child's comprehension, it can lead to his avoidance of other children.

Downloaded from www.ubaldini.org.in

Frequently, a deformed child will persist in questioning the parents as to why he is different and why he is the only one in the family who is different. Some children attempt to diminish the importance of the deformity by joking about it, while still others studiously avoid mentioning the subject. In every instance, however, these types of behavior are related to the parents' behavior and attitudes concerning the deformity.

The parental attitude is a composite of the parental health and acceptance, and particularly that of the mothers. Some mothers attempt to protect their deformed children from hardship by insistence on their avoiding any activity where they might be questioned. The consequence of this isolation is that both relatives and strangers are kept from contact with the child. Another type of mother will attempt to hide the defect by requiring the child to wear certain concealing clothing or to assume certain postures. In the reports of these instances, the mothers failed to recognize that this hiding was also their effort at withdrawal, although they did mention feelings of anxiety in the presence of strangers. In studying the children who deny the existence of the body defect, it has been found that their mothers attempt to deny anxiety by insistence on exposure of the child to strangers, relatives, and others. The mothers themselves are reluctant to make personal contacts or to discuss the disfigurement. When the subject of disfigurement arises in conversations, parents holding these attitudes tend to minimize their concern. Still another group of mothers compensate for their belief that the children are stigmatized by using the mechanism of "undoing." Here the deformity is spoken of as "cute," and a lack of personal concern is stressed. It is noted in these circumstances that the presence of strangers does not produce feelings of discomfort, but discussion of the defects does.

Differences between healthy and unhealthy attitudes of mothers have been comprehensively discussed by MacGregor *et al.*[59] Healthy mothers do not consider disfigurement as a stigma or punishment for their own behavior. They do not hide concern, and they are able to seek advice from professional persons and their acquaintances. In contrast, mothers whose behavior fits the child's pattern of "avoidance" are likely to become angry when the child fails to follow instructions to conceal the deformity. Such mothers regularly react by blaming the child when the child complains of discrimination. While the denying mother may allow the child with a defect a greater degree of freedom, his complaints of the attitudes of others usually meet with her rejection. She is inclined to "brush him off" with statements that he should learn "not to concentrate on the defect." Those mothers who "undo" the defect attempt to have the child develop a sense of distinction, which leads to impairment of reality sense.

The foregoing description of specific interaction between mother and child in relation to body structure provides the matrix from which the body-image and consequent ego attitudes and adaptation to the body-image arise. This knowledge, derived from studies of family instruction with deformed children, may well apply to children who later show body-image disturbances in the context of schizophrenic and psychosomatic conditions. Unfortunately, detailed studies are not available on the family patterning that leads to body-image disturbance in these conditions—information which is very likely crucial to understanding the personality character of the schizophrenic, whose conviction of bodily ugliness is a well-known clinical phenomenon. This knowledge is essential to formulating rational methods of prevention and treatment of the body-image disturbance.

## ¶ Special Examinations for Body-Image Disturbance

Attitudes toward the body and its parts may be elicited, and ego adaptations to such attitudes may be inferred from the data provided in the course of the psychiatric anamnesis and examination. While the usual examinations and techniques underemphasize this aspect of personality, procedures are now available which may be used to assess the body-ego integration. These techniques include modifications of the

Downloaded from www.psychiatry.org

regular diagnostic examination, new rating scales for measuring body cathexis and appraisal, projective techniques, and specific perceptual tests.

Years ago, Levy[55] suggested a method of integrating physical and psychiatric examinations for children. In Levy's method, the child, at the termination of an ordinary physical examination and while still undressed, is asked to play the role of physician and examine his own body. The physician asks him to comment on what he has noticed about the various parts of his body, observable differences between himself and others, and preferences as to how he would like to see his body parts when he is grown. In addition to these questions, inquiry is made regarding ideas and feelings about the importance or lack of importance of height, weight, strength, and appearance. Reporting on his study, Levy noted marked discrepancies between children's attitudes toward the various body parts and their actual physical structure. The visible mouth area produced the most frequent number of responses. Eyes and hair produced frequent responses from both boys and girls. On the other hand, mammary and genital responses were more evident in boys than in girls, a finding related by Levy to the fact that there is no censor of boys in exposing these parts to nakedness. Children showing a sensitivity to secondary sexual traits appeared to have many doubts as to their sexual identity. Individual points of body sensitivity were displaced to other parts of the body by some children. Jacobson[46] also suggested a method of evaluation.

Secord and Jourard[82] have developed a rating scale as a means of appraising body cathexis. Secord[81] has also devised a word-association test utilizing homonyms as a means of investigating bodily concern. Secord's test discriminates three groups of individuals relative to body concern: the narcissistic who overvalue and overprotect the body because of its intrinsic personal value; anxious persons who register bodily concern owing to physical pain, injury, or sham; and overcontrolled individuals who apparently rid themselves of body concern through denial. The first two groups in the Secord test gave numerous responses on the word-association test, in contrast with the few responses by the third group. Using two tests, the body-cathexis scale and the word association, Secord found that the narcissistic group scored high for body acceptance and high on the word association. The scores of those with high anxiety were low on body acceptance and high on word association. Overcontrolled persons scored low on both tests. Secord's testing has stimulated much interest and has considerable significance, but the work needs further study and validation.

Machover[61] recently described in a monograph the Draw-a-Person test, a projective technique which elicits unconscious attitudes and percepts of the body-image. Using this test or its modification, the Man-Woman-and-Child test, Noble *et al.*,[65] Kolb,[50] and Wille[95] found that some limb amputees include amputated extremities in their drawings. It has not been determined whether the amputated percept might have existed prior to amputation, nor is it now known whether all amputees provide such mutilated percepts and, if this is not the case, the factors that differentiate this group from those who fail to do so.

Figure drawings similar to Machover's have been used by Abel[1] in studying patients with such facial disfigurements as congenital absence of ears, harelips, absence of the nose, scarring from burns, oversized nose, or the sequelae of facial cancers and surgical interventions. Abel has found same-sex drawings to be especially productive of information supplied by the patient. Severely disfigured persons seeking corrective (plastic) surgery portrayed their problem fully in the same-sex drawing. The mildly disfigured were less likely to do so. The projections of the face in the drawings have been categorized by Abel into these four groups: specific portrayal of the individual's disfigurement; distortion of the disfigurement (a large nose for a small nose); omission of all features of the face; and a face with features but without disfigurement.

Fisher and Cleveland[32] have recently utilized the Rorschach test in relating a single dimension of body-image concern with the manner in which the individual sees his body damage.

Downloaded from www.psychosomaticmedicine.org

These investigators state that individuals may see their body as having firm protective surfaces, or as open and without protection. Definite body boundaries are linked in the Rorschach responses to emphasis on protective values of the percepts. Definite body boundaries are correlated with responses such as caves with rocky walls and with men in armor. From the information revealed by such responses, Fisher and Cleveland have suggested a relation between boundary dimension of the body-image and the development or choice of psychosomatic illness. These investigators hypothesize that individuals with definite boundaries usually develop symptoms involving exterior layers of the body. Those persons with indefinite boundaries develop symptoms involving body interior organs. The study also indicates a correlation between adjustment to body handicap and crippling. Persons supplying definite boundaries are seen to adjust significantly better than those with indefinite boundaries when amputation or poliomyelitis occurs. Definiteness of boundary also appears to correlate with a variety of personality traits in healthy individuals. This promising work remains to be verified and amplified. Bard[9] has utilized psychological tests to predict psychogenic invalidism following radical mastectomy.

Perception, as related to the postural image of the body, has been studied intensively by Asch and Witkin.[4] In this work, subjects were placed in a small, tilted room and were instructed to adjust a rod, presented on the back wall, to the true upright. Judgments were obtained with the body of the subject upright and with the body tilted. Striking individual differences were found in the extent to which the perceived upright is affected by the surrounding tilted field. Individual consistency was considerable. Witkin is continuing these studies.

M. B. Bender's[12] studies of double simultaneous stimulation of nonsymmetrical areas of the body provide a special technique of examining perception of the body-image.

During double simultaneous stimulation of the face and another part of the body, the facial stimulation is not only invariably reported but is consistently dominant to all other body parts. The genital region is only slightly less dominant, with the hand the least, and other body areas falling in between. Normal persons who make frequent errors in initial trials of reporting double stimulations tend to correct errors. Persons with brain disease and schizophrenics appear to modify their responses less readily. Linn,[57] utilizing Bender's test in studying patients with organic brain disease, suggests that the face-hand response is fused and the hand-touch response is not discriminated verbally. Linn's patients reported through nonverbal gestures for the hand-touch test but gave oral responses in the face-touch experiment. He concludes from these observations that the hand response is not the result of extinction by more dominant face perceptions of body-image but rather a nondiscriminated manifestation of fusion of the face-hand response. Linn's hypothesis is in keeping with what is known of the early experiencing of the body by the developing perceptual ego. Pollack and Goldfarb[71] tested both institutionalized schizophrenic children and institutionalized nonschizophrenic children with the Bender technique. They found that, by the age of seven, all normal children perceive both face and hand stimuli within ten trials, while the pattern of response of the schizophrenic children was significantly different and more similar to that of younger children and those with mental changes due to severe brain disease.

## ¶ Phantom Phenomena

The phantoms of amputated limbs, the first to be recognized, are also the most frequently encountered, best understood, and best described. To a lesser degree, phantoms also occur following removal of other body protuberances such as the nose, eyes, teeth, nipples, penis, and the breasts of women. Since the phantom is the expected healthy response following sudden loss of a limb, a detailed account of this phenomenon is presented as a means of discriminating the pathologic reactions to limb mutilations.

The phantom limb or digit is almost a uni-

Downloaded from www.dbraulibrary.org.in

versal phenomenon following amputation, having been reported in as many as 98 per cent of cases. Ewalt and his associates[30] studying 2,284 amputees in an American Army hospital during World War II, have developed some significant data on the occurrence of the painless phantom as compared with the painful phantom. Their report shows that only 8 patients of the total group complained of painful phantom limb, whereas the remainder had a painless phantom. From Bressler's study of the breast phantom,[15] it appears that approximately 40 per cent of the women noted their occurrence following amputation. Figures are not yet available as to the frequency of observation of the phantom of other lost body appendages.

Riddoch,[75] Henderson and Smyth,[39] and Lhermitte[56] have provided excellent descriptions of the characteristics of the phantom delusion. These writers point out that the amputee is most aware of the distal portions of the phantom such as the hand and foot. They also note that following amputation, the individual initially perceives the phantom as consisting of the whole extremity. Henderson and Smyth have characterized the sensory phenomena of the phantom as consisting of three general types. The first is a mild, tingling sensation, the basic phantom phenomenon, which is dependent upon the function of the sensorimotor cerebral cortex. The second experience is a stronger, momentary pins-and-needles sensation such as that felt in the phantom when the neuromata in the stump are touched. This sensation is apparently dependent on the functional activity of the lower spinal center. The third type consists of certain superadded disagreeable or painful sensations which are described as "twisting," "burning," "pulling," "itching," or various other complaints couched in bizarre terms. These epiphenomena are discussed in the excellent clinical reports of Bailey and Moersch.[7]

Most phantoms, regardless of type, are intermittent and more annoying than agonizing. The introspective and observant amputee may notice aggravation of the basic tingling sensation by stimulation of the stump. The aggravation, when a leg has been lost, may also be occasioned by urination, by changes in the weather, or by emotionally disturbing incidents.

Related to these general types of sensory phenomena, especially the pins and needles, are sensations referred into the phantom in the presence of dysfunction of other organs. Referred sensations into the phantom are most often elicited by deep pressure on the amputation stump, less often with algesic skin stimulation, and least by tactile stimulation. Erickson and his associates[29] have demonstrated that similar sensations may be referred into the phantom by stimulating the appropriate portion of the postcentral gyrus of the cerebral cortex. Cohen and Jones[20] have described pain of cardiac origin referred to the phantom left arm. Cronholm[22] has extensively studied the sensations referred to the phantom by various stimuli applied to the amputation stump and skin areas contiguous to this stump.

The phantom is experienced as a reality, the absent extremity occasionally described as feeling swollen, numb, or tight. Following an acute traumatic dismemberment, the amputee may forget his loss and fall as he attempts to step on the foot which has been removed. It is not unusual to obtain accounts of reflex movements in the missing extremity. The amputee often describes volitional wiggling or movement of his fingers or toes and flexion of the extremity—wrist or ankle. Weir Mitchell has observed that the conscious awareness of the phantom may be greater than that of the contralateral intact limb. The patient, preserving an alignment of the phantom with the stump, is likely to comment upon its capacity to penetrate solid objects unaccompanied by any sensation of touching. Thus, a patient lying in bed with a mid-thigh amputation may feel as though his phantom leg is flexed at the knees and the lower part is penetrating the mattress without experiencing contact with the mattress.

The phantom extremities existing after denervations of limbs or severance of the spinal cord are similar in many respects to the phantoms following limb dismemberment. Patients report that they perceive the phantom extremity in positions other than those actually maintained by the intact extremity. Occasion-

Downloaded from www.psychosomaticmedicine.org

ally, they speak of a reduplication of the phantom in which one phantom coincides with the paralyzed limb and another coincides with the limb in its healthy state. Reduplication is encountered most often in patients with high cervical transverse lesions of the spinal cord or among those with lesions in the cerebral hemispheres.

Differing from the phantom produced in the amputee, the phantom of the paraplegic does not shrink away or telescope, provided the cord transaction is complete. Also, in the paraplegic, the length and position of the phantom usually remain unaltered by postural changes of the body or by vasomotor stimulation. However, paraplegic patients do report volitional movements of the phantom and occasional homolateral associated movements. As Bors[18] reports, the most frequently willed movement in the paraplegic is in the anal sphincter.

The initial perception of the phantom becomes modified through continuing experiences. With time, the patient comes to feel certain parts less vividly than others. The faintly perceived parts tend to fade away, while others persist with undiminished intensity. In the case of the extremities, the parts which recede first are the upper arm and thigh. Next to disappear are the lower arm and calf, and these are followed in turn by the joints and parts of the hands and feet. Among the last to disappear are the toes, instep, the heel, the lateral margin of the sole of the foot or the fingers, the palm and the ulnar part of the hand. The great toe, the thumb, and the index and little fingers are retained longest.

The phantom modification and dissolution take place over varying periods of time and in some amputees are fully completed. The sequence of the disappearing parts follows the well-known neurological homunculus as represented in the sensorimotor cortex. It appears that those body areas having the most cerebral representation are richly endowed with sensory fibers that make for high sensory acuity and fine discrimination. On the motor side, the areas have high innervation ratios and the capacity for discreet and skilled movements. These highly innervated parts, dominantly perceived through usage, have not only the longest phantom life but are also subject to earliest exploration and stimulation.

Telescoping is another characteristic of the reorganization of the phantom. As the distal portions of the phantom become conspicuous in relation to the proximal segments, the position of the phantom hand or foot is at first unchanged. The patient is unaware of empty spaces or gaps between the stump and the well-perceived distal portions of the extremity. Then the amputee experiences the emptiness of the inner space, and the persisting phantom seems to become disconnected. Although it remains in its customary place and position, it has no sensation of intervening segments. Subsequently, the distal phantom hand or foot approaches the stump. In some patients the distal segment of the phantom, once connected to the stump, fades away, leaving only the toes or fingers, which may also disappear in time. In other patients the phantom hand or foot may remain intact, but in these cases it is gradually displaced into the stump, with the toes or fingers protruding. Occasionally, the stump comes to enclose both the foot or the hand. It is important to note again that the phantom extremity or portions of the extremity may diminish in size. This disconnection of the phantom size, which is frequently overlooked, is only observed if the patient is requested to compare the size of the phantom to the healthy foot.

The telescoping phenomenon is never complete. The phantom may be restored to its former extent when the peripheral stump is stimulated by pressure, as with the fitting of a prosthesis and during disturbances of consciousness in the course of severe intercurrent illness. Jackson's theories of dissolution and restitution of function within the nervous system, following either temporary or complete cessation of function of cortical or higher segmental areas of the brain stem, provide insight into the basis of the process. According to Jackson, a loss of the most recently acquired and most highly organized function ensues, with a re-emergence of more primitive functions with later acquisition of new or reappearance of some of the lost functions. Thus

Downloaded from www.dbraulibrary.org.in

earlier infantile and childhood perceptions of the lost limb are seen in the telescoping phenomena. As a whole, neurological theories lend themselves to appropriate and satisfactory explanations of the reorganization of the phantom parts representative of the postural model of the body. Neither the psychoanalytic theory of wish-fulfillment nor gestalt psychology succeeds in explaining the failure to experience the phantom extremities by those who have an aplasia of the limb from birth or an early amputation.

In the case of an acute illness effecting loss of consciousness, there is a reduction in the recently acquired modification of the body-image among those patients in whom the phantom has disappeared. The more primitive, intact body-image concept, which includes the phantom, re-emerges. It is of interest that a paraplegic patient with phantom does not experience telescoping under these circumstances. With these patients the continuing optical image of the intact extremities prevents reorganization of the body-image.

The life of the phantom has been variously reported to persist from a period of a few months to as many as twenty or thirty years. While it is common to hear that the usual phantom disappears within two years after amputation, no firm evidence is available on the period of survival. It seems probable that the failure to reorganize the body-image with disappearance of the phantom extends over a much longer period than is usually thought.

Facial phantoms, following loss of the nose, eyes, teeth, and other portions of the face, are less frequently reported. It is uncertain whether this infrequency results from the attending physician's failure to examine completely because of psychological denial by the patient, or from psychophysiological lack of organization of this area of the body. Hoffman[42] has recently pointed out that the examination for the phantom of the facial organs should be made in terms of the subjective perception of the function of the organ. This is in accord with the description of the phantom eye of patients who have lost an eye. They report scratching or itching sensations in the eyebrow, expectancy of movements of the eyeball as though the eye were present, and sometimes blinking of the phantom eye. Among patients having resections on the nose, there may be a compulsion to touch or palpate the end of the nose. Some data exist concerning facial phenomena relative to the eye, nose, and eyebrows following radical maxillectomy with enucleation of the eyeball for carcinoma of the maxillary sinus. Similar disturbances have been reported after resection of the mandible for carcinoma.

Mammary phantoms, which are discerned as a percept either of the whole breast or of the nipple, are observed principally when the patient scratches or reports itching. Their perception is episodic and less realistic than that of the limb and is accentuated by menstruation and changes in the weather. Anal-genital phantoms include those of the testicles, penis, and rectum. There appears to be no direct correlation between the occurrence of actual erection and the presence or absence of the flaccid or erect penis phantom. In the paraplegic patient, Bors has reported that phantom sensations of the bladder and rectum are more rare than the flaccid and erect penis.

The infrequency of breast, penis, and testicle phantoms has been ascribed by Gallinek[34] to the lack of proprioceptive sensibility in immovable organs. However, the fact that they occur occasionally makes this explanation inadequate. Bressler's comment[15] that the breast is not integrated into the primitive body-image of the female child in the early years of growth and that full development occurs later seems especially pertinent. Moreover, it is not unlikely that psychosocial and cultural attitudes toward the genital and procreative organs contribute to the tendency to deny the phantom phenomena that follow their loss.

The effects of psychotomimetics such as mescaline and d-lysergic acid diethylamide (d-$LSD_{25}$) as they induce perceptual disturbance and modify the phantom have not been elucidated. Zador[98] has described changes in the size, shape, and position of the limb phantoms of two amputees and of a patient who was paralyzed by poliomyelitis. The latter developed a phantom of a limb after an Esmarch bandage was applied. The writer and his associates have conducted a series of ex-

Downloaded from www.brainmary.org

periments on an amputee who continued to have pain in a phantom arm following resection of the contralateral posterior central gyrus. In this study, 18 micrograms of d-$LSD_{25}$ administered intravenously produced no change; 86 gamma of d-$LSD_{25}$ led to perception of more definite form; with a larger dose (95 gamma), the size of the phantom enlarged. Phantom pain was unaffected in both trials with d-$LSD_{25}$.

## ¶ Adaptation to Disturbance of the Body-Image

A series of emotional, perceptual, and psychosocial reactions are a natural consequence of disturbance of the body-image. The nature of these reactions determines whether the individual's adaptation is healthy or pathological. The existence of a phantom is the expected healthy response to amputation of a limb or body part occurring after early childhood. Similarly, patients who have undergone changes in body configuration as the consequence of metabolic disorder frequently report bodily perceptions at variance with those observed by the patient's medical attendant and his family. The reports of sudden changes in the body configuration which result in personality disturbance are in part reactions to disturbance of the body-image.

Whether a sudden change in the body-image results from a surgical procedure or from a metabolic disorder, it always arouses anxiety in the patient. The distortion of the customary body-image is experienced as a distortion of the self. In instances of dismemberment, mourning for the loss of the part, similar to that of separation from significant persons, is expected. Further complications are introduced, with resulting anxiety, as the disfigured person is threatened by fears of separation from and rejection by the significant persons upon whom he is dependent. Feelings of hostility may emerge toward these persons as part of the separation anxiety. The perceptual life of the patient is disturbed as regards his unreal appreciation of his own body and also his perceptions of other persons. Some amputees report unusual sensitivity and discomfort upon seeing other amputees. The extent of perceptual distortion among patients with body-image disturbance is not known. The unconscious mental life of the patient is also modified by the distortion of his body-image. The dream-life may become a wish-fulfilling type in which the disfigured person sees himself performing activities in which the lost part plays an active role. Repetitive dreams recapitulating the incident that led to disfigurement are associated with the affect of anxiety.

A healthy adaptation may be measured by the patient's willingness to discuss his disfigurement or dismemberment or functional loss and the phantom and by his ability to accept offers of aid. With plastic surgery, eyeglasses, hearing aids, dentures, and other aids to social and vocational rehabilitation now widely available, the healthy person reacts by accepting his defect and cooperating with those who can assist in readaptation. Usually, the limb amputee is willing to accept the prosthesis. Similar attitudes normally obtain among those who have lost an eye and require ocular prosthesis.

Psychopathological responses to the disturbance of the body image are manifested variously. Denial of disfigurement as a wish-fulfilling mechanism to maintain the pre-existing body-image is occasionally seen, as in the failure to report the phantom after a limb amputation. Another manifestation of denial is the unwillingness to accept devices that aid rehabilitation. Scott[80] has reported the phenomenon of psychological denial in a manic patient (amputee) after a suicidal attempt. The question of the frequency of the phantom phenomenon and its significance as an indication of psychopathology will remain undetermined until more systematic study has been made of other than limb amputees. The failure to report a phantom with absence of a body part must be distinguished from conditions in which the body-image never included the absent part or where slow modification of the image took place with progressive dismemberment, as in leprosy.[83] The presently known causes for failure to report a phantom with absence of a body part are: (1) aplasias of the part (congenital defect), (2) amputations in infancy and early childhood, (3) loss of internal organs, (4) slow

Downloaded from www.dbraulibrary.org.in

dismemberments (nonsurgical) as in leprosy, and (5) psychological denial.

The failure to reorganize the body-image over a period of time subsequent to its distortion represents a psychopathological adaptation. This maladaptation is frequent among those individuals in which the integrity of the body-image, as it existed prior to illness or trauma, is overevaluated for maintaining self-esteem. Limb amputees, in whom the presence of a limb symbolized either masculinity or femininity, generally adapt poorly to limb loss. Renneker and Cutler[74] have found that successfully married women with children adapt easier and faster to the loss of the breast from mastectomy for cancer than do those who have been unmarried or whose marriages have not been successful.

Depressive reactions occur frequently as a result of the body disfigurement. Psychodynamically, these reactions represent not only a mourning for the loss of the part but have a relation to feelings of overexpectation of rejection and fear of separation from those upon whom the patient is dependent. Repression and introjection of hostile impulses toward the significant persons are part of the reaction complex. Frank paranoidal reactions are particularly apt to express themselves following surgical procedures on patients with a self-derogatory body-image. As the expectation of a satisfying social acceptance cannot possibly be met without modification of the total personality of the neurotic patient, the hostile expectation becomes focused upon the surgeon and any others involved in the corrective procedure and toward whom the patient had built up feelings of dependent hopefulness.

Complaint of pain in the phantom or in the area of the physical disturbance may serve as a symbolic expression of the anxiety over the loss and the threat to the individual's dependency needs as well as an expression of a sadomasochistic identification, a depressive equivalent, and as a substitute obsessional symptom. The writer has found in his study of individuals with painful phantom limbs that 70 per cent had lived in close association with an amputee prior to their own loss. This appears to demonstrate the high frequency of identification as a determinant for this complaint.

TABLE 1. Comparison: Affirmative Answers to Certain Questions as Given to Amputees with Painful Phantom Limb (Without Other Physical Lesions) and Other Groups

| GROUP | PERSONS QUESTIONED | PER CENT RESPONDING "YES" TO QUESTIONS 1 THROUGH 3* | | |
|---|---|---|---|---|
| | | 1 | 2 | 3 |
| Amputees | 22 | 73 | 25 | 13 |
| Healthy | 100 | 20 | 8 | 8 |
| Psychoneurotic | 100 | 33 | 14 | 9 |
| Psychotic | 100 | 29 | 9 | 9 |

* Each person interviewed was requested to answer "yes" or "no" to the following questions numbered 1 to 3, as indicated in the table:

Question 1. Have you known intimately a person with an amputated limb (friend or member of family)?
Question 2. Was the person with the amputation a member of your own family?
Question 3. Have you lived with a person with an amputated limb?

As Kolb[49] pointed out, the characterization of the limb amputee as a terrifying and threatening individual is well expressed in English literature by Melville's Ahab, Stevenson's Long John Silver, Barrie's Captain Hook, and Poe's General A. B. C. Smith.

Fantasies of personal mutilation, usually repressed, may become remobilized by the threat or actuality of trauma of surgical procedure. Many patients with limb phantoms disclose terrifying and superstitious rationalizations which they utilize to explain the existence of the phantom limb. Magical thinking and fantasies concerning the mishandling of the separated limb or about the nature of the phantom commonly serve a guilt-allaying function. Patients with limb amputations frequently express a desire to have the separated part disposed of tenderly and respectfully, as if it were their whole body or that of a close family member. On some occasions they may even fantasy arrangement for disposal of the limb. This behavior is less likely where the illness causing the loss of the limb has been prolonged and the mourning period has been worked through prior to separation.

Psychotic reactions involving distortions in body-image follow either acute trauma or prolonged somatic disease. L. Bender,[11] in particular, has described psychotic reactions in

Downloaded from www.library.ucsf.edu

patients suffering Paget's disease, osteogenesis imperfecta, and dwarfism. The acromegalic presents a similar symptom picture. In the slowly developing disease processes which distort the body structure either directly or through interruption of the growth process, discrepancy develops between the body-image of the sufferer and the physical personality. As Bender indicates, the sufferer is made anxious by the obscurity and mystery of the poorly understood disease process. Moreover, the patient is thwarted in all his strivings, whether social, sexual, or vocational, which were predetermined before the illness. In adolescents the conflict over the idealized image and the fixed image ensues when the developing body structure fails to conform to the wished-for or ideal image. For adults suffering any of the somatic disorders described above, the body-image distortion by illness requires the difficult adaptation from a level of established satisfaction to one of ill-understood acceptance and accomplishment. Bychowski[17] and Eickhoff[28] have reported specifically upon the body-image disturbances in adult schizophrenics, and Pollack and Goldfarb[71] have studied the image in the institutionalized schizophrenic child. Kolb[49] contrasts body-image of the schizophrenic and the narcissistic in his discussion of responses to amputation.

L. Bender[10] has examined the body-image disturbance in the brain-damaged, Schontz[79] in those with hemiplegia. The body-image disturbances represented in the neurological defects are considered elsewhere in this volume by Weinstein.

While not specifically concerning body-image, the general responses to disfigurement are considered by Dembo *et al.*;[24] to plastic surgery by Updegraff and Menninger;[82] to harelip and cleft palate by Brophy;[16] to the face by Baker and Smith,[8] MacGregor *et al.*,[59] and Meerloo;[62] to radical maxillectomy by Hoffman;[42] to rhinoplasty by Linn and Goldman;[53] to mastectomy by Renncker and Cutler;[74] and to genitalia by Heusner.[40]

## ¶ Prognosis

Since body-image disturbances may occur within the context of any personality structure, only general statements may be made in regard to prognosis. The outcome of this form of personality disorder is basically dependent on the meaning of the bodily defect to the individual. The extent and disabling nature of the defect and the availability of rehabilitative services have a meaning to the patient which exists, as Kubie emphasizes, on several levels of psychological functioning—the reality level, the level of conscious fantasy, and that of unconscious symbolic fantasy. Depending upon the individual, the loss may have any meaning such as a heroic sacrifice or a deserved punishment, a realization of helplessness and vulnerability, a conviction of loathsomeness, a despicable mutilation to be hidden or accepted, or a rejection of the part with defiance toward society and social customs. The meaning may be determined only through the psychiatric study of the individual.

A productive and satisfying social existence depends on acceptance of the changed body structure and the eventual establishment of a new body-image. The need for psychiatric treatment is evident in order to modify pathological and unconscious meanings of the change in the body structure which tend to perpetuate motivations that impede maximum recovery. But this treatment alone may be ineffective if it is not coupled with the skilled help of prosthetic experts and evaluation of vocational counselors. For some patients the attitude of responsible relatives and the local society may finally decide their success or failure in readapting to productive living. In these circumstances, educational programs designed to avoid cultural stereotyping and rejection relative to one or another disability are necessary. Attempts to predict psychogenic invalidism as a consequence of the disturbance of the body-image have been made by Bard[9] in relation to mastectomy, MacGregor and Schaffner[60] in relation to nasal plastic operations, and Fisher and Cleveland[32] in relation to amputation.

## ¶ Treatment

Prevention of body-image disturbance includes all those measures designed to avoid genetic and constitutional defects in bodily development. Consideration extends also to

Downloaded from www.dbraulibrary.org.in

the role of industry and society generally in protecting the individual against accidental trauma. The individual's own psychological capacity for protecting himself against accidental injuries is certainly a preventive to the development of the body-image disorders. However, not only is the current state of knowledge in this area inadequate, but what is known is ineffectively applied or implemented by our present social structure.

In the instance of the individual confronted with an elective surgical procedure known to produce deformity, the psychiatrist and his medical colleagues may aid in the prevention of serious disturbance through proper use of the knowledge at hand. For those undergoing amputations or exposure to medications which produce body-image disruption, the preventive effects of proper preparation include advice as to the variety of body changes that may occur. In the case of amputation, the patient should be made aware of the occurrence of the phantom. Considerate inquiry into the patient's fears and anxieties is desirable. If a limb is to be amputated, the patient's desires as to its disposal and possible burial should be ascertained. Some initial discussions of the disability, its meaning to the patient, and compensation for it are advisable.

The family and other persons who are significant to the patient should be advised as to the expected post-treatment psychological and emotional phenomena. This is important so that their aid may be immediately enlisted in the rehabilitation process and especially in ascertaining the possibility of the operation's emotional destructiveness to the patient. Watson and Johnson[93] have emphasized the significance of the attitude of parents in determining the management of amputation in children. Despite excellent preoperative preparation of both the child and her parents for amputations for a bone tumor, the postoperative syndrome was complicated and aggravated by the denying and rejecting attitudes of the parents. Treatment should be instituted as quickly as possible when disruption of the body structure leads to personality disorder. Failure to do so can result in fixation of chronic psychopathic reactions. In panic reactions with pain after limb amputations, the writer has utilized a brief psychotherapeutic technique in which the following topics have been penetrated in successive order from the initial interview: (1) the concept of the phantom-limb phenomenon and any attendant rationalizations regarding this; (2) wishes and fears relative to the disposal of the amputated part; and (3) the significance of present and past attitudes toward the body in relation to real or fantasied experiences with significant persons. This procedure has proved effective in alleviating panic and painful complaints in a number of limb amputees, among those with facial disfigurement following surgery, and in women with breast deformity consequent to thoracoplasty. It has also been utilized in initiating psychotherapy on amputees who have remained chronically disturbed for years following their loss.

In disturbances of the body-image that have led to chronic personality disorders, whether psychoneurotic or psychotic, the choice of therapy is dependent on the particular variety of reactions suffered by the individual. Various forms of psychotherapy,[8, 49, 50, 87] including psychoanalysis, hypnosis,[19] narcosynthesis,[36, 50] electroshock therapy,[70, 72] frontal lobe injection,[20] and outpatient treatment with chlorpromazine[63] have been reported effective. Indications for and techniques of application of these treatments are presented elsewhere in this volume.

CHAPTER 39

# FUNCTIONAL DISTURBANCES IN BRAIN DAMAGE

Kurt Goldstein

Downloaded from www.dbraulibrary.org.in

Our knowledge of functional disturbances in brain damage is based on the patient's symptoms. Symptoms are modifications of behavior in various performance fields. If one considers the symptoms as directly dependent upon damage of the brain matter in various regions and as directly related to defects in different performance fields, one can draw some conclusions about the relationship between a disturbance of a particular performance and a specific brain damage. Although the results thus reached are useful for practical purposes, we learn little of how a lesion modifies the specific function, and of the origin of the symptoms.

First of all, the pathological-anatomical picture seldom indicates the degree of functional disturbance produced by the injury, since this depends primarily upon the extent and intensity of the injury—factors which cannot be correctly determined even by careful microscopic investigation. Furthermore, the difficulty is increased by the fact that the kind of damage —such as hemorrhage, tumor, inflammation, or intoxication—has a different effect on the functional disturbance.

The question of the relationship between the symptom and the disturbance of the brain matter's function is by no means as simple as has often been thought; indeed, one can say it has become increasingly problematical. The main difficulty consists in determining which of the observed phenomena are actually directly related to the defect of the brain—a question which is, as yet, far from clear. Increasingly, we have learned that, when we refer to disturbance of performance caused by a brain lesion, we must consider not only the disturbed performance but all the observable modifications of the patient's behavior. We know from Jackson's distinction between different groups of sequelae of brain damage (see p. 772), that this is a very difficult task. When one further realizes that, in a brain lesion, the symptoms can differ because of various conditions of the whole organism, and that they may become understandable only as phenomena depending also upon the organism's general condition, it

is doubtful whether one can speak of symptoms as caused by brain lesion alone, or whether one can do so only in an abstract, theoretical consideration of the facts.

As clinicians, we cannot be satisfied with merely theoretical interpretations of the symptomatology—interpretations based not on clinical experience but derived from studies in normal physiology and psychology—as has frequently been tried in the past. We have to try to reach a better understanding of the functional disturbances in brain damage by taking into consideration all that we observe about the patient, his whole behavior at a given moment, especially its deviation from the norm. This is what I consider to be my task in this presentation.

The material available for this procedure is so vast that to discuss a considerable part of it here would be impossible. I shall therefore try to show, by use of typical examples of symptom complexes, which factors must be considered for an understanding of the structure of symptoms in brain damage, thus enabling the reader to apply our results to other symptom complexes.

## ¶ Previous Views Regarding Brain Damage

Until recently, the symptoms observed in damage of the brain cortex were considered to be expressions of a loss of so-called "images," the aftereffects of previous experiences deposited in different circumscribed regions of the brain cortex, according to the different performance fields. It was also postulated that the symptoms could not result exclusively from the effect of these circumscribed defects—that additional factors must be involved; only thus could the variations, the alternation between normal and abnormal reactions of the patient in seemingly the same task, be understood. These other modifying factors were considered to be "general mental capacities" such as attention, memory, interest, and emotions. The additional factors were brought more or less into relationship to localized or general brain functions. The influence of the atomistic theory of brain function was so great that one overlooked the fact that, by introducing these general functions, nothing was gained. As a matter of fact, closer observation showed that these "general functions" varied in the same way as did the single performance. Attention, for instance, may seem to be sometimes grossly disturbed, and yet the same patient, under other conditions, may appear attentive or even abnormally so (cf. Goldstein,[18] p. 249). Thus we found ourselves in the same situation as before when we tried to understand the variations of the phenomena by assuming the influence of such general functions.

Today it is hardly understandable that the solution to the problem was not discovered earlier, namely: to consider the symptoms not only in relation to the dysfunction of limited parts of the brain but in relation to the individual in whom they appear; in other words, to consider them as performances of the sick individual. The concentration of study not on the single symptom but on the behavior of the total personality of the patient, during examination and in everyday life, made it more and more evident that the symptoms could only be correctly evaluated if one considered them in relation to the condition of the total psychophysical personality. This instigated an intensive study of each single symptom in relation to the behavior of the total patient at a given moment, which, in turn, became the point of departure for the concept of the so-called organismic approach to psychopathology in general (see in regard to this Goldstein[19]). It is this organismic approach which is the basis for this presentation.

The new approach was not the result of a new theoretical concept but the outcome of better observation and investigation. Closer scrutiny led to the concept that the symptoms are consequences of the sick organism's struggle with the demands of the tasks confronting it; in other words, symptoms are forms of behavior by which the individual tries, in spite of his defect, to come to terms in the best way with the outer and inner world. The approach grew out of the necessities of neuropsychiatric practice, out of the task of retraining a great number of young men with brain injuries and different mental defects with which we were confronted during and after World War I, and out of the recognition that the psychopatho-

Downloaded from www.brainlibrary.co.in

logical theories prevailing at that time, and the methods of training based on them, were insufficient to fulfill the task. There was an urgent need to find a more successful interpretation of the phenomena, particularly so because the subjects with whom we were dealing could not any more be considered as interesting objects for theoretical studies, as was often the case in psychopathology in earlier times. The disastrous condition of the young men confronted us with a strong challenge to help them in every way possible. The approach became particularly promising after the analysis of the symptomatology of a great number of patients with various brain injuries had revealed another point of view in the consideration of organismic life in general and of man's in particular, namely: that the basic motivation of the living being is to realize its own nature; that is, to realize all its capacities to the highest degree possible in a given situation. By applying this viewpoint, many seemingly contradictory symptoms became understandable, and much better results of retraining were achieved.

The structure of the organismic approach will become clearer when we consider individual symptoms in brain damage. We shall see, then, that phenomena which were once considered to be different, isolated defects appear now to be simply different expressions of the same brain damage under different conditions of the whole organism.

Before entering into the subject, I want to make a few general remarks about the period in which the organismic approach originated and the place of this new approach within the ideas of that time. It was related to the new "holistic" orientation in physiology and medicine in general, which finds its expression in such a saying as, "There is no sickness—there are only sick human beings." I refer in this connection to a congress held in 1932 under the topic *Einheitsbestrebungen in der Medizin*,[10] where men famous in anatomy, physiology, and different fields of medicine came together to discuss this question with great enthusiasm.

While the new approach brought deeper insight into the function of the organism and a better understanding of pathological phenomena, it confronted us with a number of new methodological problems. When one considers each symptom as dependent on the condition of the entire organism, great difficulty arises in determining the relationship of a symptom to the specific brain damage. This particular problem had been seriously considered fifty years before by the famous English neurologist and psychopathologist, John Hughlings Jackson, who reached a general point of view in psychopathology to which ours bears much similarity.

Jackson, as an outgrowth of his experiences with aphasic patients, emphasized that psychopathological phenomena can be understood only if one gives up the theory of images, and he stopped considering disturbances of images in brain defects as causes of symptoms. He believed that, in order to understand psychopathological phenomena, one has to begin by analyzing the modification—due to its damage—of the function of the brain, and by considering the different symptoms of aphasic patients as expressions of a disintegration of the brain matter; expressions of a lowering of the function of the brain to a level where automatic and emotional reactions still are possible, while the highest function, the propositional symbolic function, is more or less lost.

Jackson's ideas were so far ahead of his time that he found little approval. In the famous discussion between him and the French neurologist, Broca, at the British Association for the Advancement of Science in London in 1868 in which both men defended their contradictory theories about the function of the brain, Broca emerged as victor; afterward, Jackson had little influence on the work in psychopathology. Although some great men in the field at that time, A. Pick, C. von Monakow, Adolf Meyer, and others, stressed Jackson's great significance, referred to his ideas, and used them in their work, he was nearly forgotten for a long time. He had to be newly discovered. This rediscovery occurred during the period referred to previously when clinical practice demanded better procedures for helping brain-injured soldiers in England. It was the English neurologist, Henry Head, who based his treatments on Jackson's ideas and demonstrated their fruitfulness for understanding much of the aphasic symptomatology and for its treatment. A little earlier, other unbiased

Downloaded from www.cfpubliany.org

studies by Storch, Heilbronner, Pierre Marie, Lotmar, Bonmann, Gruenbaum, Woerkom, and K. Goldstein, influenced more or less by Jackson, gave different new interpretations of psychopathological phenomena which can be considered as precursory to the organismic approach.

By stressing the organismic approach as the best one for an understanding of the symptoms in brain damage, I do not want to imply that this approach has found full acceptance. Although a considerable amount of psychopathological research is more or less influenced by it, certain men prominent in the field are strongly opposed to it, for example, in this country, Nielson and some others.

Adherents to the older "classic" theory, founded on associationism and the assumption of isolated, circumscribed disturbances, base their opposition primarily on the argument that the new approach is too general and does not therefore do justice to the problem of localization, and, even more important in respect to the problem with which we are dealing here, to the great variety of modifications of performance of the brain-damaged patient.

As to the opposition concerning the problem of localization, I would like to point to various papers of my own, particularly the presentation of the subject in the German *Handbuch der normalen und pathologischen Physiologie*.[16] There I have shown that this problem is by no means neglected by the new approach; moreover, *that the approach put it on a more realistic basis*, so that many mistakes originating from the old concept can be avoided.

Proof that the new approach emphasizes the great variety of symptoms and the problem of understanding them will become apparent when we now discuss the symptomatology of patients with severe damage of the brain cortex.

## ¶ Effect of Impairment of the Abstract Attitude Owing to Brain Damage

I shall not start with a description of patients with defects in special performance fields, such as speech, motility, vision, sensation, etc., but with patients who show disturbances in all these fields in such a way that some performances in each field are impaired and even lost, while others seem relatively well preserved. This clinical picture occurs particularly in severe lesions of the frontal lobes or in diffuse damage of the brain cortex by injury or intoxication, in general paresis, etc. It can be shown that the complex and outwardly very inconsistent symptomatology of the patient can be understood as an effect of the damage to a special mental capacity which we call the abstract attitude. Before going into this matter, it seems necessary to make some remarks concerning the concept of the human mind which underlies this interpretation.[24, 26]

The normal individual displays two kinds of attitudes toward the world—the *concrete* one and the *abstract* one. In the concrete one we are given over passively and bound to the immediate experience of the very things or situations in their uniqueness. Our thinking and acting are determined by the immediate claims made by the particular aspect of the object or situation. For instance, we act concretely when we enter a dark room and turn on the light switch. If, however, we refrain from turning the switch, reflecting that we might awaken someone asleep in the room, then we are acting abstractly. We transcend the immediately given aspect of sense impressions, we detach ourselves from the latter, and consider the situation from a conceptual point of view, reacting accordingly. The abstract attitude corresponds approximately to what Henry Head has called—in relation to speech—symbolic behavior.

The healthy individual is able to shift voluntarily from one attitude to the other, according to the demands of the situation. Some tasks can be performed only by virtue of the one, some only by virtue of the other attitude. For the beginning of any activity, the abstract attitude is a presupposition. During activity, the concrete attitude is often dominant, but, should the course of action be interfered with or disrupted, abstraction is required to correct such disturbances and to continue the activity properly.

Patients with impairment of abstract attitude may not appear to deviate grossly from normals in everyday behavior, because many routine tasks do not require the abstract atti-

Downloaded from www.dbraulibrary.org.in

tude once these tasks have been set going. During observation of the patient in a variety of situations, however, it becomes evident that he does not react like a normal individual; he appears more stereotyped and reserved. He seems to lack initiative and spontaneity. Tasks which demand choice or shifting particularly reveal the defect.

From analysis of the behavior of a great number of such patients in various everyday and test situations, we[25] have compiled a list of modes of behavior in which the performances are disturbed owing to impairment of the abstract attitude.

The patient fails if he has

1. To assume a definite mental set.
2. To give an account to himself for acts and for thoughts.
3. To shift reflectively from one aspect of a situation to another.
4. To keep in mind various aspects of a task or of any presentation simultaneously.
5. To grasp the essential of a given whole, that is, break it up into pieces, isolate them, and synthesize them.
6. To abstract common properties reflectively.
7. To perform concepts, symbols, to understand them.
8. Voluntarily to evoke previous experiences, for example, images.
9. To assume the attitude toward the "merely possible."
10. To detach the ego from the outer world or from inner experiences.

It has often been said that the defect of the patients consists of an inability to cope with new situations, but that they are able to proceed in an abstract way as far as old experiences are concerned. The fact, however, is that patients fail equally in familiar situations and in new ones, if the situations demand the abstract attitude. On the other hand, they can cope with new tasks successfully, but they can do so only as long as these do not require the abstract attitude. Indeed, patients are more likely to fail in new situations rather than in old ones because the former frequently demand new sets, in other words, the abstract attitude.

The analysis of many patients' failures in different tasks has shown that a great number of symptoms are explainable as the result of this one defect and that in the same way the variations of the patients' reactions in apparently the same task can be so explained. If the patient seems to be successful at one time and fails at another, this seeming inconsistency is resolved when we realize that the tasks which appear equal to us may (as a result of the disturbance of this function) not be at all the same for the patient. The following example may illustrate this. If we present to the patient an angle built of two little sticks, with the opening downward, and ask him to copy the presentation after it is removed, he produces the angle correctly. If we present the same angle with the opening upward, the patient, after the angle is removed, is not able to produce it. For us, the angles are not different; for him, they are not only different, they have nothing in common. He says that the one (with the opening downward) appears to him like a roof; the other structure does not mean anything to him. His correct response was determined by the fact that the first structure appeared to him as something which corresponds to concrete experience; he failed with the second structure because this was not the case, because he could not assume the abstract attitude which is necessary to fulfill this task.

This is one of numerous examples which definitely show not only that the patient can react only to (for him) concrete conditions, but also how careful we should be in our interpretation, since the task set before the patient may to him appear totally different from the way it appears to us.

A few further examples from different performance fields may illustrate the failures due to impairment of abstract attitude. Just as the patient cannot deal with figures when they do not represent concrete objects, he fails further when he is confronted with ideas, thoughts, and feelings when their handling presupposes abstract attitude. He is unable to shift from reciting one series (for instance, numbers) to another (days of the week), because active shifting is impossible for him. He can follow or even take part in a conversation about a familiar topic or a given situation, but if he has to shift to another topic—even one equally familiar—he is at a complete loss.

Downloaded from www.dbraulibrary.org.in

He may be able to read a word and, at another time, spell it, but when asked first to read and immediately afterward to spell, he is unable to do so. The patient's speech in everyday life may not show much deviation from the norm. He may in certain situations have a great number of relevant words at his disposal; this is the case when the words belong concretely to the situation. He will fail concerning the same words, however, when the situation demands that he consider their meaning. His words fit only definite concrete situations. He cannot understand that the same word can have different meanings. In respect to learning, he has the greatest difficulty in rote learning and very quickly forgets what he has learned. The same difficulty exists in the behavior of the patient with regard to practical activities, such as handicraft and labor. (Concerning the symptomatology of such patients, see Ref. 11.)

I would like further to mention two important general points. The first is that loss of abstract capacity cannot be regained by retraining. Only improvement of the brain damage may more or less restore the impaired capacity. The second point is that there are different degrees of abstract behavior, depending on the extent of conceptional complexity which the performance in question involves. Thus the patient may be able to fulfill some performances which need abstract consideration. The highest degree of abstract behavior is required for the conscious and volitional act of forming generalized concepts or for thinking in terms of a principle and its subordinate acts and verbalizing these acts. Similar abstract behavior is the act of consciously and volitionally directing and controlling every phase of a performance and of accounting for it verbally.

A lower degree of abstraction is necessary in volitionally planning an act or series of acts without distinct awareness of or self-accounting for every phase of its further course. In some performance, as in intelligent behavior in everyday life, only the directional act is usually abstract, and the ensuing performance follows a concrete plan. Here the patient may be successful until difficulties arise. He may fail when the required shift demands the abstract, anticipatory deliberation. It is apparent that only careful analysis of each performance in respect to the degree of abstraction required for execution will allow us to decide whether or not the patient is disturbed. The decision is easiest if some tests which have been constructed for this purpose[25] are used.

We are inclined to believe with Jackson that the abstract capacity, the symbol function, being the expression of the most complex function of the brain, suffers first in damage to the brain cortex, while isolated lesions in the motor and sensory areas show only damage of the concrete performance "instrumentalities" (see p. 776). Not infrequently, the symptomatology consists of a mixture of damage to both parts, although the damage may not necessarily be equal in both. Thus we can get very complex clinical pictures.

The opponents to the organismic approach stressed that it took into consideration only symptoms belonging to the higher level, the abstract attitude. This criticism may appear to be justified, since some authors mentioned only these disturbances in aphasic patients, because they considered aphasia an expression of a damage of symbolic function or "intelligence." This holds true, for example, for Pierre Marie, Ludwig Binswanger, and Kronfeld and Sternberg. It is, from the organismic approach, not at all appropriate, however, to omit the symptoms belonging to defects in the lower-level function, the so-called motor and sensory instrumentalities, which are necessary for realization of the symbolic function in the performances of the organism. The very complex picture which aphasia represents, in which motor and sensory disturbances of letters, words, and other features of language not dependent on the defect of the symbolic function are often so completely mixed with those which are dependent on it, gives all the more reason to study carefully the structure of *all* abnormal phenomena. Otherwise, one cannot reach a correct conclusion as to the origin of the clinical symptoms. This is all the more necessary since defects in the instrumentalities *secondarily* influence the use of the symbolic function. Only by analysis of all symptoms can one clarify what is primarily due to the latter. Indeed, even Jackson showed insufficient interest in the effects of disturbances of the "instrumentalities," in the destruction of single

Downloaded from www.dbraulibrary.org.in

words and letters, in the disturbances of grammar, of the finding of words, and of sentence formation which are related to dedifferentiation of the function of the motor and sensory apparatuses (see Ref. 15).

The problem of the relationship between the disturbances in damage of the instrumentalities of language (the instrumentalities belonging to the concrete forms of behavior, cf. Goldstein,[11] p. 163) and those due to damage of the symbolic function interests us, particularly, because clarity concerning this relationship is essential for correct evaluation of the symptoms not only in aphasia but in all performance fields.

Jackson did not sufficiently evaluate the disturbances of the instrumentalities, because he considered the separation between the higher and lower functions of the brain cortex to be too absolute. There is no doubt that the processes in the higher and lower levels of the brain are, to some extent, associated; both belong to the "mental apparatus." The organismic approach assumes that any damage which concerns one part of an apparatus changes the function of the rest of the apparatus as well; the "parts" can be considered as only artificially separated "parts" of a whole. This is the case in the connection between the lower- and higher-level functions of the brain cortex. Under normal conditions all performances are determined by a working together of both functions as a unit. Under certain conditions, performances come into the fore which are related to the one level; under other conditions, those which are related to the other level. Such a preponderance of behavior related to one level exists if this level is important for the self-realization of the individual in a particular situation. Thus, for instance, if an individual is thinking with concentration, the concrete world is more or less forgotten; it is, so to speak, in the background (cf. Ref. 19, p. 109). The opposite holds true when an individual is totally involved in concrete behavior. The various abnormal performances correspond to the different ways in which the union of the two functions is impaired.

Jackson speaks of a disintegration from the voluntary to the automatic-emotional level. He goes so far in his separation of the two levels that he assumes, concerning language, that the lower-level activities are related to the "inferior" hemisphere, the right one, while the symbolic function is connected with the "superior" left hemisphere, an assumption which is not in accord with the newer concept of localization.[16] Indeed, Jackson has stressed, in general, the modification of the function of one apparatus owing to damage of another one connected with the first one. On this concept is based his distinction of positive and negative symptoms; the negative ones are an expression of the direct damage of an apparatus, the positive ones the effect of the modification of the function of an apparatus due to another one to which it is related. But he did not come, in my opinion, to a correct conclusion regarding the function of the lower-level apparatus separated from the function of the higher one in disintegration of brain function. He assumed that defects in the higher level did not alter the behavior related to the lower level, in so far as the lower level continues to remain "integrated." We assume, too, that impairment of abstract attitude is an effect of a dedifferentiation of brain function, a reduction of the most complicated function to a simpler one; however, this does not imply that the undamaged lower-level apparatus remains unmodified in its way of functioning. Phenomena belonging to the lower level do *not* remain fully integrated, and the preserved automatic and emotional performances of the patient do *not* simply represent the effect of the lower-level function as it existed before. It is not enough to say that the function of the brain is *reduced* from a level corresponding to the voluntary activities to a lower one corresponding to emotional and automatic performances. The character of this reduction, of this modification of the brain function, has to be considered if one wants to understand behavior on the lower level in all its details. Neither the automatic nor the emotional reactions of patients with impairment of abstract attitude appear, on closer investigation, "normal."

## ¶ The Automatisms in Damage of the Higher Level of Brain Function

The automatic reactions in damage of the higher level of the brain function show definite deviations from the norm. They do not

Downloaded from www.psychiatryonline.org

come so easily into action. Conditions in the outer world or within the individual, which usually instigate them, must now be present in a very "adequate" way; in even small deviations from the familiar conditions, the learned automatisms do not occur. So, for instance, it is not enough to ask the patient to utter the (very automatized) series of numbers; the first numbers often have to be presented orally; only then is the patient able to speak the rest of the series correctly. If the patient is interrupted at any point in the procedure, he will not be able to continue, as a normal person would. These and many other phenomena not only show that the automatisms also are functionally modified in damage to the higher level, but also point to the fact that the automatisms are normally closely related to the higher level, more closely than one usually assumes.

The observable modifications of the automatic reactions are not fully explainable by the assumption of a lack of the influence of the higher-level function; only when one considers them as a change in the normal relationship between the figure and ground in the unit they represent can they be understood. Every process in a stimulated area is accompanied by a definite excitation in the part of the organism not directly stimulated. We call the excitation in the stimulated area the *figure* and the excitation in the rest of the organism the *ground*. All performances of the organism, as well as all experiences, are so organized. Figure and ground are intimately interconnected; to every figure belongs a definite ground. The phenomena corresponding to either one can be properly evaluated only by considering the other as well. What is meant by figure and ground is most obvious in visual experiences; however, all other experiences and performances, such as motor reactions, speaking, thinking, feeling, etc., are organized in a similar way. To this organization of the performances correspond equal organizations of the physiological processes in the nervous system.

All damage to the nervous system, especially brain damage, disturbs the figure-ground organization in general or in a part which belongs to a definite performance field. The sharp differentiation of figure from ground suffers, inducing a general leveling or intermingling of the phenomena belonging to figure and background. This can, at times, be carried to the point of inversion, so that what normally is figure becomes ground, and vice versa. We expect a definite figure as reaction to a definite stimulation, but the patient may respond according to the background. This change of the normal figure-ground organization is the basis of a great number of symptoms in damage of the nervous system and in neuroses and psychoses. It is clear that reactions in isolated parts will be deprived of the influences of the normal figure-ground organization which goes on within them, and that they will thus be changed, particularly in respect to their contents. Normal figure-ground organization is, like all performances, dependent upon processes belonging to the higher level as well as to those within the realm of the instrumentalities. It is determined by previous experience, by memory. Furthermore, one has to consider that figure-ground organization in one field is related to the figure-ground organization which the whole organism represents.

In all performances the whole unit is in action. According to the significance of one or the other part for the performance, this part is in the foreground, but the performance is correct only if it occurs in correct relationship to the background which the other part represents—which changes according to the demands of a definite task. If the lower-level function is somewhat separated from the higher-level function, this will come to the fore in modifications of the automatisms, according to the significance of the higher-level function in preserving the relationship of the two levels for definite tasks of the organism—in some tasks more, in others less. Thus the patient's difficulty in starting an automatic series shows that, for the setting in motion of an automatism, some higher-level function (I would say some abstract attitude) is necessary. What has taken place following disintegration of the brain function is a damage of the normal figure-ground relationships between the two levels, which may be observed in variations of the automatic activities under various conditions of the whole organism, by which the figure-ground relationship is determined. Normally, this figure-ground relationship exists which makes possible the

Downloaded from www.psychiatry.com

fulfillment of the task to which the organism is exposed. After damage to the higher-level function, the figure-ground organizations are disturbed—the most complicated ones more than the simpler ones. This shows that the automatisms are, in general, effective, but they are not normal, being modified by the disturbance of the more complicated figure-ground configurations in the disintegration of the brain function involved.

This interpretation of the automatic performances in disintegration of the brain function corresponds to the general explanation of the automatisms and reflexes, to concrete behavior in general, which I have given on another occasion (cf. Ref. 18, Chap. V). I tried to show that these phenomena are not the effect of isolated processes in the organism but represent figures in organizations of the whole organism which differ from those in normal performances only in the special form of the organization.

There is another factor which brings us further understanding of the modification of the behavior in damage of abstraction: the influence of isolation of the lower level in its function. The change of the function of one part of a unit owing to its separation from another part cannot be considered alone as the effect of a lack of influence of one on the other. The effect of isolation itself modifies the function of the separated part. Consideration of this factor has proved to be of the greatest significance for understanding many symptoms in pathology. It has shown that the modification follows definite laws which are equally discernible in each performance field which is in a state of isolation. The modification by isolation concerns particularly the dynamics of the processes. We shall consider them in more detail later, when we take up symptoms which are the effect of direct damage to the instrumentalities (see p. 782).

## Emotional Reactions in Disintegration of the Brain Function

For Jackson, the paradigm of the lower-level function was emotional, interjectional speech which is usually fully preserved in damage to the higher level, the symbolic function. Concerning this preservation of emotional, interjectional speech, we are confronted with a more difficult problem than in the automatisms—owing to the uncertainty of opinion about the nature of emotions. Jackson was inclined to consider emotional reactions as belonging to the same category of behavior as the automatisms, and thus to consider the preservation of both in disintegration of brain function as equal phenomena. It is doubtful whether it is justified to put the two groups of phenomena under the same heading. Normally, they show a number of differences, particularly a different relationship to the total personality and to the symbolic function. Automatic phenomena represent part processes of the voluntary activities and are dependent on them. They always occur under the direction of the latter or under the direction of outer-world influences. Emotional reactions are not voluntarily produced, but their connection with the abstract attitude differs essentially from the connection of the automatic activities with the latter. The emotional activities have something in common with the abstract activities in that both represent attempts of the personality to come to terms with the world, that both are emanations of a definite attitude toward the world. The emotional attitude differs from the abstract attitude, however, in that this coming together of personality and world is more immediate, more in relation to the existence of the individual, while the abstract attitude guarantees the organization of an ordered world separated from the individual. Because of this close connection to the existence of the individual, emotions play a particular role in all forms of self-realization and occur in concomitance with, and not in dependence on, the voluntary activities. One has often assumed that emotions are simply disturbing phenomena. This is most certainly wrong. I would like to refer in this respect to newer research published by Leeper[33] and K. Goldstein.[14] Success and failure in all performances are accompanied by definite emotions. Which kind of emotion arises depends on the implications of the situation with regard to the individual's way of realizing his nature in a particular case. The correct emotions—

Downloaded from www.ohiolink.edu

that is, those which help to achieve self-realization—are of great significance for executing correct performances.

The emotions are complex phenomena; they consist of inner experiences which are not conscious in the usual sense of the word, but of which we are well *aware* (see in regard to this Goldstein,[19] p. 34). They consist further of activities by which they are "actualized"—movements of the face and body, the so-called expressive movements of different kind; of linguistic utterances such as interjections, sounds, words, and sentences which are brought to the fore in characteristic intonations; and finally of physiological processes in the vegetative nervous system.

What has been called emotional language represents the linguistic part of the motor activities (instrumentalities) belonging to emotions. The activities in emotions—and so also the linguistic phenomena—are based on innate mechanisms acquired in experiences related to the world in general, and most particularly in relation to other human beings. These motor phenomena correspond to the other automatisms in so far as they are concrete activities and come to the fore in emotional situations, as the automatisms do in voluntary activities.

From this aspect it seems incorrect to speak of emotional language; it would at least be less prejudiced to speak of linguistic means, linguistic instrumentalities for realizing the emotional attitude which a situation provokes. They represent special linguistic phenomena, but they are not different in principle from those instrumentalities which are used in abstract attitude. Emotional language is a special, not a more primitive, form of language. The emotional attitude is not a more primitive attitude than the abstract one; it differs from it by another kind of relationship to the total personality, a closer one. It seems appropriate to assume that the greater significance of emotions for the existence of the personality in the world makes the substrata underlying them more resistant to damage of the brain function. It is for this reason that they are better preserved than those substrata underlying the symbolic attitude.

From our discussion it seems that we are not justified in considering that emotional reactions are equal to automatisms. We have mentioned that the automatisms show modifications in impairment of abstraction. Does that impairment not find expression also in differences between the emotional reactions of the patient as compared to those of normal individuals? I think it does. Clarification of this point seems to me important for a better understanding of the abnormally frequent occurrence of emotional reactions and their modifications in patients.

Considering the facts, we must stress the following: Emotional phenomena usually are more predominant in patients with impairment of abstraction than in normal people. Most probably the reason for this is that the world of the patient, owing to impairment of abstract attitude, is not organized normally and so makes many normal reactions impossible. The patient, when urged to react, tries to do what he is able to do, and he is most able to produce emotional reactions, and therefore also emotional language. The emotional activities, however, occur not only more frequently than normally but they are modified as well. They show the characteristics of *isolation* (cf. p. 782); the isolation is due to the lack of the normal relatedness to the reactions in the abstract world, by the impairment of the latter.

Thus we come to the following result: Preservation of the emotional language is an expression of the preservation of emotional reactions; in individuals with disintegration of the brain function, it is *not*—as is the case in preservation of the automatisms—a direct effect of an inferior brain function coming to the fore. Preservation of emotional reaction represents the maintenance of this attitude of man toward the world, which, in normal man, exists alongside the abstract attitude. Because the emotional attitude is more closely related to the personality and more important for its self-realization, it shows greater resistance toward damage of the brain function and thus may remain undisturbed when the abstract attitude is disturbed. The emotional instrumentalities are preserved in the same way as are the instrumentalities in general in impairment of abstract behavior. This shows in the possibility of using them in concrete behavior. The odd preservation of emotional language does not present a

Downloaded from www.PsychiatryOnline.com

special problem. Whether a patient is able to produce language or not depends on the attitude under which such language is demanded in a given situation, that is, whether the abstract one or the emotional fits the situation. If the latter is the case, the patient will bring out words; in the former case, he will not. This could be demonstrated by a great number of examples which show that the patient is able to utter a word in an emotional attitude but is not able to do so voluntarily, that is, in the abstract attitude, even immediately afterward. One particularly instructive example concerning a patient of Jackson may illustrate this. The patient responded to the demand to say "no" by saying, "I cannot say 'no.'" He was not able, however, to repeat the word "no." The speaking of the word "no" in the sentence is not a voluntary act but belongs to the patient's concrete reactions. The repetition of the word "no" presupposes the voluntary attitude (cf. Ref. 15, p. 71) which he could not assume, therefore he was unable to say the word on demand. From a superficial aspect this would seem to be a contradiction, since the patient was able to say the word "no" with great emphasis when asked to do something which he could not do, that is, when in an emotional attitude. This seeming contradiction is resolved when we realize that the words appear to be the same but actually are not the same, since they represent totally different reactions of the whole organism. The patient was able to utter the word only when the situation induced him to take an emotional attitude. It is obvious that wrong interpretations of the patient's capacities can easily occur if this difference in attitude is not taken into consideration.

I would like to mention, in the latter respect, another very instructive example: it concerns the difficulty in finding words, particularly names of even the most common objects. This is a very frequent symptom of aphasic patients. No matter how similar, on face value, failures of the patients may appear in respect to the finding of words, the defects can be due to a defect of an entirely different function. In one kind of patient, the inability to name is an expression of an impairment of abstraction; in another, it is a sequela of a defect in the instrumentalities of language, a memory defect. The patients of the first kind have not lost the words but are not able to utter them in naming, because naming, as analysis has revealed, presupposes the abstract attitude. The other kind of patients, with difficulty in finding the name, have no defect in abstract attitude, but their instrumentalities of language are damaged, and therefore they cannot find the words. Only when one considers the whole picture which the patients present does the difference of the origin of the symptom become apparent. As long as one pays attention only to the effective reaction, as has often been done—in this case the difficulty in naming objects—the underlying damage of the brain function may appear the same. This fallacy occurs particularly if one records the results of examination by the plus and minus method and considers the answers only in respect to success or failure. This conclusion from the effective answer, without analysis of the way in which the patient came to the answer, the "fallacy of effect," is the cause of many mistakes in the interpretation of psychopathological phenomena and in the building of theories. It shows up particularly in failures of retraining when the interpretation was wrong.

Similar observations, as we have mentioned, can be made not only concerning the language of the patients but in regard to other motor activities which belong to emotional situations. An example may illustrate this: The patient was asked to behave as he would in a situation in which he became angry with some one and was menacing him. He was not able to do so. When we demonstrated such behavior to him, he began to laugh, apparently perplexed, not quite sure what was meant. He was not able to perform the action on demand. But, observed in a situation in which he actually got angry, he behaved instantaneously like a normal individual as shown by the expression of his face, the action of his fists, etc. This example points to the important difference which often exists between the patient's behavior during special examination and during everyday life. Observation under the latter condition, so often neglected, deserves the greatest attention.

## Symptoms Due to Direct Damage of the Instrumentalities

Up to now, our description of symptoms in damage of the brain cortex was concerned with effects due to disintegration of the brain function from the higher-level function to the lower one. We have discussed symptoms caused by impairment of the higher-level function, the abstract attitude, and have discussed the effect of the impairment of the abstract attitude on the lower-level function, the motor and sensory activities, the so-called instrumentalities, by which the higher-level function is actualized.

At this point we shall consider symptoms which are the effect of direct damage to the instrumentalities. We have to restrict ourselves here to a *survey* of the different ways in which damage of the function of the brain, concentrated in definite regions, is revealed in modifications of normal behavior. From this point of view, we have to classify the symptoms into two main groups.

### *Symptoms Which Represent Direct Sequelae of Damage to the Substratum of a Definite Region*

These sequelae rarely take the form of complete loss of a performance; more commonly, the performances affected undergo modifications. Such modifications can be considered as a result of a systematic disintegration of the concerned function. Structurally, this disintegration invariably exhibits the same features, regardless of the region involved, be it the spinal cord or the subcortical apparatus, and regardless of whether it concerns reflexes, motility, sensation, speech, thinking, or feeling. A particularly important consequence of this dedifferentiation is impairment of abstract attitude and abnormal concreteness of behavior, about which we have spoken before.

All direct damage causes a rise of the threshold and a retardation of excitation. The receptivity of the patient is reduced in the involved sense organ. It takes him much longer to react. This manifests itself in the fact that patients may succeed perfectly in a task when they are given a sufficiently long time of exposure but fail in the same task when given only brief exposure, for example, when examined by the tachistoscope. (The tachistoscope is an instrument which allows exposure in different short lengths of time.) Pathology consists of a slowing down of the physiological process.

The patient may perceive when the stimulus is strong enough and presented long enough, but he may cease to see it after a certain time, in spite of continued stimulation. Later, the sensation may appear again; it seems that the threshold changes during stimulation. This is also true in stimulation of normal individuals, but it is far more apparent in brain damage.

When excitation takes place despite obstacles, it spreads abnormally and remains effective an excessively long time. This is due to disturbance of the process of "equalization" by which the effect of the stimulation is regulated (cf. Goldstein,[19] p. 113). Examples here are phenomena such as tonic innervation, repetition of the same movements, reiteration in reflexes (clonus), etc. A word grasped with great difficulty by an aphasic patient sticks, perseverates, and influences subsequent performances.

Another characteristic effect of the damage is the fact that performances are determined to a much greater extent than normally by stimulating influences, external or internal. We call this abnormal stimulus responsiveness.

### *Symptoms Due to a Separation of an Undamaged Area from a Damaged One*

By such separation or, better, "isolation," the function of the undamaged area, and thus the performance, is modified in a definite way. The pathology can consist in an isolation of parts of the unit which the organism as a whole presents and an isolation of the subunits corresponding to definite performance fields. Isolation can occur in gross anatomical separation or in functional separation; it can also occur in psychological conditions.

It seems useful to give here a brief summary of the functional changes caused by isolation

Downloaded from www.pdfbooksfree.pk

(cf. Goldstein,[19] p. 133). The reaction appears modified in the following ways:

1. The effect of an adequate "stimulus" is abnormally strong.

2. The effect of an adequate stimulus is of abnormal duration.

3. The reaction is abnormally influenced by inadequate stimuli, external or internal. It is abnormally "stimulus bound."

4. The individual is forced to react. He appears to be easily fixated when his reaction to the present stimulus is completely successful. If his reaction, however, is not fully successful, he seems to be forced to react to another present stimulus. If, now, the correct reaction takes place, fixation will set in; if the correct reaction does not take place, the patient will again be forced to react to still another stimulus, etc. Thus he may appear very distracted. The patient seems to be driven to achieve an "adequate" reaction by which the entrance of "catastrophe" is eliminated (cf. p. 784). Fixation and distractibility appear so as the two results of the same defect under different conditions.

5. As a result of loss of the normal influence of the rest of the organism on the activity in the isolated part, the reaction appears to be lacking special contents. It appears, or actually is, more "primitive" because it lacks properties belonging to the "nature" of the individual. The degree of primitivity and diminished appropriateness depends on the place and extent of the isolation, on how large a part of the whole organism is excluded from cooperating in the reaction (cf. Ref. 19, p. 148 ff.).

6. Isolation distorts the normal figure-ground organization which is of essential importance for the outcome of any normal reaction.

All the factors mentioned above are responsible for occurrences of abnormal performances, and all of them have to be considered in the evaluation of any one symptom in damage of the brain cortex.

## ¶ Symptoms Representing the Reaction of the Individual to the Defect

So far, we have discussed symptoms in brain damage only in their relation to defects of structure and function of the brain. Our results were still somewhat unsatisfactory, particularly in regard to *understanding the variability* of the symptoms. We must try, therefore, to go a step further, to regard the phenomena not only in their relation to the damage of structure and function but in their relation to the reaction of the individual and of the whole organism to the defect. Such a step corresponds to the procedure of the organismic approach and often leads to a better understanding of the patient's behavior.

Systematic investigation of the patient's general condition while he is able to fulfill a task and when he is unable to do so reveals another fallacy, which consists of only recording the effect of failure or success in the performance. One observes, particularly in patients with impairment of abstract attitude, that the patient, unable to fulfill a simple, seemingly unimportant task, may be completely changed in his total appearance. The same man who, shortly before, looked animated, calm, in good mood, well poised, collected, and cooperative, while successfully fulfilling a task, appears now to change color, to be agitated; he starts to fumble and becomes unfriendly, evasive, even aggressive. This overt behavior is very reminiscent of that of a person in a state of anxiety. The relationship of this general condition to the capacity of fulfilling a task becomes particularly evident from the fact that such a general condition can be experimentally produced, in some patients, by presenting them with a task which we know they will not be able to perform.

We call the state of the patient, when he is successful, an ordered condition; the state in a situation of failure, a disordered or catastrophic condition. In the latter condition the patient is incapable of performing tasks in which he is usually successful, which he is able to do very well when in the "ordered" condition. Such failure lasts for shorter or longer periods of time. One observes frequent catastrophic conditions, particularly in patients with impairment of abstract capacity. Since an individual with such impairment is unable to account to himself for what he is doing or experiencing (see p. 774), we assume that he is

Downloaded from www.psychiatryonline.org

not aware of his failure; as a matter of fact, he is unable to say, when questioned about it, whether or not he has been confronted with something frightening. Hence we come to the conclusion that the catastrophic condition is not a conscious reaction to the failure but, rather, belongs intrinsically to the objective situation of the organism in failure.

Even the smallest failure may have this effect on these patients, since they are unable to decide which failure might be dangerous for them and which might not. They are, so to speak, always endangered whenever their reaction is not adequate. Thus any objective failure can bring the organism into disorder, into catastrophe, into anxiety.

I cannot, in this presentation, discuss the consequences of our description of these phenomena for a theory of anxiety (cf. Ref. 18, Chap. VII). Here, we are interested only in the symptoms which these patients show, owing to the occurrence of anxiety, which are not directly related to the damage of the brain. If we do not pay attention to this, we may be deceived about the patient's brain defect and may consider symptoms as being related to it, when actually they are not. Consideration of the phenomenon of catastrophe explains the variability of symptoms under similar conditions.

One factor which is apt to modify the symptomatology considerably is the development of protective mechanisms by which the occurrence of catastrophes is eliminated or at least reduced. It is easy to understand that all patients, when they do not essentially improve, have the greatest desire to get rid of the anxiety, for otherwise they are prevented from using even their preserved capacities and thus from coming, at least partially, to a state of self-realization.

We realize that patients with even severe brain damage and impairment of abstraction show, after a certain time, a diminution of the disordered behavior, of catastrophic conditions and anxiety, and yet, examination reveals no change whatever in the damage to their mental capacities. In such cases this can occur only if the patient is no longer exposed to tasks he cannot cope with, or is able to take the failure without reacting with catastrophe. Concerning the first point, observation of his behavior in everyday life reveals that he lives apparently in a modified environment, an environment from which far fewer tasks arise which might lead to catastrophes. How does such modification of environment take place? Observation shows that the patient is withdrawn from the world around him so that a number of stimuli, including dangerous ones, do not arise. He avoids company. He is as much as possible doing something which he is able to do well. What he is doing may not have any particular significance for him, but concentration on activities which are possible for him makes him relatively impervious to dreaded stimulation. Particularly interesting is his excessive orderliness in all respects. Everything in the surrounding world has a definite place. Similarly, he is very meticulous in his behavior as to time, whereby the determination as to when he should do something is related to events and to activities of his which always occur at the same time, or to a definite position of the hands of a clock. This orderliness enables him to prevent too frequent catastrophes.

Another interesting protective mechanism is unawareness of the defect. We observe this particularly in patients with impairment of abstract attitude, but also in patients who are incapacitated in a special performance field without mental damage, for instance, in severe hemiplegia. This symptom, called Anton's symptom, described first by Anton in 1899,[2] occurs particularly when the incapacitation is total (cf. Ref. 39, p. 38), so severe that the patient is not able to use the disturbed capacity at all. The symptom may not take place if the defect is partial and if the patient is able to use the capacity at least to a certain degree, for example, if he can move his paralyzed leg somewhat. This protective mechanism has been described as denial, a procedure which would demand a somewhat conscious activity. I do not think that such an interpretation is correct. Certainly, it can be rejected as far as it applies to patients with impairment of the abstract attitude, who are, owing to this defect, unable to do anything voluntarily. Whether the phe-

Downloaded from www.brainlibrary.org.in

nomenon becomes more understandable if one ascribes to it unconscious influences is doubtful. I think it is sufficient to consider it as an effect of a new organization of the behavior of the organism, which, though *not directly related to the defect*, occurs from the organism's tendency to realize the capacities which it has, in pathology those which are preserved. Within this new organization the effect of the disturbance does not become apparent. This would make it understandable that the patient is not only unaware of the defect, but that the defect is so arranged in his behavior, without his knowledge, that the disturbance does not show.

It is not the disagreeable experience of the failure itself which produces the new organization. This becomes evident when lack of awareness or other protective mechanisms disappear under the influence of the physician. As transference develops between patient and physician—when, for example, under the influence of the physician the patient learns to bear his disturbances and learns through his own experience that, by bearing them, his general contact with the world is improved—then he is more able to realize himself without the shelter of the protective mechanisms. With this added security, he is able to give up his safeguards. Indeed, the more the abstract capacity which makes such deliberation possible is preserved, the more is this the case.

We consider the organization of protective mechanisms as an expression of the attempt of the organism to come to terms with the demands made on it, in such a way that self-realization is guaranteed as much as possible. I would like to stress that these passively originating, protective mechanisms occur not only when the abstract attitude is impaired but also if it is by circumstances diminished, as, for example, in severe anxiety in normal individuals.

There is another way to eliminate danger to self-realization which is produced more actively by conscious interference. One should distinguish these mechanisms, which occur particularly in neuroses, from the passively originating protective mechanisms by terming them differently—by calling them defense mechanisms.

In view of these facts, we should be very cautious in the interpretation of symptoms; the possibility that some phenomena observed in the patient might not be the effect of a damage but of a protective mechanism always has to be considered. This concerns also the absence of symptoms by "denial," which might be expected in a special damage of the brain.

Somatic symptoms, resulting from defects of the nervous system, can also bring the patient into general disorder. Here also, we observe, after a certain time, a modification of behavior by which, even when the original damage is neither eliminated nor improved it is no longer effective. For instance, a patient may, after damage to one hemisphere of the cerebellum, suffer from disequilibrium, falling, deviations in walking, etc., and from different disturbances in general, subjectively and objectively, and so may be hindered subjectively or objectively in his self-realization. After a certain time the general disturbances improve, without improvement of the pathological condition (which special examination shows existent as before). Concomitantly with the general improvement, however, we see that a deviation of the body has occurred, which seems to bring about a new equilibrium, a better general condition, and thus a better possibility for self-realization. The patient, however, is not aware of his deviation.

That this general improvement is related to the deviation becomes apparent by the fact that improvement disappears immediately when one tries to eliminate the deviation; in other words, such action brings the patient into the previous condition, into catastrophe. We say that the deviation represents the individual's new, preferred condition (cf. Ref. 19, p. 340). The following few remarks may explain what is meant by this. If we consider an organism by the usual atomistic method as composed of parts, members, and organs which can be used in very different ways, and if we then look at the organism in its natural behavior, we find that many kinds of behavior which, on the basis of the first consideration can be conceived of as possible, are actually not realized. Instead, only a definite selective range of behavior can be observed. Normally, each performance is

Downloaded from www.liebertpub.com

executed only in a definite or, as we say, preferred manner. Observation of the whole organism in a situation where one performance field —be it motility, perception, language, etc.— shows preferred behavior reveals that all other performance fields exhibit preferred behavior as well. In the above case we say that the organism is in an ordered condition; it performs all its activities in the best way; it can use all its capacities in coming to terms with the demands of the outer world; it has a definite constant visual acuity, an erect position of the body, is able to speak and to act according to its nature, that is, is able to realize itself in the best way.

The organism always tries to achieve such ordered behavior in spite of its defect. It can be reached only through modification of the behavior in the damaged performance field by finding a new preferred behavior which goes along with a somewhat modified but preferred behavior all over. This must be considered in our evaluation of deviations; we have to distinguish those which are the expression of the defect from those which are an expression of the new, preferred behavior; that is, from those which are means to guarantee the new order. This distinction demands careful study of the influence of the deviation on the behavior of the whole organism, that is, whether or not it is accompanied by order or disorder of the latter. A symptom belonging to a preferred condition is characterized by the fact that any voluntary change of the new preferred behavior brings the organism into general disorder and that it returns involuntarily to that very behavior. So, for instance, should the head be in a tilted position, any attempt to bring it to the normal erect state produces not only general disorder, but the head returns involuntarily to the new preferred condition, in this case a tilted position.

What we have described here concerning the effect of a cerebellar damage can be observed in damage of each performance field in the change of the direction of the performances toward a new preferred order. This new preferred condition can be achieved in two different ways.[22] One way consists of yielding, giving in to the defect; the other, of building a counteracting mechanism by which the effect due to an abnormal condition is compensated. These two ways of eliminating the danger to self-realization do not present equal effects. By the first, the normal functioning is, in principle, unchanged. It is the more "natural" procedure; it occurs more automatically, scarcely demands voluntary activity on the part of the individual, and therefore brings greater security. By the second way the normal form of functioning in the particular apparatus is changed. It is a more volitional type of behavior; it is not as secure, leads more readily to fluctuation, and admits greater possibilities for catastrophic reactions. Whether one or the other way of adapting to the irreparable defect occurs depends on which offers the best possibility for self-realization under the given conditions. If this is guaranteed by the first procedure, it will occur, since it is the more secure procedure; if, however, this is not possible, then the second way of adaptation occurs.

The significance of the preferred condition for the best performance must be considered most carefully in all therapy, even if that condition deviates from the "normal." Any attempt to bring the patient into the "normal" condition may make all treatment meaningless and inane. The similarity of this situation in organically disturbed patients and in neurotics is theoretically of the greatest interest. Unfortunately, we cannot even touch this point here.

We mentioned before that the symptomatology of a patient with brain damage can become more difficult to understand in direct relation to the defect because of a factor other than the protective mechanisms. This factor is the development of the relation between the physician and the patient. If this relationship is good, the patient will no longer become afraid so easily and the occurrence of catastrophes may be diminished; thus, many defects may come to the fore which the patient concealed simply by not reacting because he was afraid to let them appear. The development of a kind of transference between the patient and the physician is of the greatest significance for a correct examination, for finding the defects related to the damage, for evaluation of the symptoms, and, not least, for execution of cor-

Downloaded from www.dbraulibrary.org.in

rect therapy. This development of transference in organic patients has not had the attention it deserves. In this respect I would like to refer the reader to my article about organismic therapy in this volume where I also discuss in detail the transference in organic patients (cf. Goldstein[12]).

## ¶ The Nature of "Distorted" Performances and Their Interpretation as Symbolic Phenomena

The discussion of the protective mechanisms, particularly their consideration as new preferred behavior, has some bearing on the understanding of phenomena which are usually called compensational or distortive. When we observe such phenomena, the question of whether we are actually dealing with pathology always arises. I have in mind particularly some reactions, unusual as to form and content, of aphasic, apraxic, agnostic patients. What does the material which the patient brings to the fore represent? Sometimes it certainly is the expression of disturbances in the field of the instrumentalities. Sometimes, however, one gets the impression that the material corresponds to activities and experiences which have played a particular role in the premorbid life of the personality, and which are now released, so to speak, through pathology. From this point of view such material has been considered as of particular significance for the study of the deeper level of the patient's personality. It seems to me important that we look at these phenomena a little more carefully than is usually done. They deserve attention not only in relation to their interpretative value of symptoms but from a more general point of view as well. They have suggested an interpretation as "symbolic" phenomena, which, in my opinion, is mostly wrong. The error originated because their relationship to the total condition and behavior of the patient was not fully considered.

Some utterances of aphasics, also of such whose symbolic function was generally disturbed, can easily give the impression of symbolic phenomena and often have been interpreted as such. I think they can be understood in various other ways as well which are not in contradiction to the existing basic defect, the defect of the symbolic function. Some are so-called "physiognomic phenomena"[42] and represent normal reactions which occur in a special concrete and not symbolic attitude of the individual. This is easily overlooked because these phenomena are not well known. In our culture particularly, they play a small part in everyday life and are not familiar except in the experience of artists. In normal life they are, so to speak, embedded in our realistic everyday attitude toward the world, and they come to the fore only in special situations. We do not have sufficient studies of the physiognomic behavior of our patients, but I feel justified in assuming, from my experience, that this behavior differs from normal physiognomic experiences which are related somewhat to the symbolic attitude. This relation is lacking in the physiognomic experiences of the patients. They appear particularly when the attitude of abstraction is diminished by pathology, and especially in patients with a premorbid inclination for the physiognomic attitude toward the world. Such utterances should not be considered as symbolic. For these patients, a shifting from the physiognomic attitude to the more usual attitude, which, for normal individuals is easy, becomes almost impossible. Their aspect is, so to say, fixated due to "isolation."

Other utterances are more difficult to evaluate and frequently give rise to symbolic interpretations. They are outstanding in the sense that they consist of poetic, symbolic, or even newly coined words; they may appear to be utterances of particularly intelligent, cultured, and erudite personalities. I have often observed such "quasi-symbolic" phenomena in aphasic patients. In a recent paper, W. Riese[37] has stressed the occurrence of such phenomena. He has considered them as means "evidently to compensate the naming defect of the patients." The patients' neologisms "impress the listener by their descriptive and figurative power." The language of one of his patients, "a highly educated scientist and humanitarian" before his sickness, became "after a brief initial

Downloaded from www.ghauriben.com

period of complete loss of speech, formal, solemn, poetical, dramatic, pathetic and 'Shakespearean,' frequently using quotations." He continues: "What the brain injury brought to the fore was that element in his nature which disease could not destroy, but rather released" and "I reached the conclusion that disease may occasionally reveal though in a distorted fashion what is great and noble in man's nature."[37, p. 11]

It is true that such utterances and behavior may occur in patients with brain defects. I have noted that disease may emphasize the premorbid character of the patient, especially in the way the patient now bears the defect and in what way the untouched part of the personality helps him to overcome his failures. Whether in a patient with impairment of the abstract attitude an interpretation such as W. Riese suggests is justified, I would doubt. In such cases, I think, we are dealing with phenomena of "quasi-high" value, and I assume that the patient Riese describes belonged to that group. Closer consideration may show that the phenomena represent material which previously belonged to the behavior of a high-level personality, which appears now in the form of protective mechanisms and has lost their previous meaning for the particular individual. These utterances represent the undamaged remnants of the instrumentalities of speaking and thinking, which prevail now because the adequate activities due to the impairment of abstraction are impossible. The previous particular way of speaking, the previous rhythm and preference for poetic, dramatic, pathetic expression of the personality are preserved, but this material no longer is an expression of the attitude to which it originally belonged, the attitude which is lost through damage to the brain. Some abnormalities which these utterances show, and which Riese has carefully reported, reveal that we are no longer dealing with utterances prompted by the premorbid personality of the patient. They reveal "no planning, no effort, they occur passively, apparently without intent." In all this, they show the characteristics of isolated automatisms. The rapidity and fluency with which they are uttered (which Riese mentions, and which I have often observed on such occasions) may be even better described as being "thrust out." I think that the patient utters the words in this manner because he wants to get rid as quickly as possible of the distress in which he finds himself when he cannot react correctly but feels forced to do so. As one of my patients said: "If one is asked, one has to answer," and he brought out something which occurred passively in him by *association* of previous knowledge to the task he had to fulfill now. He said definitely that he did not know and could not say how it entered his mind, but that he was forced to utter it.

Such examples definitely point to the fact that these utterances are not related to the present personality. Certainly, their prominence is an indicator that we are confronted with experiences which the individual has had before, and therefore his utterances may reveal the premorbid character of the personality, but we cannot assume that they represent the old personality as released by pathology. In any case, we must be careful to see whether we are justified in so doing or whether these utterances do not belong to "quasi-high" behavior.

I have discussed these phenomena in some detail because I consider it important for the psychiatrist to be fully aware of this problem. We meet the same problem and the same wrong interpretation in the evaluation of utterances of schizophrenics, which have often been considered as symbolic, as expressions of deep insight into the essential things of human life, which disease has revealed. Here too, I do not want to deny that the particular premorbid personality of the schizophrenic patient may become apparent in some of his behavior. This is understandable, because we assume that the patient is not totally modified in the typical schizophrenic manner but is partially normal, or, better, in some respects normal. (Federn has stressed this particularly. Cf., on this point, my chapter, "The Organismic Approach," p. 1342.) Thus he may show normal and even high-level personality behavior under some conditions, but I would deny that this particular high-level behavior is related to the schizophrenic condition. We shall understand the

Downloaded from www.dbraulibrary.org.in

behavior of the patient only when we distinguish sharply between high-level behavior and "quasi" reactions which only appear to be of high-level nature. That the latter occur in schizophrenics is to be expected, particularly when we assume that the patient's behavior is frequently abnormally concrete.

We know, since Vigotski's[40] investigation, that thinking in concepts is disturbed in schizophrenic patients, at least in some groups of such patients. This was confirmed by the work of Hanfmann,[27] Kasanin,[31] Bolles and Goldstein,[5] and others. Storch[39] was already doubtful whether one is justified in considering schizophrenic behavior as symbolic. Beck[3] has stressed, on the basis of his Rorschach studies on schizophrenics, that it is an error to assume that the schizophrenic gives the world "a form and outline which the healthier do not see," that he has "a greater power or superior ability to transmute his experience into something richer." The author wonders "whether the general belief in the schizophrenic profuse fantasy life is not due to confusing distortion with fantasy." He adds: "Fantasy actually involves a *creating* of something totally new. . . . The schizophrenics' misconstructions take on fantastic form. But this is still not fantasy. It is inaccuracy. . . . Not having the power to apprehend the presented real world is what chiefly distinguishes the schizophrenic's percepts and his thinking."

I have come to the conclusion that in schizophrenia we are dealing not with an organic defect of abstraction but with a nonuse of abstraction which concerns only a definite part of the world, and that this is an effect of the anxiety which the schizophrenic experienced in early youth in relation to his personal environment. This nonuse of abstraction is a protective mechanism against the danger of catastrophe and anxiety. (Cf. Chap. 65, "The Organismic Approach.")

The fact that the origin of the abnormal concreteness in schizophrenics differs from the origin of such concreteness in organic patients becomes apparent in certain essential differences of the symptomatology. This can be seen, for instance, in the frequent appearances of physiognomic experiences. The schizophrenic's utterances sometimes yield "symbolic" interpretations but are often revealed, by analysis, to be only pseudo-symbolic phenomena. Such phenomena are here particularly suited to appear as symbolic, since the distortion of behavior brings out much of the instrumentalities belonging to the preschizophrenic condition of the patient where the symbolic attitude plays a more or less important role in the thinking of the patient. Further attention must be paid to the fact that schizophrenics often build complex mechanisms to cover their ideas, feelings, etc., which may easily appear to be of a high-level function, owing to their complexity, but which prove to be only complex associations built on a very concrete basis. This is often difficult to unveil, because the schizophrenic has not only passively originating protective mechanisms, like the organic patient, but also has defense mechanisms, which he produces intentionally, that may give the impression of higher-level function and sometimes may be also an expression of it. The picture of schizophrenic behavior is so complex that its origin may be understood only by a very detailed analysis. In this analysis the distinction between real symbolic and "quasi," pseudo-symbolic behavior has to be taken very seriously.

## ¶ The So-called General Mental Functions as Origin of Definite Symptoms

I stressed, in the beginning of my presentation, that in the interpretation of symptoms a distinction has often been made between defects in a special performance field and defects of so-called general functions, and that this distinction is not justified since the general functions appear changed in the same manner as do the specific performances. There is not enough space here to give detailed proof of the correctness of my statement, but I would like to make a few remarks about the changes in these general functions, particularly those which are related to the personality change of the patient owing to impairment of abstract attitude. I have chosen these because analysis

Downloaded from www.psychiatry.org

of this dependence may be especially useful for psychiatrists.

First, there is the problem of memory. Under certain circumstances the faculty for reproducing facts acquired previously may be about normal in patients with impairment of abstract attitude. Things learned in school, for example, may be recalled very well, but that is the case only in certain situations. The situation must be suited to the reawakening of old impressions. If the required answer demands an abstract attitude on the part of the patient, he may be unable to recollect. Therefore he fails in many intelligence tests which seem very simple to a normal person, and may be amazingly successful in others which appear complicated to us, namely in those which can be executed without the abstract attitude. He is able to learn new facts and to keep them in mind, but he can learn them only in a concrete situation and can reproduce them only in the same situation in which he has learned them. Because intentional recollection of experiences acquired in infancy requires an abstract attitude of the adult in relation to the situation at that time, and the events in infancy were not experienced abstractively, the patient is unable to recall experiences of infancy, but we can observe that aftereffects of such experiences appear passively, at times, in his behavior. He is incapable of recollecting when asked to recall things which have nothing to do with the given situation. He can recall only when he is able to regard the present situation in such a way that facts from the past belong to it. Repeated observation in many different situations demonstrates clearly that such memory failures are not caused by an impairment of memory content. The patient has the material in his memory, but he is not able to use it freely. He can use it only in connection with a definite concrete situation. (Cf. my discussion of the problem in Chap. 65.)

We arrive at the same results in testing attention. At one time the patient appears inattentive and distracted; at other times, he is attentive, even abnormally so. The patient's attention is usually weak in special examinations, particularly so at the beginning, when he has not as yet become aware of the approach to the whole situation, something he can get only through concrete activity. When he has done so, has entered the situation concretely, his attention is usually satisfactory, and he may even appear abnormally attentive, because under such circumstances he might often be totally untouched by other stimuli from the environment to which normal persons would unfailingly react. In other situations he will seem to be very distracted, as, for instance, in those which demand a change of approach. He seems distracted because he is incapable of making a choice. Consequently, it is not correct to speak of a change in attention in such patients in terms of plus or minus. The state of the patient's attention is but part of his total behavior and is to be understood only in connection with it.

Another important problem is judgment as to the patients' emotional experiences. Usually, the patients are considered emotionally dull, and often they appear so, but it would be incorrect simply to say that they are suffering from a diminution of emotions. The same patient can be dull under some conditions and very excited under others. This can be explained when we consider the patient's emotional behavior in relation to his entire behavior in a given situation. When he does not react emotionally in an adequate way, investigation may reveal that he has not grasped the situation in such a way that emotion could arise. The patient may have grasped only one part of the situation—the part which can be grasped concretely—and this part may not give any reason for an emotional reaction. His emotional reaction appears to us inappropriate because we grasp the whole situation to which the emotional character is attached, while he reacts only to a part of it. This connection between emotions and total behavior becomes understandable when we consider that emotions are not simply related to definite experiences but are, as I have stressed before (see p. 778), inherent aspects of all behavior, are part and parcel of behavior. No behavior is without emotion, and what we call lack of emotion is a deviation from normal emotions corresponding to the deviation of behavior in general. From this point of view, the follow-

Downloaded from www.brainsummary.com

ing modifications of reactions, which are of particular interest in respect to the problem of emotions in general, are interesting: We frequently see that a patient reacts either not at all or in an abnormally quick manner. The latter occurs particularly when the patient believes he has the correct answer to a problem. Although this quick behavior might seem to be simply an effect of a change in the time factor of his reactivity, it is actually the effect of an emotional factor. To some extent, the patients are always in danger of coming into catastrophic conditions, and the quick response is an effect of their tension, of which they want to rid themselves by all means. They are forced to release tension because they cannot handle it and cannot bear it. To bear tension presupposes deliberation, considering the future, etc., all of which is related to abstraction. The difference in behavior between these patients and normal people throws light on the nature of the trend to release tension. The patients must, so to speak, follow the "pleasure principle." They must, owing to their abnormal concreteness, react to the stimulus in a way which brings release. The trend to release tension thus appears as an expression of pathology, as an effect of a protective mechanism to prevent catastrophic conditions. The ability to speed up an activity or part of it, when this corresponds to the requirements of the task, belongs to normal behavior, but in the same way as the capacity to bear tension and even to enjoy it at times, when it is necessary to fulfill a particular task. In contrast to this, patients with impairment of abstraction are only able to experience the pleasure of release of tension. They never appear to enjoy anything, a fact which is often clearly revealed by the expression of their faces. This becomes understandable when we are aware of the fact that in any kind of joy immediate reality is transcended, that joy is a phenomenon which presupposes the abstract attitude and especially the category of possibility. Thus brain-injured patients who are impaired in this attitude cannot feel joy. Experience with brain-injured patients teaches us that we have to distinguish between pleasure through release of tension and the active feeling of enjoyment and freedom so characteristic of joy. Pleasure through release of tension is the passive feeling of being freed from distress, and therefore this feeling lasts, in normals, only until a new situation stimulates new activity. Joy, on the other hand, is something we try to extend, something which admits the possibility of infinite continuation.

The two emotions of joy and pleasure play essentially different roles in regard to self-realization. They belong to different performances or different parts of a performance. Pleasure may be a necessary state of respite, but it is a phenomenon of standstill. It is akin to death. It separates us from the world and the other individuals in it; it is equilibrium, quietness. In joy there is disequilibrium. But this disequilibrium is productive, leading toward fruitful activity and a particular kind of self-realization. This difference in the significance of the two emotional states for the normal person and the brain-injured patient is an expression of the essentially different behavior of the latter and of the different world in which he lives.

The drive toward release of tension is one of the causes for the strange behavior of brain-injured patients in friendship and love situations. The lack of the experience of future forces them to look for close relationships to other people and to maintain such relationships at all costs. At the same time, close relationships are terminated suddenly should their maintenance necessitate some bearing of tension, that is, should any difficulties arise in the relationship. The following example is illustrative: One of my patients, Mr. A., was for years a close friend of another patient, Mr. X. One day Mr. X. went to a movie with another man. Mr. X. had invited Mr. A. to go along with them, but the latter did not want to go, since he had seen the picture before. When Mr. X. returned, my patient was in a state of great excitement and refused to speak to Mr. X. He could not be quieted by any explanation. He was told that his friend had not meant to offend him and that his friendship had not changed, but these explanations made no impression at all. From that time on, Mr. A. was the enemy of his old friend, Mr. X. He was aware only of the fact that his friend had been companion to another man, and he felt himself slighted. The experience had produced great tension in him. He regarded his

Downloaded from www.ebraulibrary.org.in

friend as the cause of that tension and reacted to him in a way which is readily understandable in terms of his inability to bear tension and to put himself in the place of someone else.

Another patient never seemed to be concerned about his family. He never spoke of his wife or children and was unresponsive when we questioned him about them. When we suggested to him that he should write to his family, he was utterly indifferent. He appeared to lack all feelings in this respect. At times, according to an established practice, he visited his family in another town and stayed there for several days. We learned that while he was at home he conducted himself as any man would in the bosom of his family. He was kind and affectionate to his wife and children, and interested in their affairs in so far as his abilities would permit. Upon his return to the hospital from such a visit, he would, when asked about his family, smile in an embarrassed way and give evasive answers; he seemed utterly estranged from his home situation. Unquestionably, the peculiar behavior of this man was not actually an effect of deterioration of his character on the emotional and moral side; his behavior was the result, rather, of the fact that, owing to his impairment of abstraction, he could not summon up the home situation when he was not actually there, and therefore he could not show adequate feeling and behavior. Lack of active imagination, which is so apparent in this example, makes such patients incapable of experiencing any expectation for the future. Active imagination depends on the abstract capacity.

This lack is apparent, for instance, in the behavior of a male patient toward a woman whom he later married. When he was with her, he seemed to behave in a friendly, affectionate way and to be very fond of the girl. But when he was separated from her, he did not care about her at all; he would not seek her out and certainly did not desire to have a love relationship with her. When he was questioned, his answers indicated that he did not even understand what sexual desire meant. He could not imagine any sexual situation and did not understand pictures which showed such situations. When he met the girl again, however, when she spoke to him, he was immediately able to enter into the previous relationship. He was as affectionate as before. When she induced him to go to bed with her, embraced him and put his penis into her vagina, he performed an apparently normal act of sexual intercourse, with satisfaction for both. She had the feeling that he loved her. She became pregnant, and they married. The above case also reveals the great significance of speech and voice for any relationship, particularly when other possibilities are destroyed by the defect of the brain function, as was the case here.

Some other so-called general factors which are often mentioned as obstacles to examining such patients consist of fatigue and perseveration. Here, also, observation shows that these phenomena are not always present in the same way, that they change according to the situation, as do all performances. Observation of our patients shows that fatigue is not a simple function of the duration of continuous performance but depends to a high degree upon whether or not the performance in question is within or somewhat above the capacity level of the patient. Thus a paradoxical situation may occur, where fatigue decreases as the activity continues. This happens, for instance, when a later task is "easy" to perform while the earlier tasks could be executed only with difficulty. Another point is the fact that fatigue does not express itself simply as a slowing down of performance but, especially at the beginning, as a fluctuation of performance (Goldstein,[20] p. 260). Subjectively, the individual feels not only incapacitation but also discomfort, uncertainty, and distress. The phenomena occurring in fatigue show great similarity to those observed in catastrophic conditions and seem to be closely related to them. Patients with severe brain damage tire easily because many normal tasks represent difficult ones for them, thus producing distress. While fatigue in difficult tasks may thus be understandable, we may ask whether the same point of view is appropriate to explain the fact that fatigue occurs also in continuous work consisting of a task which is within the limits of the individual's capacity. I think that is the case. Continuation means consumption of energy which deteriorates the function of the substratum, so that a task which was previously

Digitized by www.dbraulibrary.org.in

easy to perform may be changed into a difficult one; therefore, mere continuation may produce catastrophe and fatigue. This becomes evident by the fact that fatigue does not set in as early when the task is varied. Boredom and interest influence the fatigue rate. This must be considered particularly in testing situations. If, after we recognize the onset of fatigue, we should change the task, the patient may then perform without fatigue and may do so better, both subjectively and objectively. This is particularly true if the succeeding task is within the capacities of the individual, and if the change does not demand a voluntary shifting on the part of the individual, which, as we have mentioned previously, is an especially difficult problem for many brain-injured patients. Automatized performances may be continued for a long time without the patient showing and experiencing fatigue. We frequently observe, however, severe breakdowns after excellent performances. This suggests that the symptoms of fatigue are not only signs of catastrophe but also indications of imminent catastrophe—warnings, which, thoroughly considered, may help to prevent the latter. Patients with a mental defect which appears in a lack of planning and foresight are particularly prone to fatigue, since they do not recognize the protective danger signals and thus become abnormally tired.

Perseveration is a frequent phenomenon in brain damage. I am inclined to assume that it is a secondary phenomenon due to incapacitation in some performances, and a means to avoid catastrophe occurring under such conditions. Perseveration occurs particularly when the patient is forced to fulfill tasks with which he is unable to cope. For instance, a patient who has difficulty with arithmetic may be able to answer promptly as long as he has to solve problems which are within his capacity. The moment he is given a problem which he is unable to fulfill, he may either be thrown into a catastrophic state and not react at all, or he may repeat the last correct result or a part of it, that is, he perseverates. If he is then given an example, however, which he is able to solve, he may again answer correctly, and all perseveration will disappear. The same patient may show perseveration under some conditions and distractibility under others, so that it becomes evident that we are not dealing with a primary defect of rigidity. As we have explained previously, the sick organism tries to react as well as possible to the task set before him. Confronted with assignments which he cannot fulfill, he tries to react to that part of the task in which he is able to succeed by means of his remaining capacity, and he sticks to that rigidly, because thus he can best avoid catastrophe. But under certain conditions he becomes aware that he has not fulfilled the task correctly. Then he gives up the first reaction, I think, because continuing it does not help in overcoming distress. He tries again and may become attached to another part of the situation to which he is able to react, but again may feel that he is not performing the task demanded. Thus he appears abnormally distractible. Neither rigidity, perseveration, nor distractibility is a defect per se; they are phenomena coming to the fore under special conditions which can be defined. They can be avoided—at least to a certain degree—by the same means by which abnormal fatigue can be avoided, because ultimately they originate from the same cause.

## ¶ Some Remarks Concerning the Method of Examination

I would like to conclude with some remarks concerning the method of examination which follows the rules prescribed by the organismic approach. From our discussion it is evident that only a method can be successful which takes the relationship of each performance of the patient, each success and each failure, to the whole behavior of the patient and the whole organism into consideration, and which particularly keeps in mind that a performance can be evaluated correctly only in respect to the trend of the organism for self-realization. The organismic approach by no means overlooks the significance of the study of details, correct reactions and failures, of the quantitative deviations from the average and the influence of previous capacities of the individual patient; it uses all available quantitative methods and applies statistics to the evaluation. But one should be aware that statistics can be really helpful only when we are con-

Downloaded from www.dbraulibrary.org.in

fronted with quantitatively different material, and that, in the symptomatology of brain cortex damage, particularly those which are of interest for the psychiatrist, we are mostly dealing with qualitative deviations from the norm. Statistically valid results, therefore, are not too important for the increase of our knowledge of what pathology did to the patient and what we can learn from pathological findings for understanding normal behavior.

According to our evaluation of the significance of abstract attitude for all performances, the capacity of abstraction should be tested in the beginning of any examination. Whether the abstract attitude is impaired and how much it is impaired can be evaluated by observing the patient under the conditions of various modes of behavior which can be correctly executed only in this attitude. Some tests have been constructed which allow one to judge the patient's capacity in an easier and more correct way. The tests differ as to whether the material used is language or the execution of some performances—matching, sorting, making choices, etc. The results with the first group of tests are sometimes difficult to establish because of the ambiguity of language and because they are not always simple to apply when the patients are suffering from language defects. The advantage of the other group of tests is not only that they do not use language but also that they are so organized that judgment can be based directly on the results of the behavior of the subject in the test.

As an example of the first group of tests, the Proverb and Phrases tests by Hadlich, John Benjamin[4] may be mentioned; as an example of the other group, the Vigotski test should be mentioned, particularly in the presentation by Hanfmann and Kasanin;[27] further mention should be made of the various performance tests of Goldstein and Gelb,[24] Goldstein and Scheerer,[25] Weigl,[41] and others. (See also the papers by Von Domarus,[9] Beck,[3] Cameron,[7] and Angyal,[1] and the psychological monograph by Goldstein and Scheerer.[25])

The use of various tests in examining the same patient is recommended, since each test differs somewhat as to its applicability and definiteness in determining the impairment of abstraction and as to its ability to characterize the various forms of abnormal concreteness. The technique of the Goldstein-Gelb-Scheerer tests enables one, by the use of various materials and by the application of various specified subtests besides the main test, to determine whether or not a patient can assume the abstract attitude, to measure somewhat the degree of the impairment, and to find out the specific type of concreteness to which the patient is confined. This proved to be particularly helpful in distinguishing between the defect in organic patients and in schizophrenics.

## ¶ Bibliography

The bibliography is not intended to cover all the literature on the subject, which is too extensive to enumerate here. It comprises those references which are particularly relevant to my presentation, and publications which contain surveys of the literature in particular fields. The designation (Lit.) at the end of a reference indicates that the publication named contains further references.

CHAPTER 40

# COMMON NEUROSES OF CHILDHOOD

Joseph B. Cramer

Downloaded from www.dbraulibrary.org.in

PERHAPS NO BETTER COMMENT can be made on the history of neurosis in childhood than to point out that there is no mention of children in Kraepelin's classic treatise[66] published in 1904. A few papers on mental illness in childhood were published between 1880 and 1910.[23, 56, 62] They reported and described cases of insanity in children as clinical anachronisms, with a kind of curiosity that exists when any disease ordinarily affecting adults appears unexpectedly in a child. Without a theory of mind, the clinicians could think causally only in such terms as constitutional deviation (degeneracy), heredity, fatigue, and religious obsession. Such "causes" hardly provided a basis for therapeutic action. Diagnosis in phenomenologic, adultomorphic terms was the end of the road. Irreversibility was assumed by these clinicians.

To find something recognizably related to present-day notions of causality, one has to go back to the sixteenth, seventeenth, and eighteenth centuries, when occasional references to feelings and needs and to parent-child relationships appeared in learned clinical treatises on nursing, feeding, and other child-rearing activities.[18]

The term "neuroses" had little meaning, nor was it applied to children until the advent of psychoanalysis. Attention to the individual's development during childhood first came from the attempt to understand the neuroses of adults. Breuer and Freud, studying hysteria, established the relationship between neurotic symptoms and childhood experiences. Freud's aphorism, "No adult neurosis without an infantile neurosis," reflected the fact that he regularly discovered childhood symptoms in the past life of his adult patients. Though the infantile neurosis discovered by Freud is certainly pertinent to the clinical syndromes discussed here, it is not to be considered identical with them.*

* Glover[42] clarifies the distinction between the infantile neurosis of Freud and the clinical syndromes called "the neuroses of childhood" in the following statement: "Freud's aphorism . . . serves to emphasize not only the developmental factors in mental disorders, but

It was only after Freud's work that the term "neurosis" was applied descriptively and conceptually to children. Kraepelin's careful descriptive case studies made it necessary for the thoughtful person to ask questions regarding pathogenesis. For descriptive psychiatrists these questions also led back to the development of the illness and the person. Adolf Meyer, whose work may be viewed as a mid-point between analytic and descriptive psychiatry, very early in his career emphasized the importance of the individual's development. His psychobiology required a biographical study of the patient. These data led to childhood and the study of childhood neuroses. It became obvious that experiences of childhood, parental attitudes, and the social environment were of more basic importance than physical or hereditary influences in causing childhood neuroses.

In accordance with the fact that the first data from psychoanalysis provided evidence of the importance of childhood sexual experiences, the study of childhood neuroses was first aimed at the investigations of like factors, and they were found to be present. Early investigators of childhood neuroses tended to explain the conditions entirely on this basis. This view seems now to be a little distorted but these early studies produced evidence that children did indeed experience, at successive stages in development, erotic excitement in specific body areas—the oral, anal, and genital zones. The oedipal stage, being that in which sexual problems could primarily be located, also was emphasized in early investigations, which, however, did not begin directly with children until several years *after* Freud's formulation of the infantile sexual theory.[39]

The technique of psychoanalytic investigation was modified by Anna Freud,[31, 33] who provided a method suitable for the analytic study of neurosis in childhood itself. At about the same time Klein[65] developed a method based on interpretation of the meaning of child's play without recourse to verbal confirmation.

It was not only the change in attitude toward mental illness but also a change in social attitudes toward children which prompted the passage of laws, first in Australia, soon afterward in the United States, establishing special courts for children. Justice could no longer be dispensed to children on the basis of what was right or wrong for adults. It had to be based on more than a legal concept of criminality. The more the judges learned about psychological causation, the more prevention-minded the courts and the public became. Clifford Beers, who had recovered from mental illness, devoted himself to the prevention of mental illness; a national movement, for which Meyer suggested the name, "mental hygiene," was initiated and became the motive force for much subsequent study.

Thus the psychoanalytic study of neurosis in childhood and the mental-hygiene movement became the joint instruments for the development of the child-guidance clinics in the United States in which much of the study of the neuroses of childhood has been carried on during the last thirty or more years.

Until recently most of what is known about the neuroses of childhood had come from psychoanalytic study by psychoanalytically trained therapists. A few not very systematic efforts to study children and infants were begun soon after the method of child analysis came into use. In the last few years direct observation of infants and children has been carried on systematically in many kinds of child-study laboratories.[9, 15, 41, 42, 57, 68] This method has been more rewarding for having had the data from psychoanalysis as a guide to what to look for and how to look. New data have been added, and concepts derived from reconstructions alone have been reformulated and improved.[36, 84]

From direct observation have come the important clues to those influences from his basic physical make-up and from his social world which determine the manner in which the child adapts to the crises or milestones of his development. The milestones and crises,

the fact that no hard and fast line exists on the one hand between the mental reactions of normal children and of mentally disordered adults, or on the other, between those of abnormal children and of apparently normal adults."

Downloaded from www.dbraumann.com

and the ways in which he learns for good or bad to solve them, become patterned either as the beginnings of his character or, in adverse situations, as the beginnings of his neurosis.

## ¶ Diagnosis

The criteria for the diagnosis of neurosis in childhood go beyond the specific behavioral derangements of the disturbed child himself. There are certainly characteristic symptoms, common to most cases, but the meaning of the symptomatic behavior is more pertinent to diagnosis than is its form. Strictly speaking, the diagnosis of neurosis, even with a broad use of the term, should exclude those illnesses in which derangements of development or constitution, organic disease of the brain, serious pathology of any specific organ system (for example, colitis), or gross neglect or other adverse social influences constitute the prime determinant. In the neuroses of childhood, mental conflict resulting from psychological trauma is of prime importance, and the evidence for this may not come alone from the behavior of the child.

The list of signs characteristic of neurosis in childhood is a familiar one, but neither a single sign nor any constellation of signs is pathognomonic. Enuresis, for example, is present in many cases of neurosis, but not in all. Also, it occurs in the psychoses of childhood, in the serious derangements of development, and, in fact, in all types of childhood mental illness.[6, 45, 63]

Specifically diagnostic of the neuroses in childhood are:

1. The absence of a steady state of mind. The neurotic child, whether mainly fearful, mainly anorectic, or mainly overactive, fluctuates in his behavior between, on the one hand, states of relative adjustment during which he feels and often appears quite well, behaves in an age-appropriate way, and deals fittingly with reality, and on the other hand, states of distress during which he feels and looks sick and tests reality poorly.

2. Free anxiety. The neurotic child undergoes conscious mental suffering. The presence of a parent whose attitudes or behavior tend to subsidize various alloplastic binding devices may provide relief from subjective suffering much of the time, but some subjective and conscious mental distress exists.

3. Irritability. The neurotic child has little margin of safety in his adaptive resources. They are stretched taut even when working well. Thus a seemingly innocuous stimulus may cause considerable excitation and may initiate a decompensated state.

4. Encapsulability. In the neurotic child the disease is "localized" even when his incomprehensible behavior reflects intense suffering. At no time is there a complete disorganization of mental function. He may look as if he has "gone to pieces," but even if he makes no sense to the puzzled adult, he is not, so to speak, out of contact with himself—only beside himself. (Encapsulation is not central, for example, to the psychoses.)

5. Autoplasticity. The neuroses are characterized by adaptive devices which tend to bind anxiety *within* the mental apparatus. Overactivity, for example, though it may be irritating to the environment, expresses, like pacing the floor, a *self*-orientation, as do most of the common neurotic signs such as daydreaming, masturbation, fears, obsessions, compulsions, bed-wetting, and even the sleeping and eating disturbances. (Autoplasticity is not, for example, central to the antisocial character disturbances.)

The neuroses of childhood have to be differentiated from normal behavior, from transient difficulties of adjustment, from psychosis, and from those disturbances of social adaptation which are secondary to, or significantly determined by, organic disease of the central nervous system. Especially in childhood the diagnosis of neurosis is complicated by a lability of signs and by the multipotentiality which is inherent in an ongoing, not yet fully developed process. One sick child may manifest, in nearly equal quantities, antisocial tendencies, fears, and early signs of somatic disturbance. If his disease is not checked and it becomes chronic or is reactivated intermittently, more

Downloaded from www.brainbrowser.com

clear-cut patterns of one particular symptom complex will eventually predominate. Thus distinctions between psychosomatic disease, psychopathic states, and the more circumscribed symptom neuroses become much clearer after childhood.

## ¶ Etiology and Pathogenesis (Dynamics)

In the neuroses of childhood, disharmony or conflict exists between components of the mind. No childhood illness should be considered neurosis unless evidence for some internal mental conflict can be found.

Neurosis in childhood is caused by social experiences which are traumatic; that is, inappropriate in respect to the capacity of the mental apparatus of *that* child at *that* moment to contain and integrate them in a manner consistent with the maintenance of normal development. Since normal means something different depending on where one is, and especially depending on how old one is, adaptive devices of the child's mind find different responses in different environments and at different ages. Thus, differences in what constitutes a noxious stimulus may depend on various cultural influences.

The mental apparatus of the child may be viewed, for conceptual purposes, as an organ system. Its self-regulatory activity may be likened, then, to that of other organ systems which contribute their shares to the maintenance of life and growth. For the child to remain healthy, each system, in conjunction with all of the others, must maintain its appropriate steady state as a kind of matrix within which its contributory function may operate.

Different points of view with regard to the etiology and pathogenesis (dynamics) of childhood neurosis stem from differences in various theories of mental function. There is general agreement about what the mind does, but many different positions have developed in respect to *how* the mind functions and what its boundaries are, and, especially, what kind of a climate it needs in which to do its work effectively.

The psychoanalytic theory has not been accepted by Adler, Jung, Rank, Horney, Fromm, and Sullivan as an accurate explanation for aberrations of mental function.

Adler[1, 2] indicated that feelings of inferiority are of primary significance in all children. He assumed that such feelings burden every child, regardless of the environment in which development takes place, and that mental function is determined by this burden. He was the first to propose the importance of the striving for power and domination in Western society as a direct determinant of behavior. This was the first departure from the drive-centered etiological position of Freud.

Jung[60] early stressed the emotional interaction between children and parents as the primary determinant of developing mental function. He did not find evidence in his work to confirm the libido theory of Freud.

Rank,[74] with his theory of birth trauma, stressed the separation of the infant from the mother and the deprivation of the pleasurable situation in the womb.

Horney[55] objected to an implication (to her) that psychoanalytic theory included a concept of universal normality. She felt thus that neurosis could be characterized in relative terms. She objected to a biological basis for the object-seeking of the child and denied that child-parent attachments were instinctually determined. Her emphasis on the primacy of cultural determinants went along with her rejection, especially, of Freud's concepts of penis-envy as a central factor in the psychology of women.

Fromm[43] also stressed the cultural determination of the form of expression and satisfaction of man's needs.

Sullivan's[86] hypothesis is perhaps the most complicated of those which have been advanced as basically different theories of mental function. He has attempted to formulate a theory of mind which will diminish the conceptual limitations of a "one-body" system. To Sullivan, the process of human development is absolutely synonymous with the process of socialization. His theory of interpersonal relations is an attempt to show how the patterns

Downloaded from www.dbraulibrary.org.in

of the culture determine the mental function of the individual. He sees psychiatry as the study of processes that go on between people rather than as the study of one sick person.

It follows that explanations of cause derived from psychoanalytic investigation are based ultimately on the psychoanalytic theory of instincts. The horse phobia of little Hans can be understood as the end product of a mental conflict between the mental representation of an age-specific biological drive and a mental representation of a life experience (perception) which thwarted the aim of that drive for satisfaction. This theory provides a basis for a conception of mental conflict limited to the unit organism and viewing culture as a factor affecting the adaptive demands. Other theories would explain the phobia as an end product of a mental conflict between culturally determined tendencies on the one hand and either environmental frustration or limitations of genetic endowment on the other.

It seems quite likely that a useful and comprehensive theory of mind will eventually incorporate concepts from psychoanalytic theory and also from the creative efforts of those workers who view the social environment more as a part of mental function itself. Fortunately for child psychiatry, not only psychoanalysis but also new discoveries in other realms of clinical science have helped to gain acceptance for the notion of multiple causation. For, of all illnesses, the neuroses of childhood are among the most difficult to which to assign any single ultimate cause. Is the cause of neurosis the adaptive failure, or is the adaptive failure the neurosis itself? Is the cause the traumatic event, or is the cause the inadequacy of the apparatus to cope with the event which impinges on it? Causal explanations can be made only in terms of the concept by which the disease is defined. It has become customary and useful to refer, therefore, to a variety of causes, to none of which singly can primacy be assigned, but which together result in evidence for disease. At best, one can generalize only in terms of factors regularly present in all cases.

## *Trauma*

Traumatic experiences were thought at first by Breuer and Freud to be *the* cause of neurosis. They considered such experiences to have inherently and categorically noxious values. Traumatic experiences are an essential ingredient without which the disease does not occur, but the trauma is not inherent in the nature of the event. Thus the event, as far as cause is concerned, is reduced to a kind of parity with those qualities of the organism which make the event traumatic to that child at that time. Pearson,[72] after outlining four basic childhood needs* and three corollary fears† to which children are subject, states:

> Anything that prevents the effective satisfaction of the child's psychological needs or that increases the fears . . . will have a deleterious effect on the development of the child's personality and is likely to produce an illness. Such occurrences are known technically as traumatic events. They can be grouped into three classes:
>
> 1. acts of fate
> 2. adverse parental atitudes
> 3. exposure to premature and excessive sexual stimulation.

It is possible that the last of these may be somewhat too narrowly defined, since there is evidence that premature and excessive stimulation of other than a sexual nature may act as a traumatic experience to the child. A traumatic event may be a direct cause of neurosis. It may, moreover, in certain cases have the effect of reviving a symbolically related conflict which is in process of resolution or has been dealt with unsuccessfully at a younger age. There are certain experiences which have an inherent capacity for traumatizing a child. Among the more obvious are: loss of one or

* (1) He needs the security and backing of two present parents. (2) He needs their love and understanding. (3) He needs an optimum period of gratification for his infantile sensual desires. (4) He needs opportunities to express his hostilities, antagonisms, and aggressiveness, so that he may learn what these feelings are like and how to deal with them effectively.

† (1) Fear of being deserted, (2) fear of not being loved, and (3) fear of being mutilated.

Downloaded from www.dbraulibrary.org.in

both parents, with inadequate substitution and inadequate resources for mourning; physical illness; injury; starvation; or neglect.

### *Parental Attitudes*

The attitudes and character of the child's immediate family and important human objects may also constitute one of the principal etiological factors. This particular determinant may exert a far more constant pressure toward psychopathology than do traumatic events. Mothers or their substitutes provide a constant influence on the child's attitude toward his impulses and therefore on the choices he has of ways in which to make ever-changing use of those impulses as he matures and develops.

The significance of cultural factors in the determination of parental attitudes and the place of such factors in understanding the child's illness are matters of much clinical and theoretical interest at the present time. Obviously, in dealing with neurotic children, only an accurate evaluation of the antitherapeutic elements in the environment will make appropriate intervention possible.

The data from psychoanalytic study seem to indicate that parental hostility, inconsistency, overprotection, seduction, or dependency mainly reflect instinctual conflict in one or both parents. This is specifically activated in their relations with the neurotic child. Such a construction would indicate that a causal therapy should refer to the parent's "hidden" or "reciprocal" neurosis. Often the most obviously distressed parent is not the primarily neurotigenic one, or the one most basically involved in neurotic interaction with the sick child.

There is, of course, always evidence for cultural determination of parental attitudes and conflict. By and large, these are construed as attitudes so universal and so necessary for survival in a particular culture that they must be adopted even if they place the subject child under an adaptive burden by being inimical to his developmental needs.

The analysis or interpretation to a parent of unconscious conflict with respect to cultural pressures is quite different from the analysis or interpretation of parental conflict in respect to instinctual pressures. To complicate the situation further, there is a strong implication, from recent studies of neonatal behavior and physiology, that specific genetic constellations in the child are important determinants of parental behavior, especially in respect to that particular child. The need for further definition of the determinants of parental attitudes is quite obvious.

### *Constitution*

Possibly even more constant as a determinant of adaptive patterns, good and bad, is the hereditary constitution of the child. In many instances the hierarchy of determinants of neurotic behavior is not clear. An example of this challenging problem is that of the overactive child who presents presumptive, but not gross, evidence of a damaged brain, together with positive evidence of destructive family attitudes. No adequate method with which to allocate primacy of determination yet exists. Some of the factors in the constitution which are generally considered to be inherent are intellectual capacity and physical type. It seems possible also that instinctual drives vary in innate quantity or strength from individual to individual. Recent studies and formulations, especially those of Hartmann,[54] tend to affirm the notion of innate variations as well in the capacity of other psychic institutions, that is, the ego and superego. The shape and form of either the child's character or his neurosis are probably influenced, therefore, by the strength and nature of these innate qualities. They are, however, so difficult to evaluate that their probable role in the development of neurosis in childhood cannot be analyzed in the same way as can those of traumatic and attitudinal determinants.

Some authors view the total constitutional make-up of the child as having been quite implacably determined from birth, and imply that even neurotic developments reflect this "given" make-up.[47, 81]

Downloaded from www.freepsybooks.org.in

## ¶ Classification

Nosological difficulties have been with us since the development of a dynamic orientation to mental phenomena. Recently Szasz[87] has contributed a critical assessment of the various schemata which have developed. Perhaps the most convenient system is based simply on the relationship between the phenomena of the illness and the stages of personality development at which they occur.* Kanner[51] uses a behavioral system, subdividing the problems of behavior into categories relating to the major kinds of performance: sexual activity, anger, jealousy, fear, anxiety, hypochondriasis, obsessions and compulsions, hysteria, delinquency, hospitalism, and schizophrenia. Psychoanalytic formulations are not used by Kanner in his classification scheme which is, in fact, a carefully complete list of symptom complexes. Nor does his outline refer to a dynamic concept of neurosis as a factor in classification.

Pearson's scheme is dynamic and is based on psychoanalytic theory and the psychoanalytic concept of neurosis.† No distinct and separate classification of the neuroses of childhood exists, and, in fact, it is probably not possible clearly to delineate one.

## ¶ Neurosis During the First Three Years of Life

Emotional difficulties are strongly colored by the adaptive problems characteristic of the age of the child who has them. Hyperactivity of the newborn and even of the fetus in the late stages of gestation has been construed as evidence of mental distress. Sonntag[82] did, indeed, find some evidence for correlation between hyperactivity, regurgitation, insomnia, and excessive crying in infants, and emotional stress of the mother during pregnancy. Greenacre[50, 51] has also contributed some interesting formulations concerning effect on personality of prenatal and birth experiences. Early in the history of psychoanalytic investigations, Otto Rank[74] found evidence that the experience of birth itself might be regularly viewed as a trauma in respect to its influence on the adaptive process in the mental apparatus and concomitantly on the development of personality or its disorders.

Recent investigations have added to what was known from anamnestic reconstruction and have confirmed the importance of the early months of life in the pathogenesis of mental disease. Direct evidence for a significant relationship between psychopathology and very early trauma is more clearly visible in the more serious disturbances of mental function—the serious character derangements and the psychoses. But even in the more benign conditions, events of early life have important contributory influence. The term "neurotic" may be applied to abnormal mental states occurring even in the first year or two of life. The earliest sign of mental conflict is crying, when it occurs under conditions in which it makes no obvious sense.

Continuous or extensive crying, crying in the absence of evidence of gross physical pathology, or crying that is not relieved by the response of the mother indicates an unresolved state of mental tension. The anxious cry in the immediate postnatal period may be associated with the physical and psychic trauma during birth or the immediately preceding intrauterine period. By the end of the second week, however, assuming an understanding and appropriate response to the infant's needs, this instability usually ends. Should crying persist, it indicates that the ordinary cycle of accumulation of needs and their satisfaction is not being fostered by the mother's response. Crying in the young infant may thus be related to a state of apprehension comparable to the

* Gerard's summary[44] is based on this relationship, as is the one used in this chapter.

† Pearson[72] classifies the emotional disorders of childhood as follows: (1) Direct reaction to present environmental errors; (2) acute and chronic anxiety states; (3) anxiety hysteria; (4) conversion hysteria (a) after the phallic phase of development is attained and (b) pregenital conversions; (5) organ neurosis; (6) compulsion neurosis; (7) perversions; (8) psychosis; and (9) character neurosis.

Downloaded from www.pdfbooksfree.pk

free-floating anxiety which occurs at later stages of psychic development.

Recent studies, such as those by Mirsky[69] on the pepsinogen secretion of large population samples, have tended to suggest some modification in concepts of the pathogenesis of derangements in mother-child relations. In the absence of visible evidence for extremes of behavior associated with variations in the requirements of certain infants for adequate need satisfaction, the breakdown of a harmonious relationship between infant and mother was formerly attributed largely or entirely to adverse maternal attitudes. Thus, if an infant had no history of birth trauma, no congenital deformities, and no abnormalities of his vital functions, it was assumed that any normal, that is, not neurotic, mother would understand and respond adequately to his expressed need. The studies of peptic ulcer and the statistics on the incidence of high rates of pepsinogen secretion have pointed to the strong possibility that certain special needs, related to variations in inborn physiological functions, may be expected to call for responses that even a normal mother may be unable to reconcile with her own expectations and with conventions of child rearing applicable to the average child. A mother, therefore, may be normal for one child but neurotigenic or "ulcerogenic" to another. It is obvious that, in addition to the foregoing possibility, the more ordinary deviations in the attitude and behavior of the mother, such as frank rejection, cruelty, impatience, forced feeding, neglect, rigidity, or excessive laxness in routine will provide a climate conducive to neurotic developments in early infancy.[8, 42]

Kris[67] differentiates from true object-relationship an "anaclitic relationship" to mothers or substitutes in early infancy, the aim of which is relief of tension rather than the reassurance and support of a specific person. Often an infant's tension is exacerbated when handled by his own mother, and one can see that the tension is reduced when handling by a more neutral substitute results in the cessation of the anxious cry.

Symptoms which develop to reduce tension in early infancy are quite varied. Head rolling, rocking, thumb-sucking, and even genital stimulation are seen commonly enough. The pattern of turning attention and psychic energy back to the self when confronted with difficult adaptive tasks, or with frustration, is central to neurotic behavior at any age. The potentiality, resident in this pattern, for restriction of activity, of shared pleasure, and of healthy object-relations is obvious. The implications for distrust, loneliness, and anxiety are also quite apparent.

The most common cause of crying is physiological hunger, and eating, itself, is, in earliest infancy, the most regular avenue for relief of the discomfort which is neither physiological alone nor psychological alone, but always both. The feeding experience is among the earliest and most concentrated of those which gradually acquire meaning to the child.[34] Discomfort emanating from an experience for which comfort is needed and anticipated can lead to confusion and conflict, first on a more mechanical, but later on a psychological basis. Food refusal and vomiting are the most common early signs of psychological eating disturbances. Refusal of food indicates a sacrifice of the comfort of satisfying a physiological need in favor of avoiding the intolerable discomfort of the psychologically unsatisfactory feeding experience. The food refusal, at first a rather simple defensive operation on the part of the infant, carries with it meanings which are threatening to the mother and against which she must defend by a frontal attack on the child's behavior. It is, in fact, the mother's unwitting anticipation of a hostile or retaliatory interest on the infant's part which makes her incapable of objective understanding of the infant's needs in the first place. The impasse within which the feeding experience creates in the infant a need to defend himself against the repeated experience of discomfort leads to the state of anxious apprehension, conducive only to a further inability to eat, a further threat, therefore, to the mother, and a repetitive neurotigenic cycle.[31]

Vomiting may be initiated in connection with major or minor organic illnesses from birth onward. Again, the experience of discomfort leads to apprehensiveness in connection

Downloaded from www.dbraunbooks.co.in

with food intake, and the development of a symptom is fostered when meaning related to the mother-child relationship is superimposed.

Persistent thumb-sucking is always a sign of some unresolved mental conflict. Yet a marked change in social attitudes toward this symptom has led to a change in the relation of the symptom to later developments of a neurotic nature. Until the time when thumb-sucking was seen to be connected with inadequate sensual satisfaction from feeding, this symptom regularly became an arena for the perpetuation of conflict between mother and child. Forceful repressive measures produced a balance in favor of excessively strict super-ego controls. With a more tolerant attitude toward the symptom, thumb-sucking often persists even until puberty. But the permissive social attitude has not resulted in the prevention of neurotic illness, since the cause is not corrected by overindulgence any more then by a too suppressive attitude. For thumb-sucking, like any other symptom, can only serve as a partial and inadequate solution to an internal psychic conflict.

The last major symptomatic expression of mental conflict in early childhood is sleep disturbance. When no evidence for physical distress is present, the anxiety manifest by sleeplessness, with its attendant irritability, reflects a vigilant attempt at protest against a frightening impression of the environment.[28]

Another group of clinical phenomena which indicate the existence of unresolved mental conflict are those which are prominent from the time of walking and speech development until about the beginning of the fourth year. Symptoms most characteristic of this age group are fecal retention; overactivity; stammering; temper tantrums; rituals, especially of play, ordinary routines, and cleanliness; defiance and disobedience; outspoken jealousy of siblings; aggression, especially toward age-mates; hair pulling; and hair swallowing.

Soiling and wetting beyond the appropriate training age, as well as the persistence of symptoms present in earliest infancy, are signs more characteristic of the diffuse derangements of development (that is, nascent antisocial disturbances and the psychoses) than they are of neurosis in this age group, since implicit in the concept of neurosis are concepts of internalized conflict and of organized defenses.

Until now the term "behavior disorder" has been avoided in describing the various disturbances of the early period of childhood, though it can easily be seen that all of the symptoms mentioned qualify for such descriptive terminology. Because of the incomplete differentiation of the components of the mental structure, one cannot speak of ideas or feelings being expelled by the conscious ego, that is, repressed. Thus one fundamental quality of neurosis is not present. But a behavior disorder in earliest childhood, as in any later stage, does reflect the existence of a state of conflict (antagonistic forces in the broadest sense) within the mind, and thus relates to neurosis or psychically determined deviant behavior at any later age. The character of the symptoms of neurosis during the second and third years gives evidence of an incomplete development of the state of consciousness.[89] The two-year-old who, on the toilet, withholds his stool despite his mother's training efforts, and then soils when she has pulled up his pants and left him, presents a great puzzle with regard to how conscious he is of his behavior and even of the local sensations and general feelings involved. In this instance the soiling represents the regressive behavior or the sign of poor development, while the retention of the stool begins to assume the more complex characteristic of neurotic symptom-formation.[75]

During the second and third years the neuromuscular system ordinarily matures to the point where voluntary control of elimination can be achieved. Purposeful motor activity begins to be put in the service of active, independent mastery of the environment. The first teaching or training of the child by mother and other adults involves prohibitions and encouragements of activities which have, for the child, learning, mastery, and growth values when they are *not* invested with affectively loaded meaning. But when the same behavior modalities need to serve a more urgent purpose of tension relief or of solving painful mental problems, the nonconflictual development of (ego) adaptive skills is complicated

Downloaded from www.dbraulibrary.org.in

by defensive operation against the misunderstood drives, and the condition for neurotic development is present.

In this period of training and mastery there can be noted the beginnings of evidence for structuring of the mental apparatus. The postulation of an earlier anticipatory prestructuring by Klein[65] is based on a hypothesis much more difficult to verify by observation.[48]

The dependent child can be seen to attempt a differentiation between right and wrong, good and bad, depending on indications of approval or disapproval by mother of the behavior which expresses his impulse and his problem-solving efforts. This is the age at which children may so often be observed, when unaware of the presence of the adult, to reach for something or to bang something and then to talk to themselves in a prohibitory or warning manner as if the parental injunction were a separate, not-yet integrated institution, a part of, but yet not a part of himself. The open self-criticism indicates the inability of the child to know and feel, as his own, the prohibition of the parents. Internalization of the parental standards as conscience or super-ego can take place successfully only if the disharmony between the impulses and the externally derived restraining forces is kept quantitatively consistent with the state of maturation of any particular child.

Sleep disturbance occurring at this age in a child who has not had these symptoms earlier is not common,[28] but it occurs in those children whose marginal success in maintaining a severe control while awake is threatened by the loss of parental protection and control during sleep. It is in this age period that the questions are often raised as to the judgment of overcompliant or overconforming behavior. Good behavior is not ominous per se, but it may be viewed as neurotic when accompanied by signs of strain or by "leaks" which indicate the excessive degree to which it serves defense and is therefore not ego-syntonic.

## ¶ Neurosis During the Fourth and Fifth Years (the Oedipal Period)

One might express the achievement of a steady state of equilibrium in children of this age group by the declarative statement "I am a male" or "I am a female." The child who can feel the unconditional verity of this statement by about the end of the fifth year of life is mentally healthy. Comparable statements which may be analogously referred to earlier stages could be similarly formulated. For the anal stage (second and third year) "I am a separate person," and for the first year (oral) simply "I am." In the fourth and fifth years, the development of the mental apparatus has proceeded to the point where the existence of internalized psychic conflict can be clearly demonstrated. There is a sharper definition between conscious and unconscious, and there is evidence of repression and of the "return of the repressed" in the symptoms of the neurotic child.

A brief recapitulation of some specific historical developments may provide a clue to the understanding of this most important area of childhood neurosis. Before the discovery by Breuer and Freud of the infantile neurosis, the fears of a neurotic four-year-old were incomprehensible. What ensued with regard to "treatment" was based on conscious manifest explanations by the child or the parent, often incredible, at best acceptable only by way of considerable rationalization or other sacrifice of reality testing. At this age there is a tendency of the disease to self-limitation of a sort.* Thus, the disappearance or modification of distressing symptoms may have been followed by various possible developments. In some cases the high quality of "sanitation" (from a mental-health standpoint) in the environment must, in fact, have resulted in a complete arrest with subsequently healthy development. More often, constriction of function as a result of character pathology or a later outbreak of psychoneurosis or other sequelae ensued, but its relation to the childhood neurosis was not recognized.

With the discovery of the infantile neurosis and infantile sexuality, a giant step was taken. But the reconstructions of the predisposing childhood illnesses, emphasizing as they did the sexual conflict and the sexual symptoms,

* The work of Breuer and Freud proved that this self-limitation may be only apparent and that a more correct attitude would be to view the disease as having "gone underground."

Downloaded from www.dbraulibrary.org.in

and formulating defense largely in terms of fixation and regression (that is, according to libido theory alone) proved, on later direct study, to have only an incomplete resemblance to the actual childhood illnesses. The relationship of characteristic sequelae to current and recurrent neurotic developments had to await first the work of Anna Freud and other investigators of the psychology of the ego and second the more intricate and explicit investigations of Erikson,[25] Greenacre,[52] Hartmann,[53, 54] and others. These provided a more careful evaluation of pre-oedipal development and its relation to oedipal conflict.

With these data at hand, it is possible to make a tentative distinction between two classes or types of childhood neurosis in the oedipal stage. In both there is a conflict regarding sexual identity, and there are characteristic symptoms common to both. Fear of bodily harm (castration fear) exists in all the neurotic children at this age, and penis-envy, either outspoken or masked, can be found in all the neurotic girls.

The two types, A and B, may be contrasted with respect to (1) the character of the symptoms, (2) the dynamics of the disease, (3) the "premorbid personality," and (4) the human-object environment.

Type A may be thought of as a pure type, an excellent example of which is the famous little Hans.[37] Symptomatically, this type is characterized mainly by fears and phobias. Masturbation, nightmares, and enuresis are other frequent symptoms. The personality structure remains relatively intact at an age-appropriate level of function; ego-functions, such as learning and motility, remain quite unimpaired, and there is little tendency to disorganization. Avoidance and displacement are used successfully to insulate or wall off the unconscious conflict. Anxiety appears mainly when these defenses are thwarted. Quite specific, often highly symbolic stimuli are necessary for the activation of the conflict and the break-through of symptoms. In this type of childhood neurosis there is little evidence for psychic conflict during the earlier (pregenital) stages of development. Antecedent problems of feeding, sleeping, or training are rare and minimal.

There is usually a history of psychic trauma. The traumatic event usually consists of a threat of bodily harm. Illnesses and operations occur in the context of attitudes which reflect the parents' unresolved sexual conflicts, and these are especially noxious. One or both parents are often found to be acting out within the family environment in reaction to sexual conflict, with evidence in their behavior of counterphobic or sexually stimulating activities. The parental attitudes which have an adverse effect on the child in his efforts to deal with his sexual-identity problems are confined largely to matters which are phase-specific to the child. That is, they are noxious to his development only in this stage.

Type B is more protean in its manifestations. Although symptoms of Type A do regularly appear, the symptomatology of Type B is by no means so limited. In addition, jealousy, destructiveness, overactivity, tantrums, irritability, and negativism are common. All of these reflect a degree of organizational deficit. Anxiety is bound, in Type B, if at all, much less systematically, and the devices used by the child are more primitive and less effective. Learning, motility, and other developing ego-functions are interfered with. Though this type is classified with the neuroses of childhood, it may be viewed quite properly as a stage in a psychopathological process already developing by the time the oedipal period was entered. Pregenital determinants are much more apparent in the symptoms and in the characteristic, not very effective, defensive operations. The history will give indications of previous feeding, sleeping, and training difficulties and of persistent tension during the earlier years of life, often of a subclinical degree.

There is usually evidence that the parents have had anxiety or unconscious conflict not only in respect to sexual but also in respect to pregenital needs and impulses. In this latter type of child, the environmental stimuli adequate to activate conflict are quite nonspecific as to their meaning and are not necessarily phase-specific for oedipal problems. Secondary developments in dynamics and in symptomatology leading to regressive clinging and loss of control of impulses appear much more quickly in this type of neurotigenic environ-

Downloaded from www.bookbuilbar.com

ment than in the more encapsulated pure cases of Type A. The implications for a substantial tendency toward character pathology in Type B are quite apparent.

## Neurosis from the Sixth to the Ninth Year

As is the case in neurosis appearing at earlier stages in the life of the child, the timing of the appearance of manifest illness in this stage has special significance. When development has proceeded through the oedipal period without incident, there is implied a process of structuring of the mental apparatus and a balance of forces in favor of ego and super-ego controls.

The period roughly between the sixth and ninth years has been called the period of psychosexual latency. As the term implies, this concept stemmed originally from an idea that the sex impulses remained latent during this time. Subsequently, this notion was revised, for the study of neuroses in children of this age group has indicated quite clearly that recession of sex (and other) impulses does not truly occur, but rather an increasing repression and a renunciation of erotic activity of both an active and a fantasy nature.[13, 14, 15, 32, 38]

The ego, supported in its development by a widening of social relationships and an increasing knowledge of both the human and inanimate object worlds, becomes stronger.[19] As this occurs, energy is directed into substitute channels. The intense involvement of the child, in life and in fantasy, with his immediate family lessens, and reduces the demands for coping constantly with large quantities of highly charged emotional stimulation of a very personal nature. This is the stage at which the super-ego becomes increasingly a factor in the growth experiments and the problem-solving efforts of the child. It is concomitantly the age at which socialization, according to rules beyond those of the family itself, have to be respected and obeyed.

Adaptive failure and the outbreak of a neurosis are more common in connection with starting school or failing to adjust to school than at any other one time in the life of the child. The unconscious involvement of the total family in reciprocal systems of neurotic adaptation frequently provides a climate, before the child has to go to school, in which the tolerance of his defenses forestalls the break-through of symptoms. His attempts to deal similarly with exacerbations of anxiety in the school environment cannot be so easily tolerated. In general, he may respond with a breakdown at school, or, even if able to contain himself at increasing cost *while* at school, he may decompensate at home. Eventually, if the strain continues, he will be unable to sustain an age-appropriate, nonsymptomatic behavior in either environment. Often, the breakdown of defenses is hastened by the failure of either teachers or parents to understand the reactive nature of the child's inappropriate adaptive efforts and the nature of the reciprocal economic and dynamic relationship between home and school.[64]

When school represents a threat to the vulnerable child and he responds with behavior which tends to displace his unresolved conflicts into the child-teacher unit, the resultant tension often produces a climate within which learning cannot proceed. The educational process becames the arena for further symptomatic developments, and a typical vicious circle is initiated in which fear, shame, negativism, and all the other scattered components of the child's behavioral pattern become focused in an inability to learn. This may have the disastrous effect of forcing more desperate and ineffective adaptive efforts, while reducing opportunities for constructive relationships with teacher and peers.[73]

Phobias, compulsions, conversion phenomena, learning inhibitions, and, indeed, any of the more discrete and circumscribed symptoms of the psychoneuroses may appear during the latency period. When these symptoms appear at this stage for the first time after an earlier symptom-free childhood, they are likely to be more persistent and stubborn than similar, more transient, and limited symptoms appearing during the phallic or oedipal stage. A stormy oedipal phase may quiet down with little intervention. It seems to be, like a stormy

Downloaded from www.cambridge.org

adolescence, "more normal" than a stormy latency period.

Tics are a frequent sign of neurosis appearing first in the latency period.[46] They are fleeting spasms of groups of muscles which result in blinking, grimacing, or jerking of the arms, legs, or head. They may be shown to represent, in a partial or distorted manner, a defensive movement—at first actually and later symbolically—reactive to a trauma which occurred earlier in the childhood of children whose super-ego development was influenced by severity and inconsistency on the part of the parents. Peter, aged seven, for example, blinked, gasped, and threw his arm in front of his face, at the same time flexing his thigh and bending at the waist. The entire, painfully bizarre constellation was a habitual, uncontrollable partial re-enactment of a shocked and panicky recoil from the anesthetic applied before a tonsillectomy at age three during which a circumcision, which he had not been told about, was also performed. Following the double operation he was symptom-free for a year until the birth of a younger brother, when his severe tic appeared.

Stammering is also a frequent symptom of neurosis in the latency period, often appearing in children whose speech up to that time was normal.[22] Stammering, especially common in boys, frequently follows immediately on a physical trauma such as a broken leg or arm. The injury acts as a precipitant of castration conflict, expressed in speech pathology in those children whose oedipal conflict is superimposed on a personality constricted by an early need for suppressive control of impulses.

Disturbances in conduct are among the most common signs of childhood neurosis in latency. These include all the many derangements of behavior which interfere with social adjustment at school, at home, or on the street. There is a spectrum of conduct disturbances ranging all the way from daydreaming and problem solving in fantasy, through restlessness and overactivity, to disobedience, stubbornness, and aggressive antisocial acts. In general, the impairment of ego control in the outwardly directed conduct disturbances is associated with a corruptible conscience, and there is a concurrent tendency to avoid punishment.[58, 59] In some cases punishment is sought over and over in order to pacify an overstrict conscience toward which is directed both the protest and the need for retaliation.[3, 40]

Stealing in neurotic children usually contains a highly symbolic, predominantly sexual aspect referring to unresolved castration problems. In children with "deeper" character problems, stealing often reflects, besides, a repetitive search for satisfaction of unrequited oral-dependency needs.

Exhibitionism, peeping, and fetishism also appear in the latency period, most frequently together with other symptoms of a more diffuse nature which may be more disturbing to the parents and more prominent.[20] Occasionally, however, a perverse sexual symptom may be well defined and may be the principle reflection of the child's central conflict. In all such instances the appearance of perverse symptoms reflects a serious unconscious fear of bodily harm and an environment in which symptom-formation of a more circumscribed and highly developed defensive nature has not been possible.

Vegetative disturbances also occur during this age period.[5, 26, 35, 79, 80] Though they should perhaps not be classified together with the common neuroses, the dynamics are often similar. Recent investigations tend to suggest that children whose psychic conflicts are reflected in manifest chronic organ-system derangements may have specific predispositions of a physiological nature.[69]

While the relationship between the signs and symptoms of illness and the existence of mental conflict is quite distinct in latency children with the patterns described, there are partial evidences for neurotic components, either contributory to or reactive to more serious and pervasive deviations of development and of character, which are common in this period. In the more grossly disorganized cases, the influences of neglect, deprivation, cruelty, and other environmental factors, active from the beginning of the child's life, play a more prominent role. The resulting constriction of ego-function and the inability of such

Downloaded from www.pdfbooksfree.pk

children to trust adults have important prognostic and therapeutic significance.

## Management, Treatment, and Prevention

In order for a child to be mentally healthy and to develop normally, he must live in an emotional climate with adequate tolerance and adequate resources for age- and phase-appropriate adaptive functioning.

If one assumes that anxiety and temporary conflict are inevitable and wholesome concomitants of adaptive experimentation throughout childhood, one may see the behavior of a child at each stage of development as a gambit which "feels right" to him at that moment in order to master provocative stimuli and to reduce unpleasant tension. The feedback which he gets from his human-object environment defines in large degree his feeling of optimism or pessimism about the potential success and satisfaction of his intuitive or maturationally determined problem-solving behavior. Let us take, for example, the rejection of food in the first or second year of life. This behavior may be viewed as adaptive and experimental, determined as well by his internal biochemical state as by distractions and "threats" implicit momentarily in the environment. The persistence of such behavior to the point of weight loss and malnutrition would be obviously maladaptive. An environment, however, which can await the outcome of the infant's experiments, in response to feelings and homeostatic tendencies which follow his first move, will permit for a full development of his adaptive potential by responding only to objective signs of inadequacy. But a food refusal may easily stir up immediate unconscious maternal fears. These have the quality of premature pessimism: "He is already starved (sick) enough to need help." or, "If I do not intervene, things will turn out bad." The food-forcing mother, responding with action determined by her pessimistic fantasies, becomes an immediate party to a confusing environmental reaction to the child's experiment in adaptation. The failure of his experiment forces a repetition which can only heighten the tension in the mother-child system. Similarly an experimental stool withholding at three or four years of age may activate neutral maternal fantasies, in which case the experiments of the child toward homeostatis receives support. It may at worst, however, activate unconsciously fearful or pessimistic fantasies in the mother, for example, "He will burst," or, "He will be sick," which drive her to action that restricts her child's experimentation and prevents his autonomous resolution of a mastery problem.

The mother of a four-year-old boy, with a symptom of severe stool withholdings, indicated that bowel movements had been a problem to her child since he was six weeks old. At that age she began to notice that his face became red when he was having a movement. She became distressed. She had the idea that he was having pain at stool and conjectured that his anus was too small. Three pediatricians reported normal physical findings. She still felt that his anus must be too small, or his face would not be red at stool. A fourth pediatrician indicated to the mother that the child's anus needed enlarging, and a program of dilatation with mechanical dilators was instituted.

The understanding of a childhood neurosis comes from a synthesis of anamnestic and derivative data. From the history comes a serial picture report of adaptive efforts and failures and the climate in which these took place. From the examination of the child and the interview with the mother, come expressions of the current ways in which communication and understanding are blocked by the mutual activation of problems in fantasy, to which wholesome and age-appropriate solutions have not been learned. The failure to adapt results when the anxiety associated with the "loaded" fantasies prevents adequate environmental support of a reasonable experimental use of age-appropriate mental resources. An illustration from the case of a four-year-old phobic boy is pertinent. One of his "anti-neurotic" experiments consisted of dealing with his fear of bodily harm by provoking mild pummelings by a slightly bigger playmate. When he began to get too anxious, he would

Downloaded from www.jrahamani.org.in

come home to play by himself. Then later he would go back to repeat the experiment. His mother began to force him to "fight it out" when she became anxious that to let him come home "would make him a sissy or a fairy." The child then began to develop somatic complaints and "war fears," which kept him in the house altogether.

It is increasingly evident that, in the neuroses of childhood, management and therapy should consist primarily of providing a climate in which the adaptive experiments of an adequate ego are not hampered. "Nourishment," in the sense of combating the effects of deprivation, is secondary. Neurosis implies an inherent capacity for self-limitation and healing—thus the rationale for collaborative psychotherapy. Tendencies of the environment (represented by the mother) to react irrationally to the child's seemingly inappropriate adaptive efforts are attacked, together with those distressing mental confusions of the child which determine those same experiments. Any procedure which either lessens the repetitively reinforcing or "unhealthy" response of the parents or substitutes, or which diverts and confines the adaptive experiments of the child to an environment in which a constructive response is forthcoming, or both, is therapeutic.

Child analysis is one reliable treatment method.[31, 65] Its reliability and appropriateness in neurosis stems from two factors. It is a method by which the cause of the illness (the mental confusion with its attendant symptomatic expression, suffering, and frustration) can be made understandable to the child. His anxiety is relieved by a gradually developing, shared understanding of why he feels bad. At the same time, he is under no pressure, because of the absence of "toxicity" in the analytic situation, to resort to inappropriate and ineffective adaptive patterns. The analysis provides a setting in which the inappropriateness of existing symptomatic patterns is made manifest, and there is also a person at hand who can offer suggestions for alternative, more constructive coping procedures in a context in which they make sense and are not threatening.

The effectiveness of analysis in the neuroses of childhood stems from the fact that the method gives the therapist the control he needs to manage the child's illness. It is a procedure in which the type and quantity of healthy experiences during treatment tend to insulate the child against a neurotigenic environment which may be difficult to modify. It goes without saying that child analysis, though it may be effective even with little improvement in the sanitation of the environment is more likely to restore the neurotic child to health if the responsible adults undergo concomitant changes in control, in attitudes, and even in values. To this end, psychoanalysis for one or both parents is often recommended.

The technical aspects of child analysis are beyond the scope of this chapter. Verbal free association depends on the adult patient's ability to use his sophistication and logic to overcome distrust. Children, especially neurotic children, cannot so easily convince themselves that it is logical to assume reliability and restraint on the part of an adult regardless of his training and diplomas, so that until their verbal development is quite advanced, or until they have overcome initial distrust, verbal free association cannot be counted on as a central resource toward uncovering conflict. The analyst has to be more active and do more of the "translating." The material out of which reconstructions and interpretations can be made may come from play or from nonverbal behavior, and interpretation refers relatively more to life events and relatively less to transference events and fantasies.

The use of this treatment method is, unfortunately, determined often by availability of resources rather than by the clinical indications. Many children whose neuroses could be appropriately treated analytically cannot be analyzed for lack of resources or for lack of money.

Analytic treatment of children, even when modified according to necessity or convenience, may be distinguished from all other management plans in that significant alienation of the child from the parents and teachers is inevitable during the treatment. In all other treatment plans the relationship between the treatment and the life situation is more complementary, less substitutive.

Downloaded from www.psychiatry.com

Analytic principles may apply to some extent to any plan in which the child plays with or talks with the therapist. When the conditions for a child-therapist relationship which can stand on its own feet cannot be arranged, the outcome of the illness must depend heavily on alteration in the environment.

Efforts in the direction of creating a more sanitary environment for the neurotic child comprise the rest of the spectrum of therapy for the neuroses of childhood. "Therapy" of the environment may be attempted by support, by interpretation, or by direction to any or all of the important adults in appropriate settings. Character change in the parents usually takes an amount of therapeutic investment which is hard to arrange. Often the direction and guidance which can be formulated from a knowledge of the child's needs and from the derivative conflict situations of life at home can be used by the parents, especially if they have support, to control and correct repetitively noxious behavior, and to give the child and the family a respite during which the natural "healing powers" of the child may be re-established and a downhill course be reversed.

The popularity of parent- and teacher-education programs in schools and in the community at large, and the avidity with which pediatricians, social workers, and others working with children and families seek understanding indicate the wide acceptance of responsibility for improving the climate in which the neurotic child may be helped.

Most neuroses encountered in practice are chronic by the time they are brought to the attention of the psychiatrist. Perhaps in no other field of medicine does the specialist so rarely see really acute illness. Nor is the child psychiatrist in his practice often afforded opportunities for complete prophylaxis. These opportunities fall rather to the pediatrician in the well-baby clinic or in his intimate contact with families, or to the psychoanalyst of the parent-to-be. It is mainly as consultant and teacher that the psychiatrist can help others to *prevent* the common neuroses of childhood. What prevention there is, which is most pertinent to child-psychiatry practice, may be compared with that important aspect of medical practice which concerns itself with the prevention of complications, chronicity, and deterioration so that self-limitation may be permitted and healing subsidized.

Definitions of the neuroses of childhood are tentatively formulated only in closing, since it is an illness so complicated and one about which so little is known: The neuroses of childhood are diseases of the mind characterized primarily by partial decompensation (maladaptation) in social (human-object) relations. There exists mental conflict of a degree and kind incompatible with health. The derangement of mental function is expressed in a variety of ways. The mode of expression (the form taken by the neurosis) is determined by hereditary and constitutional factors, by developmental patterns, by the stage of development at which the mind is disturbed, or by the response of the social environment to the homeostatic tendencies of the child's disturbed mental apparatus. (Previous conditioning may add a predilection for certain organ systems or for specific constellations in the human-object world of the child.)

In the neuroses of childhood, age-appropriate reality testing is in large part preserved, being lost or distorted only in partial and circumscribed aspects of mental activity.

Neuroses in childhood may be acute (and self-limited). This occurs when the primary cause is removed before the developmental pattern is specifically altered by the inclusion of nonconstructive, aggravating mental reactions to the noxious stimuli or events. A chronic state of the illness may develop rapidly. Nevertheless, if the cause is removed, the potentiality for healing or "self-limitation" of the disease may be present for some time. Under such circumstances, some "scars," not necessarily "crippling or deforming" are likely to remain.

CHAPTER 41

# SEVERE EMOTIONAL DISTURBANCES IN CHILDHOOD: PSYCHOSIS

Margaret S. Mahler, Manuel Furer, Calvin F. Settlage

Downloaded from www.libraullibrary.org.in

THE SEVERE EMOTIONAL DISTURBANCES in childhood consist of a heterogeneous group of syndromes which include, besides child psychoses, the sequelae of hospitalism and anaclitic depression,[91] certain delinquencies, tic disease, grave psychosomatic conditions, and organic syndromes. They are distinguished from the neurotic disturbances in childhood by their greater irreversibility and by the fact that their psychopathology is based on a defect in the system ego (whether inborn or acquired), a defect in the adaptive, inhibitory, and steering agency of the personality.

We have chosen from among these groups of severe emotional disturbances to describe psychotic syndromes in children, because the psychoanalytic investigation of these has led to our conceptualization of ego-pathology and reconstruction of the early stages of ego development. Hence our psychoanalytic point of view seemed best suited to throw some additional light on this particular area of psychopathology of childhood.

## ¶ Summary of the Literature

The serious disturbances in childhood that result from emotional deprivation have long been studied by various workers.[10]

From a psychoanalytic point of view, in 1941 Margaret Ribble[86] emphasized the disorganizing and relatively irreversible effects that such deprivation through deficiency of mothering has on the development of the body and psyche of the infant.

In a series of papers initiated in 1945, René A. Spitz[91, 92, 93] has reported on careful studies

of emotionally deprived infants which have led him to delimit two clinical pictures in infancy which he calls hospitalism and anaclitic depression.

"The term hospitalism designates a vitiated condition of the body due to long confinement in a hospital (or institution such as a foundling home), or the morbid condition of the atmosphere of the hospital."

Spitz studied 164 children in two institutions, as compared to 34 children reared at home, with Hetzer and Wolf baby tests and extensive use of films. The outstanding result of his study was that the developmental quotient of the infants in one of the institutions (foundling home) dropped almost in half during the first year of life, and half of that at the end of the second year. These babies were also very susceptible to illness and showed a relatively high mortality rate.

At 18 months to 2½ years of life, the survivors could not eat alone, were not trained for cleanliness, and spoke only a few words. At 8 to 12 months in the other institution (nursery) the infants were active, agile, and vocal. The background of the children of both the foundling home and the nursery is similar. Both institutions provide good housing, food, and medical care. The "visual radius" of the nursery is much greater, owing to the activity of the mothers present who take care of their own children, as well as the fact that their vision out of their cots is not blocked. In the foundling home the crib sides are covered, and stimulation from adults comes only from the nurses present at feeding time. Locomotion was restricted in the foundling home so much that, as a result of this lack of motion in the early months, hollows have formed in the babies' mattresses.

In the nursery, located in a penal institution for delinquent girls, the babies are the mothers' only source of pride and pleasure, and consequently they receive a good deal of care and attention from their mothers. On the other hand, in the foundling home each baby has "one eighth of a nurse" only.

Spitz concludes that the deterioration and lack of development of these latter infants is due essentially to the lack of mothering.

A follow-up study[93] of the two groups of children 2 years later showed that the foundling-home children progressively deteriorated in body development, in handling of materials, in speech, and in adaptation to the environment (such as toilet training). They were underweight and undersized. On the other hand, the children in the nursery had continued to develop well individually (bodily) and socially.

In 1946, Spitz described another severe disturbance of infancy which he called anaclitic depression.[94] This is a condition in which infants who have just established a constant cathexis of a need-satisfying object (the mother) lose this object and develop a mourning reaction which can progress to a state of depressive withdrawal and debilitation. Spitz found 19 severe and 26 mild cases of this syndrome out of a total of 123 infants observed in an institution. In each case the mother had the full care of her infant until between 6 and 8 months of age, when she was removed from her child for a period of 2 to 3 months. The syndrome did not develop in infants who did not have this particular history, but, on the other hand, not all of those whose mothers were removed developed symptoms. Substitute maternal figures were available to some of these infants, but these women, who were delinquents, were often unloving. It is noteworthy that the syndrome developed more frequently if the previous mother-child relationship was a good one.

The syndrome develops in the second half of the first year and first shows itself by a consistently sad expression on the infant's face. If an observer approaches at this time, the infant tends to cling. However, after a short period of time, the reaction to the observer is one of apprehension, and an attempt to make contact provokes crying. The observer may be accepted after a long period of attempting to interest the infant, but the sad expression does not disappear. Finally, a complete withdrawal and dejection develop, with a frozen rigidity of expression. An attempt to engage the infant's interest at this stage occasionally gives rise to screaming.

When the mothers are restored to these

Downloaded from www.brainpickings.org

infants, there appears to be a complete recovery and they become friendly and gay. If the mother is not restored, the process continues, and there is a picture of stuporous, deteriorated catatonia or agitated idiocy which appears to be irreversible. It is further noted that 34 out of 91 children in the institution where the mothers were not restored died over a 1-year period. During the episodes of milder depression, the infants appeared to be more susceptible to colds, they lost weight, and were unable to sleep.

Spitz considers this syndrome the equivalent of the "primal parathymia" which was described by Abraham (1924) as the infantile prototype of a later depressive psychosis. Spitz also states that he considers this syndrome to be a psychosis, the signs and symptoms of which differ from those of later life because of the immaturity of the psychic apparatus. He states that, in the second half of the first year of life, the ego is organized enough for the control of motility and of the expression of negative and positive affects, disturbances of which can be called psychotic. The cardinal symptoms that are present in the infants observed are the dejected expression and posture and the distaste for locomotion. He explains that an infant, after 6 months of age, can seek an adult, and that the infants do attempt to regain the lost object world as do adult psychotics, but in infancy it takes the form of finding a substitute object. In the particular situation of the institution under study, this was limited by the fact that there were few substitute love-objects to be found, and also by the fact that the infants' locomotion was prevented.

He explains further that there is a parallel with melancholia in adulthood, in which the aggression of the super-ego is turned on the ego, by pointing out that this super-ego was originally the external love-object and that one could consider that in anaclitic depression the sadism of this external love-object is directed against the ego of the infant. The connection between anaclitic depression in infancy and other psychotic states is, as yet, not clarified. We have the impression that the main difference might be in the fact that anaclitic depression, with or without its sequelae, is inflicted upon an infant with per se normal ego anlage.

The important common feature in an infant who later develops child psychoses and those who have anaclitic depression is an interference with the libidinization of its own body (particularly its boundaries) as well as a disturbance of the progress toward "object-constancy," that is, toward libidinal cathexis of the surrounding world. Parallel with this developmental lag, neutralization of the drives, especially of aggression (or amalgamation of aggression by libido), and the directing of aggression away from its own body becomes thwarted.

It is our impression that in anaclitic depression, even though the ego anlage is normal, the lack of mothering results in an investment of the primitive ego with unneutralized aggression. However, this ego will be able to seek out and utilize whatever it can find of what it needs to repair the damaged mother-child unity and to restore the same.*

In anaclitic depression there is not a defect either in the child or in the mothering partner but a loss of the real object in the outside world, at the crucial stage of the normal mother-infant symbiotic relationship.[91] On the other hand, in autistic and symbiotic child psychoses, it is the mother-child unit which is deficient (as will be described in what follows). This deficiency results in a confused orientation between the self and the outside world, and, whether the mother (the first love-object) is actually available or not, sustained cathexis of the whole object is more or less irreversibly disturbed. In other words, there is an intrinsic defect of the sociobiological adaptation in the latter cases, whereas there is an inflicted, rather than intrinsic, damage in the anaclitically depressed infants of Spitz.

At the present time, further understanding of the relationship between anaclitic depression and similar conditions and the syndromes of child psychoses is not available. The missing parts of the theoretical framework, for com-

* Compare A. Freud and Sophie Dann's study of concentration-camp children who seemed to be able to build object-relationships on extremely scanty opportunities. They also utilized every bit of that which they could find in each other.[32]

Downloaded from www.dbpublishing.org.in

parison of the two afore-mentioned groups, will have to be provided by further investigation and data about the infancy of those children who later develop child psychoses, and by follow-up studies of the later childhood of those who had been anaclitically severely depressed in infancy. The meaning of this statement will become clearer after we have reviewed the literature pertaining to and have discussed the schizophrenialike pictures in children, which we intend to do in the following.

Different authors use many different names for children with various psychotic disturbances. Some call them atypical children, others, schizophrenic children; workers in the field readily apply the term "autistic," while still others hesitate to call the psychotic child schizophrenic and prefer the term "schizophrenoid." Each author has his own reasons for his choice of the name by which he designates these conditions. While the term "atypical" is perhaps both too cautious and too broad, the designation "autistic child" is a generalization from only one type and is one of the frequently found features of the many other types of childhood psychoses.

In the forties Kanner[56,57] described a special syndrome among the varied pictures of child psychosis—a syndrome which he called "early infantile autism." This condition is characterized by profound withdrawal and lack of contact from the very first years of life, an obsessive demand for sameness in the environment, a lack of communication in the use of language, and a preference for relationship with inanimate objects. Kanner's view, which is elaborated by Rank,[84] is that it is the mother's and/or parents' inability to create a warm emotional climate ("the frigidaire atmosphere") which prevents the child's ego from developing its capacities for the externalization and taming of the drives. The result, in Rank's terms, is the "fragmented ego." Rank and her co-workers state that the personality structure of these children represents "fragments of various stages of development showing high achievement of some of the executive functions of the ego, while other manifestations of the ego or instinctual drives remain crippled or are on a much lower level."

Lauretta Bender[4] defines child schizophrenia in terms of a "clinical entity occurring in childhood before the age of eleven years which reveals pathology of behavior at every level and in every area of integration or patterning within the functioning of the central nervous system, be it vegetative, motor, perceptual, intellectual, emotional or social." The schizophrenic process is conceived of by her as a form of encephalopathy which interferes with the normal biological developmental patterns. Some of the observable disturbances in the child, such as the disorders of temperature regulation and sleep rhythm, are considered direct evidence of inadequate patterning, while the presence of "neurotic defense mechanisms" are felt to be the particular responses of the child to the anxiety engendered by the basic defect in homeostasis. To explain the wide variability in psychopathology, Bender introduced the concept of plasticity. For example, some of these children are withdrawn and blocked, while others are brilliantly articulate and apparently gifted; in the same child there are simultaneously present both early and more advanced patterns of maturation and development. Finally, Bender was impressed with the similarity of the failures in adaptation of the schizophrenic child and those described by Gesell for the fetal infant. She concluded that childhood schizophrenia is a "developmental lag of *the biological processes* from which subsequent behavior evolves by maturation at an embryological level." She emphasized that the very primitive nature of the child's functioning is the source both for the defects and for an unusual capacity for development. The psychological problems of the schizophrenic child, she states, concern the overwhelming anxiety about body-image, object-relationships, orientation in time and space, and meaning of language. According to her, "The disturbance in identification processes, that is, difficulties in identifying one's self and thereby relating to the rest of the world, is the essential psychological problem." She does not distinguish autism from the large group of schizophrenias in children but groups them rather according to the age at which the disturbance became manifest.

Annemarie F. Weil,[99,100] in her studies, con-

Downloaded from www.pbookshop.com

tinues this emphasis upon the "failure in balancing homeostatic patterns." She points out that these children do not acquire latency characteristics and that, in contrast to neurotic children, their developmental deviations are more abundant, varied, and especially interchangeable. There is a history of either overintensity or underintensity of reaction from earliest infancy. She differentiates a special group of severe disturbances of ego development "characterized by lack of progression as contrasted with even more serious narcissistic disturbances of a regressive type," and she considers that their behavior cannot be distinctly related to a specific level of development (Mahler's Group III).[76] Weil defines the faulty ego as consisting of a deficiency in the development of object-relationship with its consequences, lack of acceptance of the reality principle, a deficiency in reality testing, and failures of the synthetic function of the ego and of the proper use of age-adequate defenses. The cases described are more like those Bender considers invasive in interpersonal behavior rather than withdrawn, and are not autistic as described by Kanner. These children, she states, do not overcome the stage of primary narcissism, the drives are relatively untamed by the ego, and only primitive defenses, such as "as if" imitation, almost delusional denial, and introjection and projection are at the disposal of their egos.

Despert[15-18] was one of the first to describe the clinical picture and therapeutic process in childhood schizophrenia and to define differential diagnostic criteria between neurotic and psychotic pictures in children. She emphasized the affective withdrawal and, especially, the "dissociation between language sign and language function," that is, between the accumulation of words and the paucity of their use for social communication.

Geleerd[41] observed the pathological significance of temper tantrums, later editions of the small infant's affectomotor panic, in children with "arrested ego development." She described how they could be soothed only by supplying a mother-substitute on the level of what we would call a symbiotic partner. She described the difference between ordinary temper tantrums of small children and those met in these patients, during which they were out of contact with reality and acted delusionally as if they were warding off an attacker. She concluded that these children have not set up an image of the mother within themselves, so that they are dependent on the actual presence of their mother; they cannot separate from the actual mother figure without withdrawing into a world of fantasy of omnipotence. Geleerd's[39] recent concept of identification with the omnipotent attacker and alternately with the impotent victim promises to be quite fruitful in research in child psychosis.

Bergman and Escalona,* in a study of unusual sensitivities among very young children who also fall into this general group, offer another explanation for the unevenness of ego-functioning. They postulate an insufficiency of the stimulus barrier which results in premature and fragile ego formation. Bergman and Escalona emphasize that protection from traumatic overstimulation in the normally developing infant is supplied both by this protective stimulus barrier (Reizschutz) and by maternal care.

Bradley's, Potter's, and many others' pioneering work should be referred to as well.*

## ¶ Differential Diagnosis

In terms of psychoanalytic concepts, the psychoses of childhood are due to inadequate differentiation and inadequate functioning of the ego, and, as in adult psychoses, represent a conflict between the ego and reality. Neurotic childhood disturbances, on the other hand, which have a much greater reversibility potential, are due to traumata and fixation in the area of psychosexual development and represent a conflict between the ego (super-ego) and the id.

We should like to emphasize that we believe the group of child psychoses is not a distinct and well-defined disease entity. We are dealing with certain constellations, groupings, or pat-

* An excellent and exhaustive review of the literature has recently been done by Ekstein, Bryant, and Friedman in the new edition of Bellak's book, *Schizophrenia: A Review of the Syndrome.*

Downloaded from www.dbraulibrary.org.in

terns of symptoms—that is to say, we are dealing with *syndromes*. Two syndromes of early infantile psychosis seem rather clearly distinguishable: one is "early infantile autism" and the other, described by Mahler, the "symbiotic infantile psychotic syndrome." These syndromes are related to each other. They often overlap, and they have at least two basic features in common: (1) alienation, or withdrawal from reality, and (2) severe disturbance of the individual child's feeling of self-identity. If these two cardinal features are not evident, we would not designate a child's disturbance as psychotic. A third group of child psychosis is the more benign group described by Mahler, Ross, and DeFries[76] as well as Gelcerd,[40] in whom autistic, symbiotic, and neurotic mechanisms are used simultaneously or alternately by the ego. In all these children the disturbances of reality testing and of the sense of entity and boundaries of the body-image are evident.

Among the various severe psychiatric disorders in children, the so-called organic cases are most likely to present a problem in differential diagnosis. Their prominent clinical feature also is a defect of the ego. Their main symptoms are in the nature of disturbances of intelligence, motility, visual motor coordination, etc., but in the pure cases the two afore-mentioned cardinal symptoms of psychosis are absent or not prominent. In contrast to the psychotic child, the organically damaged child, within his own limitations, orients or adjusts himself relatively well to reality. These children cope with their social environment to the best of their ability, in spite of their reduced cognitive function. We might formulate the differential diagnostic criteria in an oversimplified manner as follows: The organically damaged child tries, to the limit of his ability, to utilize his reduced endowment for adaptation to reality, particularly social reality; the psychotic, in contrast, with an uneven but often extraordinary endowment in certain dissociated areas, is particularly unable to use his endowments for social adaptation. The clinical diagnosis is complicated, however, by the fact that there often are admixtures of organic disturbance and psychosis.

## ¶ Psychoanalytic Concepts

Our hypothesis of infantile psychosis is based upon two of Freud's fundamental concepts. It is a quasi-sociobiological proposition. Freud[33] emphasized that, whereas the animal has an instinctual faculty for sensing danger in the outside world which enables it to take appropriate action to cope with such danger, this faculty has atrophied in the human being. In the human being the ego has to take over the reality testing which the id neglects. The predicament of the human young is immensely complicated by still another biological circumstance—namely, by the fact that he is born at an earlier, less matured stage of physical development than any other mammal. These two interrelated circumstances—namely, the atrophy of the instinct of self-preservation and the immaturity of apparatuses at birth—result in the human infant's absolute dependency for his very survival on the nursing care of a mother or a mother-substitute for a long period. Long after the child has been born, a species-characteristic social symbiosis between the infant and mother is necessary.

Within that twilight stage of early life, which Freud designated as primary narcissism, the infant shows no sign of perceiving anything beyond his own body. He seems to live in a world of inner stimuli. The first weeks of extrauterine life are characterized by what (according to Ferenczi) we call the stage of hallucinatory wish-fulfillment. Whereas the enteroceptive system functions from birth, the perceptual-conscious system, the sensorium, is not yet cathected. This lack of peripheral sensory cathexis only gradually seems to give way to sensory perception, particularly to distance perception of the outside world. However, the functioning of the undifferentiated ego apparatuses of the infant, that is, the affecto-motor reactions, such as crying, enables him from the beginning of life to signal and summon the mother to minister to his needs. The mother thus serves as an external executive ego. This is the first phase of the mother-infant unity, and it has been termed the presymbiotic or normal-autistic phase.[65]

Downloaded from www.dbpublibrary.com

Under normal conditions the presymbiotic, normal-autistic phase of the mother-infant unity gives way to the symbiotic phase beginning at about the age of 3 months. Through the periodic, rhythmically recurring experiences of painful accumulation of tension inside his own body, followed by the regularly repeated experiences of gratification which he cannot provide for himself, the infant eventually becomes dimly aware of the fact that satisfaction *is* dependent on a source *outside* of his bodily self. Thus he gradually comes to recognize an orbit beyond his own body. During his wakeful periods the 3- to 4-month-old baby seems to perceive, temporarily at least, that small part of external reality which is represented by the mother's breast, face, and hands, and (in a gestalt kind of perception) her ministrations as such. When this occurs—usually by the end of the third or in the fourth month—the baby's reactions gradually become less diffuse, and his activities seem more goal-directed toward the above-described need-satisfying part-object in the external world. A certain degree of ego development is indicated by our observation that by then (at 3 months of age) the baby can wait. He follows his mother's now-familiar preparations with his eyes. We have no evidence, though, that even at this stage the mother is perceived as a specific whole person. The practical fact that the mother or the nurse can still be replaced by any equally gentle nursing and mothering substitute seems to indicate that the 3- to 4-month-old baby is aware of the mother only as a need-satisfying quasi-extension of his own self. This phase of dim awareness of the object marks the beginning of the phase of symbiosis in which the infant's own and the mother's body-ego boundaries seem fused, confluent, and confused. The infant and his mother are an omnipotent symbiotic dual unity.

Toward the end of the last third of the first year, a tentative experimentation at separation-individuation sets in, at least as far as his body is concerned. This can be observed in such experimenting as his pulling alternately his own and his mother's hair, ears, nose, etc., and the familiar putting of food into the mother's mouth which often is mistaken for the beginnings of altruistic behavior. This primitive initial phase of individuation, occurring at the height of the symbiotic phase, advances toward the separation-individuation phase proper. This occurs parallel with the maturation and consolidation of such autonomous functions of the ego as locomotion, the beginning of language, and ideation.

The steps of separation are taken while in search for the need-satisfying object. This separation-individuation depends to an unusually great extent upon interaction between the child and the mother, upon stimulus and response between the two partners of the dual unity. The mother is both the external ego and the one who triggers separation. Erikson,[26] Spitz, Sylvester, and many others rightly stress the circular nature of this early mother-infant somatopsychic relationship. This emphasis on its circular nature is important. In addition to or instead of the baby's lack of sending power, there may be grave deficiencies and incompatibilities on the mother's part of the symbiotic unit. The mother either may be lacking in empathy or may so completely anticipate her infant's needs as to stifle any initiative from him.* In the latter case we find that the mother continues to regard that particular infant as part of her own self. These deficiencies then interfere with the growing infant's normal individuation.

Physicians and others who work with children's problems lean toward either of two extremes: They either believe that it is the mother in the symbiotic dual unity who is responsible for schizophrenia—known as the "schizophrenogenic mother"—or else they assume that early infantile psychoses are wholly due to the infant's hereditary or constitutional deficiency. In order to understand the pathogenesis of severe emotional disturbances in children, we must think in terms of a circular process. According to Spitz, there is an absence of an "inner organizer" in the human infant. Therefore, the symbiotic partner must be able to serve as a buffer against inner and outer stimuli, gradually organizing them for the in-

* According to Hartmann, Kris, Loewenstein, and Anna Freud, the gratification-frustration sequences are necessary for the development of psychic structure.

Downloaded from www.pbookshop.com

fant in orienting it to the inner versus the outer world. The infant, in turn, must be able to utilize the mother to this end.

The second 18-month period of life is the one in which—after quasi-bodily experimentation (from the end of the first year)—firmer delimitation (cathexis) of the boundaries of the self seems to occur, which is prerequisite to separation-individuation. Ever since birth there have been gradual normal shifts of distribution of libido from the inside of the body (the viscera) to the periphery of the body, particularly the libidinal zones. As we said before, of particular importance in the separation-individuation phase is the advent of locomotion; this faculty seems to add tremendously to the autonomy of the child's ego. The child now has the capacity to experiment with physical separateness from the mother in an active way, rather than to experience separation passively as he hitherto did. Freud stated that "absolute mastery of motility is one of the basic characteristics of the mature ego." This control of motility, when adequately and comfortably established, provides the pattern for the subsequent development of control of emotions. Parenthetically, we may state that in tic disease and in certain acting-out problems, the continual experience of the ego of being overwhelmed by inner, uncontrolled forces has a disorganizing effect which interferes with its further development. Taking place concurrently with self-differentiation in the second year of life, the child gets acquainted with and tests a much broader segment of reality. The reality-testing function depends upon perception, motility, and memory, as well as other functions of the ego. Through these functions the child eventually achieves a clear distinction between the self and the object world.[53]

Cathexis of the perceptual-conscious system permits recognition of stimuli and provides the possibility for differential evaluation of stimuli. At birth the infant presumably can receive stimuli through all of the senses, but the inherent stimulus barrier and the maternal executive ego function together to protect from excessive stimulation. We are familiar with the early beginning of visual contact with the external world as is indicated by the manner in which the eyes will track a moving object. We also have evidence of early auditory reception. However, the sensory capacities of the mouth (oral cavity)[91] and the mouth-hand coordination[92] seem to contribute more dynamically to body-image formation and thus to the beginning of the reality-testing function of the ego. Involved in this are the senses of proprioception, kinesthesia, touch, taste, and smell. The ability to distinguish between the self and the nonself, to separate inner reality from outer reality, is necessary for the ego to localize and evaluate correctly and to integrate within the memory-traces the increasing amount of stimuli received by the senses. At a later time, a stable image of the self, especially of the body, and then a stable concept of the self are the most important anchors and frames of reference for ideational processes.

Just as growth of certain so-called autonomous ego-functions is biologically predetermined, psychosexual maturation is also biologically predestined, both of these proceeding, even though object-relationship and reality testing may not.* Psychosexual maturation implies progressive libidinization of the so-called erotogenic zones (oral, anal, and phallic). It seems that the most consequential maturational happening occurs with the phallic phase. The massive concentration of libido in the genital zone causes, per se, important shifts of cathexis in terms of body-image. This proceeds via the pregenital libidinal phases, resulting in bisexual identifications and eventually in firm establishment of sexual identity. The distinct feeling of sexual self-identity receives decisive experiences along the line of the solution of the oedipal conflict—beyond the more or less marked bisexual identifications. During latency, more complex and qualitatively distinct images of self and object world are formed. If integration of these contributories—concept of the self and object world—has been disturbed, representation of one's self as belonging to one sex integrated within the cohe-

* According to Hartmann, Kris, and Loewenstein, maturation indicates the processes of growth that occur relatively independently of environmental influences; development indicates the processes of growth in which environment and maturation interact more closely.

sive cathexis of the ego becomes jeopardized by the hormonal upheaval of puberty. (See case of George, described below.)

## ¶ Types of Child Psychoses

It is our hypothesis that the various types of psychoses in children can be understood as psychopathological distortions of these normal phases of development of the ego and its functions within the early mother-child relationship.

### *The Syndrome of Infantile Autism (Kanner)*

From our sociobiological point of view, early infantile autism represents fixation at, or regression to, that first, most primitive phase of extrauterine life which we have described above as the normal autistic phase. The most conspicuous symptom is that the mother, as representative of the outside world, seems not to be perceived at all by the child. She does not seem to exist as a living beacon of orientation in the world of reality. The self, even the bodily self, seems not to be distinguished from the inanimate objects of the environment. There seems to be an innate, primary lack, or a loss of that primordial discrimination between living and lifeless matter which Monakow called protodiakrisis. It may be argued whether this negative hallucinatory behavior, this turning a deaf ear toward mother and to the entire world, is or is not an acquired, specific, and active warding off of the mother. If it is an acquired somatopsychic defense, it is so archaic and develops so soon, at or after birth, that its psychic content and meaning cannot be discerned. These children's anamnesis contains descriptions of the earliest behavior, which reveals that there was no anticipatory posture at nursing, no reaching-out gestures, and no specific smiling response.[96] It is characteristic of them to become attached to a high chair, a toy, or some other lifeless object. Mothers describe the infants' behavior in the following ways: "I never could reach my baby." "He never smiled at me." "The minute she could walk, she ran away from me." "It hurt me so when I saw other babies glad to be in their mothers' arms; my boy always tried to creep away from my lap as soon as he could." "He never greeted me when I entered, he never cried or even noticed when I left the room." "She never was a cuddly baby, she never liked to be caressed, she did not want anybody to embrace or to kiss her." "She never made any personal appeal for help at any time." This last remark, by the very observant mother of an autistic child, describes most succinctly the disturbance as seen in terms of social behavior.

The entire symptomatology and behavior pattern of the infantile autistic syndrome is formed around the fact that the autistic infant or child is unable to utilize the auxiliary executive ego-functions of the (symbiotic) partner, the mother, to orient himself in the outside or the inner world. The most basic modalities of matter are thus unintelligible to him. He has to create substitutive modalities of orientation in order to cope with stimuli from within and from without. To begin with, he must and does create and tries to enclose himself in a small, utterly restricted world of his own. His most conspicuous and characteristic behavior patterns are the classical features described by Kanner—the obsessive desire for the preservation of sameness, a stereotyped preoccupation with a few inanimate objects or action patterns about which he shows the only signs of emotional attachment. Correspondingly, he shows utter intolerance of any change in his inanimate surroundings. These features, then, may serve as differential diagnostic criteria to distinguish infantile autism from organic syndromes. Other characteristics of the primarily autistic child's appearance and behavior are his intelligent, even pensive facial expression, in spite of the fact that he does not focus but seems to look through you. In his behavior the primarily autistic child differs from the organic as well as from the primarily symbiotic-psychotic child by his seemingly self-sufficient contentedness if only he is left alone. These autistic children behave like omnipotent magicians if they are permitted to live in, and

Downloaded from www.dbraincenter.org.in

thus to command, their static and greatly constricted segment of inanimate environment. Either they are completely mute (talking to their inanimate fetish companions or imaginary objects by gestures), or, if they do speak, their language is not used for functional communication. Instead, their language serves as quasi signals, such as are seen in earliest infancy. These autistic children, with signals and gestures, command the adult to serve as an executive extension of a semianimate or inanimate mechanical kind, like a switch or a lever of a machine. But they use the same gestures, sounds, or words, trying to coerce—to conjure, as it were—the living part-object as the thing they covet.

What is the meaning, what is the function of this autism? It would seem that autism is the basic defense attitude of these children by whom the beacon of emotional orientation, the living primary love-object, the mother, cannot be utilized, that is to say, is functionally nonexistent as such. The child devoid of emotional ties is unable to cope with the complexities of external stimuli and inner excitations that simultaneously threaten his very existence as an individual entity. Autism is an attempt at dedifferentiation and deanimation. It may be looked upon as the mechanism by which such patients try to shut out, to hallucinate away, the potential sources of sensory perception, particularly the infinitely variable ones of the living world, which demand emotional social response. One of the first signs for which parents seek help and guidance frequently is these children's failure to heed or even to hear the parents' communications. The parents prefer to believe (notwithstanding other symptoms of autism) that their child is deaf or hard of hearing. Some form of massive cathectic withdrawal from the distance-perceptive sensorium seems to be at work. This seems to be borne out by the following diagnostic examination:

In order to establish a first tentative diagnosis, we may drop some metal object near the child to make a loud noise. The autistic child behaves as if he heard nothing. One is reminded of the normal autistic phase in which the distance receptors are not yet functionally tuned or, as we say in psychoanalysis, not cathected. That this lack of response (there is no startle reaction) is a kind of negative hallucinatory denial of perception rather than real deafness is proved by the fact that if you now turn on a victrola and play a familiar tune the child will turn and listen with rapt attention and may also move rhythmically, beat time to the record, or at least look at the revolving disk with fascination—having been made aware of it by the sound alone. From these observations we may then draw conclusions regarding the therapy and management of these cases.

When we observe this type of psychotic child clinically, the most striking feature is his spectacular struggle against any demand of human—of social—contact. It would seem that these children's capacity to master their inner feelings, their own thought processes, their motility, their highly selective and restricted sensory awareness all but overtax their undifferentiated, defective, and rudimentary egos. They cannot cope with unsolicited and unexpected stimulation from the external world. They cannot mediate between external and internal stimuli. In short, it seems as though these patients experience outer reality, beyond their own stereotyped constricted one, as an intolerable source of irritation, without specific or further qualification. Therefore, these children seem to have managed to build up, or maintain and solidify, their original massive, negative-hallucinatory stimulus barrier against the impingement of the outside world. Their psychotic defense mechanisms aim at dedifferentiation and deanimation of inner and outer reality.

Psychoanalytic concepts help us to understand still other features of infantile autism and to differentiate it from organic syndromes and symbiotic child psychosis as well. These children are, more often than not, toilet trained at the age of normal children. This relative ease of toilet training seems to stem from two factors: One of these seems to be an insufficient erotization of the body surfaces and orifices; the second, the paradoxical situation that it is precisely the lack of emotional involve-

Digitized by http://www.libtool.com.cn

ment which makes toilet training an uncharged *conditioning* process for these children. The autistic child neither eats nor defecates to please the parent, nor does he refuse food or withhold his stools to spite the mother.

Most autistic children have a relatively low cathexis of their body surface, which accounts for their grossly deficient pain sensitivity. With this cathectic deficiency of the sensorium goes a lack of hierarchic stratification of zonal libidinization and sequence. This is evident from the relative paucity of autoerotic activities, and a facility for substituting one for the other. Instead of autoerotic activities, they show autoaggressive habits such as head knocking, self-biting, or other self-hurting, mutilating activities, and a mixing up of oral, anal, and phallic contents. In fact, these autoaggressive activities seem to serve the purpose of boundary cathexis of a distorted and deranged libido economy, constituting a pathological attempt *to feel alive* and whole. Autoaggressive manipulations seem to help these children to feel their bodies, to attain a sense of identity. These autoaggressive activities serve to sharpen the awareness of the body-self boundaries and the feeling of entity, if not identity.

## *The Symbiotic Psychosis Syndrome (Mahler)*

The symbiotic psychotic child's primitive ego, unlike that of the autistic child's, seems to have progressed in development to the symbiotic phase and, more often than not, shows beginnings of differentiation in terms of separation-individuation. The symbiotic syndrome represents fixation at, or regression to, a more differentiated stage of personality development than the autistic, namely, to the stage of the need-satisfying part-object. Therefore, the clinical pictures are infinitely more complex, mottled, and variable in children with this syndrome than is the case in early infantile autism. We found it most helpful, in trying to understand the clinical symptomatology and dynamics of the primary symbiotic psychotic syndrome, to visualize the accelerated rate of maturational growth of ego apparatuses in the second and third years of life. The maturational spurt in the second year puts the normal toddler in the position of relatively advanced physical autonomy. His emotional and developmental growth and independence must catch up, must keep pace, as it were, with this somatic maturational spurt. Maturational growth of the central nervous system and of apparatuses is preordained and rather independent of environmental and emotional influences. However, some children's emotional development in this age period seems to lag far behind. Babies who, for intrinsic or environmental reasons, cannot separate, whose ego cannot differentiate from the mother, are unable to cope with this maturational spurt and thus cannot proceed from the symbiotic phase of normal development. They cannot separate from the mother when their maturational growth inadvertently enables them to do so. With age, the discrepancy between maturational and developmental growth increases. When the rate of growth of autonomous ego-functions and psychosexual maturation surpasses the emotional differentiation from the mother, these children's brittle ego-structure tends to fragment. Perhaps the function of independent locomotion is one of the autonomous ego-functions the maturation of which is the most disconcerting to this type of patient, since it enables him to move away from the mother physically before he is emotionally prepared to do so. The child who could not achieve emotional differentiation from the mother is thereby unprepared now to be functionally separate from her. Despite his own matured independence of functioning, he appears emotionally utterly bewildered and panicky; the same is true of his coping with the sexual and aggressive impulses which inadvertently proceed toward zonal maturation. Therefore, it takes only a slight additional frustration or trauma to set off an ego fragmentation in these children. This, however, may not become apparent before the age of 3, 4, or 5 years.

A close scrutiny of the developmental history of the symbiotic psychotic child often shows unusual sensitivities which Bergman and Escalona described—an unevenness of growth and striking vulnerability of the budding ego to any minor frustration. In the anamnesis of

Downloaded from www.dbraulibrary.org.in

these children, you will find evidence of extreme reactions to the small failures which normally occur in the exercising, practicing period of partial ego-functions. For instance, such children will give up locomotion for months because they fell or sat down with a bump. There usually is a complementary environmental trauma such as abrupt, though probably unconscious, change of attitude on the part of one or both parents which occurs at the onset of the separation-individuation period. These changing attitudes of parents at different ages of their children was particularly emphasized by Coleman, Kris, and Provence.[14] The acute break with reality is ushered in by what essentially proves to be a separation and annihilation panic, such as enrollment in the nursery school, hospitalization with separation from the mother, the birth of a sibling —all events which may serve in effect as a trigger.

The symbiotic psychotic syndrome is aimed at restoring the symbiotic-parasitic delusion of oneness with the mother and thus serves a function diametrically opposite to that of the autistic mechanism. Clinical symptoms may and often do become manifest between the ages of 2 and 5, with a peak in the fourth year, which is in the phase of psychosexual development designated as phallic. This phase coincides with that developmental level of sociobiological growth which we know as the oedipal constellation. The regression may be insidious, so that the prolonged prepsychotic phase of schizophrenia remains undiagnosed until school age, or it may be acute and fulminant. The clinical picture is dominated by agitated catatoniclike temper tantrums and panic-stricken behavior. These are followed by bizarrely distorted and often feverishly increased reality testing and hallucinatory attempts at restitution. They seem to be attempts to restore and to perpetuate the delusional omnipotence phase of the mother-infant fusion of the first year—a period in which the mother was an ever-ready extension of the self, always at the service and command of "His Majesty the Baby." The stereotyped speech productions show a predominance of hallucinatory soliloquy with the introjected object. The child's actions symbolically dramatize introjective reunion, as we shall illustrate below. Since constant panic is unbearable, the primarily symbiotic syndrome may and often does give way to a regressive yet stabilizing secondary retreat into autism. This is the result of the very break with outside reality and loss of identity which are the cardinal symptoms of psychosis. When we see these children clinically, their originally symbiotic anaclitic behavior has been replaced by secondary autistic features. "The mother in the flesh" and outside reality have by then slipped away. Their objects are introjected.

Only on rare occasions can we observe the slipping away of the object world, the actual process of loss of identity, and the fragmentation of the ego. It was possible to reconstruct some of the processes involved in George's case. (Compare also Kubie's case described in his paper, "Say You're Sorry."[62])

George was 6½ years old when admitted to the Children's Ward with fulminant symptoms of symbiotic psychosis. We will omit details of his early developmental history except for the few most pertinent data. Immediately after George's birth, the father left for the Navy. Mother and infant saw practically nobody but one another. When George was age 2, the father returned, and George's first conspicuously abnormal behavior dated from this time. His father was disinterested and morose. George had had no opportunity to experience and eventually overcome at the appropriate age the normal uneasiness of the infant and toddler about strangers. No wonder, then, that in his third year of life he seemed utterly to misunderstand the affective meaning of social situations, because of projection of his unneutralized aggression. For example, he would cry if greeted by an unfamiliar person with a friendly hello, "as if the word were a serious threat." If friends or relatives patted him on the shoulder or the head, he would become terrified, state that they hit him, and seemed frightened that they would harm him. His speech, which characteristically was not needed during George's prolonged symbiotic relationship with his mother—because symbiotic partners communicate in a preverbal or nonverbal atmosphere—all of a sudden became overcathected. At the age of about 2½ to 3, George's

Downloaded from www.pbraudhanay.org.in

mutism abruptly changed to flighty and panic-stricken language, which his mother described and aptly called "talking tantrums." Whenever frustrated, or even without apparent cause, he would pace around the room, talking angrily to himself about something which seemed entirely irrelevant to his environment. At the end of George's third year of life, the mother became pregnant. George began to have night terrors. When George was past 3, his baby sister was born, and George became acutely disturbed. During the last months of his mother's pregnancy he developed an absorbing, exclusive interest in examining his inanimate environment by touching the objects. He became conspicuous by his strange compulsive interest in barrels, beer barrels in particular (they lived near a brewery). He would stop and touch each barrel and examine it with care. Following this preoccupation with barrels, he became fascinated by pipes of all sorts, which again he would have to stop and touch, commenting on their size, shape, or other characteristics. Since his father was a plumber, he could play with the pipes in his shop for long periods. After a few months he developed a similar preoccupation with electrical appliances. He would endlessly pretend to be plugging a cord into a socket. Later George developed an intense interest in fires, and this was predominant at the time of his hospitalization.

George's case is only one example in which the slipping away of reality is ushered in by the loss of the innate human faculty of discrimination between the animate and the inanimate, the living and the dead. To this primal discrimination Monakow has given the name "protodiakrisis." It seems to depend on and consists of impressions of warmth, resiliency, turgor, deep tactile sensations between two living higher organisms in contact with one another. In his third year George demonstrated his utter confusion of the workings of living bodies and inanimate systems. For example, George was panic-stricken when he had to pass a certain picket fence for fear of the holes in it; and he became frantic and later obsessed with the workings of electrical appliances. The nature of the sexual difference of bodies was confusing to George.

Shortly after the baby sister came, George wanted to wear her clothes, and often also his mother's dresses. He insisted that he wanted to be a girl, preferred female animals, and asked his mother perseveratively why he should not be a girl. When George entered kindergarten, he had no contact with and was terrified by the other children, and could be kept in school at least for a while only because of the great appeal he had for his teacher. He spoke to her of his sister and again and again of his pet kitten: "I have a cat at home. It's a girl cat. I like my cat. I am a girl cat." His behavior in school became so bizarre that the teacher referred him for hospitalization.

After a far too exclusive and morbid symbiotic parasitic two-year period with his mother, George was suddenly faced in a hostile, extended environment with separateness from his mother in the functional-maturational sense, without being emotionally at all prepared to give up the delusion of omnipotent fusion with her. George seemed to have tried frantically to adopt countercathectic devices against fragmentation of his brittle ego. He tried to counteract the threatening loss of the libidinal object world by attempting to recapture it in a concrete sense using the contact-perceptive faculties of his ego. We see this kind of frantic reality testing very frequently in this type of psychotic child. George compulsively and feverishly tried to finger, "to feel" things. He obviously tried to distinguish between—to compare—beer barrels with his pregnant mother's body. Later, after his baby sister's birth, George compared, in this tactile way, concrete symbols of male and female anatomy.

The bisexual problem augmented to a spectacular degree this boy's struggle to regain his symbiotic completeness with the "lost mother." Castration fear and envy of the intimate relationship of the girl baby and the mother seemed to drive George into intense body hallucinations which were characterized by psychotically destructive contents.

The outstanding hallucination during hospitalization was his seeing a fire destroying his little sister. At first George verbalized during these fire hallucinations, and hence we knew how to read his agitated behavior when it betrayed these visions.

It seemed that his hallucinatory and delusional restitution attempts consisted of incorporative and destructive tendencies toward his

Downloaded from www.brainlibrary.ir

sister and mother. In his clearer periods he would state: "I'm afraid of killing my mother. I have ideas of wanting to kill her. Yes, I think of killing her, and these thoughts upset me so. That gives me bad feelings in my head. It makes me so upset when I am home. Doctor, you are supposed to take that out." He showed all kinds of self-mutilating and self-destructive tendencies. At the same time, George's hallucinations served restitution as well, which the following example will illustrate: While sitting next to the nurse whom George loved and also hated most, he appeared to hallucinate the big fire. During the conflagration George unzipped his overalls and began pulling at the nurse's skirt as though gathering up the ashes. He then put his hands in his overalls as if pouring in what he had gathered. This went on for a short time, then he zipped up his overalls and sat there smiling. "I've got a Hollinger (name of the nurse) in there . . . that's what I've got in there."

George was hilariously elated for the rest of the day and sat off in a corner, communicating with the introjected beloved.[61]

By this behavior and the resulting affect, we saw that George introjected the loved object and by so doing succeeded in restoring his former symbiotic unity with the mother.

Patients like George, who began with an insoluble symbiotic problem, thus sever the ties with unbearable reality, submerge into their self-created autistic inner reality, and erect their own object world represented by the introjects. These patients thus secondarily regress into autism to maintain their lives and entity in some dedifferentiated, deanimated form. In other words, continual separation-annihilation panic being unbearable, children who begin with a symbiotic psychosis will use autistic mechanisms as defensive measures. This is a means of warding off the danger of losing whatever minimal individual entity they may have succeeded in attaining, either through development or through treatment. They try to preserve whatever autonomy they may have attained by the mechanism of autism. To repeat, these autistic reactions are secondary attempts to ward off the threatened re-engulfment into a symbiotic relationship since such fusion would destroy the individual entity the child has barely attained.

## *More Benign Child Psychosis*

In 1948 (published in 1949) Mahler, Ross, and DeFries[76] described a third group of "more benign" cases of child psychosis. In these cases there was also a low tolerance to frustration and lack of emotional differentiation. However, owing to better structural development of the ego, these children remained in better contact with reality and functioned more efficiently.

The symptoms in these children develop more insidiously. They employ, besides psychotic projection and introjection, denial and condensation as well as abundant neurotic defense mechanisms. These children may never break down completely, or they may become frankly psychotic during latency and particularly with the upheaval of puberty. This third group of Mahler *et al.* resembles to a great extent some of the cases whom Elisabeth Geleerd described in 1946[40] and, recently, in 1957.[39] In the latter paper she classifies some of her cases between Mahler's third group of benign schizophrenia and A. Weil's[100] cases. The difference between Weil's and Geleerd's cases seems to be that the former's cases did not present frankly psychotic pictures during adolescence, whereas many of the latter's cases did.

We found in these cases, as did Geleerd and Weil, low tolerance to frustration, emotional immaturity, unevenness of development, uncontrollable impulsivity, mood swings, tenuous relationships, and poor judgment, plus all kinds of neurotic traits such as phobias, compulsions, and hysterical and hypochondriacal traits and symptoms. These children are in contact with reality and are not delusional, but at the slightest frustration they are apt to withdraw into their own fantasy world. They coerce their environment, especially their immediate family, and are prone to severe temper tantrums, as described by Elisabeth Geleerd. Some of these pseudoneurotic or borderline cases of benign schizophrenia, according to careful longitudinal studies, especially during long psychoanalytic treatment, may show marked improvement and

Downloaded from www.pdfbooksworld.com

may weather adolescence better than anticipated. Some, however, become frankly psychotic (cf. Geleerd, Hawkins). Many more careful follow-up studies will be necessary to clarify this question.

## Treatment

Treatment of the psychotic child aims at the restoration of, or establishment of (1) greater body-image integrity, which should convey a better sense of entity and identity, (2) with simultaneous development of object relationships, and (3) restoration of missing or distorted maturational and developmental ego-functions. In achieving this the child must progress through the previously missed or unsatisfactory phases of development (presymbiotic, symbiotic, and separation individuation), the therapist serving a substitutive function by providing a more readily utilizable auxiliary ego. It is quite common, for example, for psychotic children to have been toilet trained before they reach the anal phase of psychosexual development. As a result, they not only fail to experience the libidinal gratification associated with the normal erotization of the anal area, but they were deprived of the feeling of control and mastery which accompanies toilet training achieved after the myelinization of the central-nervous-system pathways involved in conscious control (at about 18 months of age). The libidinal gratification has importance not only in balancing and neutralizing the aggressive drives resulting from the inevitable frustrations and overstimulations experienced by any child, but also for a more adequate development of the body-image. The deficiency of the body-image is due to the lack of libidinal cathexis of certain important areas of the body periphery, especially the erotogenic zones.

The therapist then (at the appropriate time) will encourage a "living through" of this phase of development, providing suitable substitutive anal expressive material such as clay and finger paints, and also permitting and even encouraging a *temporary* regression to actual soiling or defecation in the treatment situation, if this be the child's need. In so doing, the therapist usually is placing himself in opposition to the mother. If symbiotic fusion with the mother is still the only way of adaptation the child knows or can accept, the psychotic child, even more than the neurotic child in a similar situation, will perceive the therapist as "the devil's advocate," and panic may ensue. Extreme caution, therefore, is necessary, particularly if the child is being treated as an outpatient while continuing to live with mother.

Barbara, age 6, was diagnosed as suffering from a symbiotic type of childhood psychosis and was treated in a residential institution. Prior to placement she manifested acutely psychotic behavior in which she had no relationship to anyone, she ate ravenously with her fingers in an animal-like way, she stayed up most of the night for several nights wandering aimlessly about the house singing and talking to herself, she repeatedly took off all of her clothes, either attempting to climb into the toilet bowl or running down the street in the nude, entering any door of any house. Barbara's mother had been diagnosed as an ambulatory schizophrenic. The history revealed generally severe emotional deprivation and a particularly harsh and much too early toilet training. As an example of this child's early experience, it was reported that much of her first two years of life was spent in a crib which was completely covered by a blanket except for one small corner through which the child would peer out at her surroundings. In treatment with a woman therapist, Barbara's first activity consisted of soiling herself, defecating in the corner of the playroom, and playing with her feces. This behavior was repeated almost daily over a period of several weeks. The therapist was accepting of this behavior, offering no rebuke or criticism while continuing to reach out emotionally to the child. Finally, having been permitted to have this experience, Barbara stopped the actual defecation and smearing of feces and turned to the use of clay as substitute means of expression. She continued to live through and work through this phase of development for a good many months thereafter. This and similar remedial regressive experiences made Barbara slowly and gradually ready for object-relationship by simultaneously helping her to feel and accept her

Downloaded from www.freepsybooks.com

own body as a separate entity and particularly her femininity, first on the body-image basis and later on the basis of the idea of being a girl.[71]

We found in several instances that recognition, enjoyment, and acceptance of the own stool coincided with giving up the pronominal reversal, as if the recognition of the scybalum which had been within and actively was pressed out, helped to establish body-self-identity. This is "I." I made this, but it is not me. More observation and research, however, are necessary to ascertain this connection.

James was first seen at age 3½. The outstanding presenting symptoms were failure to develop intelligible language, failure of adequate relationship to other people, and a general hypertonicity or muscular tension which caused awkwardness in movement. The history revealed that speech had begun to develop seemingly normally until age 14 months. At that time father went into the service and the family life was disrupted. Mother, who prior to this time had been living with her own mother, was forced to move completely across the country to a strange city. She was very upset by this and frankly stated that her own anxieties and needs claimed all of her attention. Simultaneously with the above, James developed a very severe case of diarrhea which persisted for several months, causing him great bowel distress and considerable pain and irritation of the anal area, and causing mother an even greater amount of anxiety. Also in the history was the fact of a sudden weaning from the bottle at age 9 months. Mother, a generally insecure person, did this upon the advice of a friend. James reacted to the weaning by becoming a thumb sucker, immediately and avidly. Observation of James showed that his tongue in his attempted speech was curled concavely and was in the position of the tongue of a sucking infant. In treatment the therapist provided candy for James to suck on and demonstrated that sucking was all right by sucking candy himself and encouraged thumb sucking. Initially James refused the offer of candy. Again, we see that the maternal tabu was operative in this child, whose ego was so rudimentary and psychotically fragmented. This evidence of conflict (probably with mother) should be a warning to the therapist to use caution in permitting or even encouraging this necessary reliving of missed infantile experiences without adequately preparing the mother and also the child for it.

Seymour, an autistic child, at 5 showed readiness to relive some of the missed or hurriedly passed libidinal experiences. His asking for his fetish pillow was taken as an indication that he would be ready to relive the phase and overcome some of his oral frustration. However, the mother's unconscious fear of regression and the boy's by that time strong symbiotic need for the mother made him completely refuse the bottle of milk which unobtrusively was made available to him. He withdrew from the analyst for a while and became quite suspicious.

Hence in Seymour's case the therapist refrained from introducing milk or other foods which would perhaps cause even more anxiety about loss of fusion with mother. Gradually, as Seymour permitted himself oral gratification, and as he became very active and eager in this process, improvement in speech with clearer enunciation became evident.

In addition to permitting and aiding the living and working through of early developmental phases, the therapist provides particularly those ego-functions lacking in the child which are necessary to the development of a concept of self. The therapist may have to serve as a substitute stimulus barrier, protecting the child from excessive stimulation from the environment. At the same time the therapist draws the child's attention away from the threatening inner stimuli by engaging him in their common pursuits.

Because of such ego deficiencies as faulty reality testing, primary-process type of thinking, and poor orientation as to time, place, and person, the communication of the psychotic child is often so obscure as to be incomprehensible. Accordingly, the therapist must be able to delve into the primary-process type of symbolic behavior of the patient with great empathy and without anxiety (cf. Sechehaye).[88] At the same time he must be able to translate the patient's primary-process material which leads eventually to assimilation, integration, and synthesis. This type of activity on the part of the therapist aids in the gradual establishment of the boundaries between the self and the rest of the world and accordingly allows

Downloaded from www.dbeditchan.org.in

for reality testing in distinguishing between the inner and outer environments. In time, the patient's ego becomes better structured and differentiated, and he can begin to take over these functions for himself.

Another seemingly contradictory task of the therapist is to set limits, particularly to the overwhelming self-destructive and aggressive impulses, to protect both the child and himself from harm and to prevent unnecessary or panic-creating destruction of the physical environment. He must try to establish sufficient contact with the psychotic child so as to convey to him that the therapist cannot let him harm himself and others and that he will protect him against his rage reactions. In general, there needs to be a firm definition of limits and boundaries in both the play situation and the interpersonal relationship. The therapist needs to function in such a way as to reflect adequate responses back to the child's soundings, thus helping the child explore and gain some judgmental ability concerning himself and his environment. It may be necessary to help the child maintain coherence in the play, which is all too inclined to become scattered and meaningless. The therapeutic endeavor ever so often, if not always, is and has to be started through the cognitive function, as emotional adjustment can only be attempted after a measure of control—often purely intellectual or conscious habitual control—has been established.*

The case of Danny, age 4, illustrates the need for this type of substitutive ego-function by the therapist. Danny was brought to the child psychiatry clinic with two major complaints: (1) He was an extremely fearful child, laden with what, at first glance, appeared to be phobias—for example, fear of the dark, fear of wild animals, fear of witches, fear of dogs; and (2) he was a management problem tending to get wild and uncontrollable; various forms of parental threat and physical discipline either had no effect or provided only a temporary control. It was learned that both parents were quite anxious and quite immature people. Mother had had a stillborn child prior to the pregnancy with Danny, and this had greatly increased the already existing feelings of inadequacy and inferiority. When Danny was born, he had a congenital atresia of the bowel which required surgery on the second day of his life, and which resulted in a colostomy. The colostomy was surgically closed at age 4 months. At age 8 months Danny had a surgical repair of bilateral inguinal hernia under general anesthesia. At age 10 months he was again taken to surgery for circumcision. Mother recalled that Danny seemed to suffer a good deal with each of these experiences, and felt that he had a "conscious reaction" to the circumcision and to the separation from mother at age 10 months.

In a play situation Danny characteristically would begin to play in a seemingly reasonable fashion with a fairly good rapport with the therapist. Shortly, however, the therapist could perceive that Danny's fantasies were stimulating him increasingly. He would have the therapist make witches or wolves out of clay and would then use these in fantasies where people were threatened by them. Very soon Danny would be screaming wildly while running about the playroom or running in and out of the playroom and generally throwing play materials about the room. The same sequence would occur if he chose to paint; what would begin as a fairly orderly process of applying paint to paper would end up with an impulsive dumping of the paint jar on the floor. Meanwhile Danny would be alert to every new sound or stimulus in the environment. If a door slammed, a dog barked outside, the steam radiator hissed, Danny would stop his play, listen attentively, and insist that the noise be identified and explained. Whereas with a neurotic child we would try to learn about the fantasies connected with this preoccupation with noises and work on the probability of frightening primal-scene observations to which this frightened fascination perhaps referred, in this case the ego had to be strengthened and controlled regression facilitated rather than undone.

The therapist not only attempted to reduce outside stimuli to a minimum, but he gradually insisted that Danny not divert from his play to identify every extraneous noise. When Danny began to get excited in his fantasy play, the therapist would actively intervene and quietly but firmly stop the play for the time being. At the

* This is in marked contradistinction to the therapeutic process with neurotic patients.

Downloaded from www.vobraindia.org.in

same time the therapist would state in simple terms that Danny, in effect, was scaring himself with these play stories. As the play stories became established in pattern and their meaning could be understood, the therapist verbalized their meaning in terms of Danny's fears of not only what could happen to him but what his anger would do to others. Eventually witches and wolves were translated into Danny's fears about himself and his mother. As these various things were accomplished, Danny began to develop a feeling of control of his fantasies and his impulses. Simultaneously with the work with Danny, mother was treated to relieve her of her guilt about Danny's "defectiveness" at birth and to make her able to be firm with him in setting limits in controlling him.

Because of the primary-process character and therefore incomprehensibility of the psychotic child's behavior and communication which is difficult to understand, it is absolutely essential to have a close and effective informative alliance with the mother, if the child lives at home, or the substitute parent-figures if the child is in an institution. The communication of the psychotic child often can be understood only if the therapist has prior knowledge concerning the events of the child's life which took place in the twenty-four or more hours preceding the therapy session. This is even more important than with a neurotic child, since the cause-and-effect relationship between stimulus and behavior needs to be almost immediate or current in the psychotic child's experience for him to perceive and understand it.

The psychotic child often needs considerable verbal reassurance as to his basic worth and as to his basic integrity as an organism. There usually is much distortion and defect in the body-image concept, this being reflected in the fear of body-disintegration, in castration anxiety, and in panic reactions.

At one stage in treatment Barbara (see p. 830) was working out her concern and her questions about her female self. She began by putting her slacks on backwards, calling attention to the seam which was now over her genital area. Similarly, she approached this subject by putting her jacket on backwards, then viewing herself in the mirror from the rear—the jacket had a seam which normally ran down the middle of the back. Eventually she exposed her genital area and examined it in front of the mirror. As she did so she asked questions of the therapist concerning the difference between boys and girls. It became obvious that Barbara felt her mother had taken her little boy genital away from her. The therapist reassured Barbara with the explanation that little girls were born to be as they were and that there was nothing wrong with her. Eventually this subject led to a full discussion and explanation concerning the female function of bearing children.

At another time Barbara was engaging in play in which she had clearly established a large girl doll as a representation of herself. She had the doll engage in some "naughty" behavior and then proceeded to beat the doll unmercifully. The therapist intervened, preventing Barbara from beating the doll (herself), insisting that we would not allow that her doll-child be beaten. For a while Barbara persisted in her attempts to beat the doll, but when she saw that the therapist would not permit this she gave up and instead became very tender to the doll. The therapist then began to explore with Barbara the meaning of the play. Although it was important to determine the meaning of the play, it was equally important to Barbara's developing identity and self-esteem to prevent the "beating."

With psychotic children it often is necessary for the therapist to serve an educational type of function. Specific examples are to teach the child about relationships in time, about the functioning of the body, and about the realities of various social relationships, when the child is ready for such knowledge. Because of the early and pervasive ego disorganization, most psychotic children fail to acquire these important and basic concepts at the appropriate age. The problem differs from that with neurotic children in that it is not so much a matter of distortion out of a neurotic need as it is distortion out of failure of structuralization.

Danny (see p. 832), when he first came for treatment, had no concept whatsoever of the sequence of the days of the week. Some vague awareness of this time relationship began to

Downloaded from www.pbookshop.com

emerge around the regularity of his visits to the therapist on Monday, Wednesday, and Friday. When Danny showed a desire to anticipate or predict the visits, the therapist attempted to concretize the time concept by representing days of the week by pieces of clay. After doing this the pieces representing Monday, Wednesday, and Friday were arranged in a row separate from the row representing the full seven days. Danny repeated this activity on his own and inside of two weeks he could correctly state the sequence of the days of the week and indicate particular days both past, present, and future.

While engaging in fantasy play Barbara had a herd of cows go out in the pasture and defecate before they ate their feed. When the therapist expressed interest in this she revealed the fantasy that the cows would die if they ate food without first moving their bowels. This fantasy, of course, had much meaning in terms of Barbara's psychopathology. On the other hand, it was felt to be important that Barbara have a clear understanding of what happens to food in the body and of the relationship between ingestion and elimination. Actually, with further exploration of the fantasy and with a realistic explanation of the eating and eliminating functions, Barbara revealed that she had visualized the abdomen as an empty space. This had to do with her concept of the baby in the mother's body, which in turn, led to another fantasy to the effect that she somehow must have harmed her mother in order for her mother to have been so rejecting of her.

Thus far we have been discussing treatment technique as it applies to psychotic children in general. There are specific differences, however, in the treatment approach to the basically autistic psychotic child as compared with that to the symbiotic psychotic child.

It seems apparent that, at the outset, the autistic child is best suited for individual psychotherapy, since he needs the one-to-one relationship to lure him from his withdrawn state. He cannot profit fully from the specialized educational techniques and other environmental supplementation of special residential schools until he has begun to accept the symbiotic type of relationship. On the other hand, the symbiotic psychotic child can profit from the special environment as soon as his panic reaction subsides, since he needs diversified substitute relationships in place of his former parasitic fusion with the mother. The fact that the parents are very much emotionally involved in the child's illness, whether primarily or secondarily, requires extrafamilial environmental supplementation for both types. By this means, adults who are not pathologically emotionally involved with the child can provide properly timed and gradually introduced reality values and opportunities for development of the ego while generally fostering age-adequate individuation.

The autistic child is most intolerant of direct human contact. He indulges in reality testing by smelling and tasting (licking or biting the objects). Hence he must be lured out of his autistic shell with all kinds of devices such as music, rhythmic activities, and gentle pleasurable stimulation to induce him to use, eventually, his higher sense organs.* Such children must be gradually approached with the help of inanimate objects, always keeping in mind that gross bodily contact, even stroking, cuddling—which one might want to use therapeutically in an attempt to reassure a deeply disturbed child—is of no avail and often a deterrent with primarily autistic children. Cases of the autistic type, if forced too rapidly into social contact and into facing the demands of the social environment, may be thrown into as fulminant a psychotic process as we see in some of the symbiotic child-psychosis cases.[67]

Bobby was treated in a residential institution, treatment beginning when he was 6 years of age. The family had known Bobby to be a quiet, reserved child who seemed content to play by himself and who made few demands upon the rest of the family. They did not recognize him as having a problem until he went to school. Here he was found completely unable to learn because he made no attempt to relate to the teacher or to the other children in his class. When studied diagnostically he was found to be quite uncommunicative, but nevertheless there was evidence in his isolated play behavior that he had a good

* When autistic children begin to contact the object and test reality, they first use the primitive sensory modalities of touch, smell, and taste. They may lick or bite the therapist.

Downloaded from www.LearnPsychology.org.in

intelligence potential. He was quite skilled in making complicated objects out of clay. He showed a great interest in the record player and would watch it for hours, seemingly being as fascinated by the mechanical repetitious movement as by its sound. As long as he was left to his own devices he was relatively contented. As soon as demands were made upon him he would become irritable and ultimately would have violent "temper tantrums" in which he would bite himself on the hand, slap himself in the face, and hit his head against the floor or wall. (Cf. Ref. 41.)

In the beginning period of treatment, Bobby was quite happy to go to the playroom and he engaged in activity of a seemingly creative sort in an active and persistent way. He particularly enjoyed making miniature victrolas out of clay, and also building castles out of blocks which he would knock down with great glee. In all of this activity the therapist was ignored or treated as an inanimate part of the environment. There was no attempt at communication of experience. Bobby would use the therapist as an extension of himself, for example, to reach an object which was on a shelf beyond Bobby's reach. Any attempt to establish either verbal or physical contact with Bobby was shrugged off. If the therapist persisted in trying to get Bobby's attention, for example, by turning Bobby's face to the therapist and holding it there, Bobby would appear as if he was annoyed, then would appear as if he would cry, although he never had tears, would become red in the face, seemingly with rage, and finally would scream out and bite himself repeatedly on the back of the hand. The same type of pattern would occur if the therapist frustrated Bobby's omnipotent gestures for help in securing a particular play object.

Very gradually, over a period of many months during which the therapist did not force himself upon Bobby, Bobby began to pay increasing amounts of genuine attention to the therapist. He would be waiting for his appointments and would be upset if they were not kept promptly. He would ask for things verbally and in particular became quite well related during the routine of going to the store for candy. The relationship continued to be quite tenuous, however, and Bobby was always withdrawn and autistic again after interruptions due to illness or vacation.

In the primarily symbiotic type of psychosis it is important to let the child test reality very gradually at his own pace. As he cautiously begins this testing of himself as a separate entity, he constantly needs to feel supported by emotionally "uncontaminated" (Dr. Ernst Kris's expression) auxiliary egos of a team of adults who represent diversified substitutes for the pathological symbiotic fusion. Continual infusions of borrowed ego-strength may have to be given for a long, long time.

Barbara (see p. 830), early in the treatment situation, acted out her symbiotic defense by relating immediately and quite unselectively to almost any adult in her environment, particularly women. Barbara was a quite verbal child and would use her verbal facility to establish and maintain contact for as long a time as was possible. She asked a great many questions and apparently kept some control over her inner impulses and fantasies by actively directing her attention to tangible objects in the environment. Once she realized that she had a steady relationship with the therapist, she would come directly and immediately to the therapist's office when she was brought to the Treatment Building. For a long time she would burst directly into the office, opening the closed door, and was quite unable to understand that she had to wait until her appointment time was due. She would not leave the office except in the company of the therapist, and it was necessary for the therapist to go with her to the car when she was returned to her own building. She would go to the toilet with the bathroom door open, partly because of the lack of awareness of social convention, but primarily in order to avoid having a closed door between her and the substitute symbiotic partner.

It was felt to be definite evidence of progress in her individuation when she could wait for her appointment, or when she could actually make the therapist wait for her. Ultimately, she gave up her unselective clinging attachment to people and began to show a more judicious and normally reticent way of relating. Needless to say, these changes occurred only after a good deal of treatment in which the therapist was functioning much of the time as a synthesizing and integrating agent structuring Barbara's ego-functions and her concept of herself as an individual.

Downloaded from www.psychiatryonline.org

In the secondary autistic type of a primarily symbiotic psychotic child, one needs carefully to evaluate the child's ability to relate, considering each child as an individual case. The initial aproach is much the same as with the primarily autistic child. The fact that the autism is a defense against a previously established symbiotic relationship makes the defense no less intense. Once the symbiotic relationship is re-established, however, progress tends to be comparable to that of the primarily symbiotic psychotic child, and the prognosis, therefore is better than with the primarily autistic child.

A fundamental principle of this mode of treatment is that the therapist works toward becoming a substitute mother figure. He offers himself as a symbiotic partner and allows and aids the child to *relive—re-experience*—in a different way the early phases of psychic life so important to separation-individuation and independent functioning.

It is apparent from this statement that, in contrast to the less severely disturbed child, the psychotic child has been from the beginning of treatment and continues afterward to be more dependent upon his mother. During the treatment there may be times when the child needs to be separated from the mother because institutional care is indicated. Despite this separation, the mother or a substitute for her must be regarded as an essential part of the treatment program at all times. Even though the child may be able to function on a higher level, he will continue to require a certain degree of anaclitic relationship and infusion of ego-strength, perhaps throughout his life. It is vital, consequently, that the actual mother or person who will substitute for her be simultaneously guided as to the special needs of the psychotic child or, if necessary, simultaneously receive treatment. The goal is to re-establish a relationship that offers promise for the child's growth and development.

CHAPTER 42

# JUVENILE DELINQUENCY

Adelaide M. Johnson

Downloaded from www.dbraulibrary.org.in

DELINQUENCY HAS BEEN with us from the time man began trying to civilize himself by establishing certain social codes of behavior. John Locke,[20] the great English educator, three hundred years ago deplored delinquency in the same vein as we do today. Six thousand years ago an Egyptian priest carved on a stone, "Our earth is degenerate. . . . Children no longer obey their parents." What do we mean by the term "delinquency"? We refer to that behavior which is opposed to those tenets held by society and the law in our particular culture. The major offenses are stealing, truancy, fire setting, vandalism, and cruelty of all degrees up to murder. Even though the jurist calls delinquent that behavior which deviates from society's code, today, increasingly, such antisocial children and people are not considered capable of responsibility for such behavior. Just as the individual's responsibility for neurotic or psychotic symptoms has been repudiated by most modern psychiatrists, so has the delinquent's responsibility for his acts been considered. Although the super-ego, the conscience, the moral part of his personality is affected, still, as we proceed with a consideration of the etiologic factors in all forms of delinquency, we shall see that the patient is involved in experiences beyond his capacity to make choices and which obstruct his normal development.

"From many sources comes the cry that the Juvenile Court is coddling young criminals and that children should be punished for their offenses," says Judge Winnet[31] in a recent address to the American Medical Association. The Judge sees no evidence that punishment has ever ameliorated the situation and believes that "punishment does not reach the causes of delinquency . . . public punishment . . . can only increase resentment and rebellion and the sense of being outcast." Similarly, Judge Winnet feels that evidence shows that punishment of the parents has been so impracticable as to be worthless.

In the young child we are prone to speak of his having a behavior problem when he defies law and order. When the child reaches preadolescence and adolescence and opposes society's tenets, we call his misbehavior "delinquency." When authority is circumvented by the older age groups, the term "psychopathic personality" is assigned.

Since the first juvenile court was established in 1899, in Illinois, over 3,000 such courts have emerged. Why has this growth been so

vast? The answer is found in the previous irrationality of following a criminal procedure as applied to children.

That delinquency is increasing steadily seems undeniable, if the observer considers a statewide area and not some special locality. Many authorities think there is a national trend toward increased delinquency above what we might expect from increased population. This is said to be particularly true among girls. In some fairly representative cities authorities state that, considering the increase in population, there has been no increase in delinquency over the past years. In some cities, and especially in suburbs, the figures are rising, but many investigators correlate such a rise with better police work and record keeping. More delinquency or not, no one can doubt that it is on the increase as a practical problem that we encounter, and one that must be met. With the exception of specific circumscribed areas, few contend that delinquency is on the decrease. The juvenile courts fail in approximately 50 per cent of their cases. Such problems lead to certain conclusions: One is that our agencies and resources for helping children are inadequate in number, or that we do not offer the right kind of psychiatric and community service in dealing with the problem. Both factors, of course, may be operating. To offer the appropriate kind of service, we must first arrive at an understanding of causes.

## ¶ Causation of Delinquency and the Differentiation of Groups

In discussing causation of delinquency, there are two common pitfalls. Either a discussant sees causes as too complex and manifold to unravel, and one feels hopelessly discouraged listening to him, or another discussant creates uneasiness by oversimplification of the entire issue. There have emerged, however, some fairly clear concepts of causes related to this challenging problem. The central thesis of causation, as viewed by many students today, leads us to see two large categories of antisocial behavior—the unconsciously driven individual delinquent from the so-called "good or normal" family, and the gang or sociologic group operating at any economic level. It may be well, for the moment, to forget about overlapping of these two large groups. What operates causally in the individual delinquent is, to a large extent, different from what propels the gang or sociologic form of delinquency, and this, in turn, dictates different treatment measures for the two groups. Fifteen years ago—and even widely today—many investigators telescoped all delinquents into one category. This has led to vast confusion in understanding etiology and personality structure and in prescribing treatment. Some years ago many psychiatrists talked as if all delinquents had problems that only the psychiatrist should treat. Sociologists maintained a similar position for themselves as the therapeutic agents. As research progressed, it became clear that certain cases could only be relieved in the psychiatrist's office, while large numbers of other delinquents would be helped only by the sociologic-community approach. Everyone will not agree with the author, but many students of the problem today see the validity of the concept, etiologically, of the two great categories of delinquency.

Let us consider the individual delinquent about whom we know far more today and about whom many are more in agreement as to etiology. Vast areas are still to be explored with regard to personality structure and treatment.

## ¶ The Individual Delinquent

For treatment to be rational, etiology must be explicit. Arrival at our understanding of clinical evidence for etiology has necessitated drastic changes in our previous understanding of traditional psychoanalytic theory. The psychoanalysts' first interest was in the neuroses, and for years, with few exceptions, research was concerned largely with this aspect of psychopathology. In understanding the neuroses, one conceives of a too-punitive super-ego. Until recently, pathology of the super-ego was viewed only in terms of its being too punishing to patients. For many years any antisocial acting

Downloaded from www.dbebib.ir

out was explained in terms of a patient's being excessively guilty about conflicts or being driven by constitutionally unmanageable instinctual drives. Alexander[2] conceived of the need for self-punishment as a motive for acting out. It is granted that the individual delinquent frequently suffers from neurotic guilt, yet the question that Alexander did not answer was why the resolution of guilt was sought specifically in acting out. The reflected preventive attitude for all patients had been, "Do not repress the child so drastically or he will become guilty, neurotic, or act out." Therapists, as well as parents, have become greatly confused, thinking that prohibitions in all forms lead to too much guilt and thus, neurosis. Some therapists unwittingly permitted and fostered acting out in, especially, the sexual sphere. Prohibitions of a culture in themselves do not lead to unhealthy guilt; rather, they are an important aspect of security. As far as the prevention of neurosis is concerned, the prohibition of antisocial activity merely requires the presence of a parent sufficiently well integrated to accept in legitimate ways the hostility expressed by the child over the limit-setting that society demands.

It has become increasingly clear that many parents, particularly those with poorly integrated impulses, have become uneasy about setting limits, even concerning matters which are specifically destructive to society, such as stealing, pathologic sexuality, or even murderous intent. Yet it is evident that certain specific things, such as stealing, fire setting, murder, and sexual destructiveness, cannot be countenanced in our society if the child is to develop comfortably in that society. Freud[8] himself said:

Let us get a clear idea of what the primary business of education is. The child has to learn to control its instincts. To grant it complete freedom, so that it obeys all its impulses without any restriction, is impossible. It would be a very instructive experiment for child-psychologists, but it would make life impossible for the parents and would do serious damage to the children themselves, as would be seen partly at the time, and partly during subsequent years. The function of education, therefore, is to inhibit, forbid and suppress, and it has at all times carried out this function to admiration. But we have learnt from analysis that it is this very suppression of instincts that involves the danger of neurotic illness. You will remember that we have gone into the question of how this comes about in some detail. Education has therefore to steer its way between the Scylla of giving the instincts free play and the Charybdis of frustrating them. Unless the problem is altogether insoluble, an optimum of education must be discovered, which will do the most good and the least harm. It is a matter of finding out how much one may forbid, at which times and by what methods.

As most of us clearly recognize, there is, then, specific behavior, the expression of which should arouse guilt in everyone. The guilt alone is not unhealthy. Neurosis need be feared only if rage has been harshly repressed, along with the prohibition of such antisocial activity.

Concern in more recent works is with the development of that form of pathologic superego which permits antisocial behavior. Clinical evidence[19] shows it to be lacunar, weak in some respects, punitive in some, and normal in still other areas. Many people have strong latent antisocial impulses, yet never act out such fantasies. In recent years students have been concerned with defining the specific stimulus, if any, to the acting-out behavior with lucid definition of possible secondary causes. We wish to consider the problems of the direct acting out of forbidden antisocial impulses: namely, stealing, truancy, fire setting, and direct sexual acting out in the individual delinquent.

## ¶ Historical Contributions and Etiology

The provocative contributions of Reich,[21] Alexander,[2] Alexander and Healy,[3] Healy and Bronner,[18] Schmideberg,[22] and many others have long been known to the student of delinquency. It was Aichhorn[1] whose contributions first unquestionably moved delinquency out of the nihilistic depths of constitutional inheritance, into the realm of dynamic understanding.

August Aichhorn, friend and associate of

Downloaded from www.dbraulibrary.org.in

Freud, published the first real milestone on the road to an understanding of the problem of delinquency. *Wayward Youth*[1] has been a stimulus to students of the problem since the publication of this readable and challenging approach. Actually this was almost the first attempt to study the baffling problem of antisocial behavior in a manner that stimulated a fundamental treatment approach. Although today we see more clearly etiologic specific stimuli, know more of the pathology of the super-ego and ego in these children, still any student must concede that Aichhorn raised this baffling problem from the gates of the reformatory to a level of dynamic understanding and challenge. Not only did Aichhorn open up a new field for psychoanalytic inquiry, but the warmth, optimism, and imagination of this man have for decades stimulated the personal growth of many students in the field. *Searchlights on Delinquency*, edited by K. R. Eissler[6] and published by International Universities Press in 1949, was dedicated to Professor Aichhorn on his seventieth birthday. Any student of delinquency will refer to the brilliant introductory chapter, "General Problems of Delinquency," by Eissler. Although there have been notable advances on many fronts relative to understanding and treatment since the publication of this work, reference to it will suggest a storehouse of provocative concepts as well as known facts. In fact, this work is the only reference to date in which so much can be learned. Aichhorn did not, however, make any differentiation between the individual and sociologic delinquents—a distinction which many students believe is necessary to more basic understanding.

Any student of delinquency will find himself indebted to Healy and Bronner[13] for their fundamental contributions. Although, like Aichhorn[1] and Alexander,[2] they made no distinction etiologically between the individual delinquent and the sociologic form, they contributed much to our understanding of secondary causes in the individual delinquent and much that is primary in sociologic delinquency. These workers noted clearly such gross pathologic distortions as forging in the parent and stealing in the child. They did not note the subtle unconscious etiologic correlations to be described by later research workers. Healy and Bronner attributed to coldness and rejection by the parents the child's inability to develop a normal inhibiting super-ego, so that one child in a family may steal and another will not, depending upon the one being unloved and the other loved. This is a part of the truth. Even granting that unloved children do not develop a healthy super-ego, it does not follow that coldness of parents alone can lead to the super-ego lacunae we observe. Some very cold parents can create such great guilt or need to make restitution to a needed object that a very punitive super-ego is developed in a child. This is one of the settings from which stems the masochistic child.[18] It is equally true that there are also relatively warm parents whose child may act out antisocially—especially in some of the sociologic delinquents.

Schmideberg[22] takes us back to a more nihilistic view in that she suggested that people who act out their conflicts have a greater constitutional inability to tolerate frustration than do the more inhibited persons.

There is frequently confusion regarding the use of the phrase "acting out." The expression "acting in the transference" was first used recurrently by Freud to refer to the phenomenon which was seen during psychoanalytic therapy in which the neurotic patient repeated in the tranference, without insight, certain salient episodes in his earlier life.

Eduardo Weiss[30] aptly described it in the following way:

> By acting-out is meant the behavior of a person who repeats without insight an unconscious psychic situation out of his past in terms of current reality. A man, for instance, repeats intense feelings of hostility towards his brothers and sisters by quarreling with his fellow workers. . . . Freud considered transference as a form of acting-out. According to Freud one acts-out instead of remembering. However, psychoanalytic experience teaches us that patients in analysis often act-out emotional situations which they have already remembered. . . . Freud's formulation can be modified by saying that one acts-out instead of remembering fully with the appropriate attending emotions. . . . While acting-out is a substitute

Psychiatry Online www.brainmind.com

for recall, it does not have the therapeutic effect of the latter. The patient who acts out has still to acknowledge that *his present behavior is a reproduction of past experiences*. . . . I fully agree with Anna Freud who says that the patient who acts-out *exclusively* cannot be analyzed.

In most recent years the phrase "acting out" has come to be used almost exclusively in referring to that behavior against authority which is specifically forbidden by our society. Actually, except for the moral issue, there is no sharp line of demarcation between the acting in the transference and the kind of phenomenon expressed by the unconscious acting-out problems with which we are dealing. This is in keeping with the view commonly held today: that ego and super-ego are not separate entities, but merge imperceptibly on the spectrum of reality testing. At one end are observed highly moral aspects of the ego—that there can be no alternatives to conforming morally. Proceeding to the opposite end of the spectrum, increasingly complicated alternatives and choices become obviously permissible, since ethics is not involved; it is more in this latter area that acting out during analysis occurs.

Since the early work of Johnson and Szurek,[19] collaborative studies by other students on antisocial acting out have continued. From the initial studies emerged the thesis that antisocial acting out in a child is unconsciously fostered and sanctioned by the parents, who vicariously achieve gratification of their own poorly integrated forbidden impulses through a child's acting out. In turn, the child's behavior stimulates the parents to added need for this gratification. One or both parents, in addition, unconsciously experience gratification for their own hostile and destructive wishes toward the child, who is repeatedly destroyed by his behavior. It is possible, in every case adequately studied, to trace the specific conscience defect in the child to a mirror image of similar type and emotional charge in the parent. The focus of these observations has been not on the activities of the kind seen among deprived and other sociologically determined gang groups but rather among individual children of poor or of privileged class, frequently from families of "good" reputation and high social standing.

The super-ego defects in these children are frequently in only one or two areas and are rarely widespread. A child may steal but never be truant. Another may set fires and do nothing else that is antisocial. In another, only the sexual sphere will be implicated through the acting out. To be sure, like other people, these patients have neuroses with conflict and guilt, but they have also the super-ego weakness in one or more areas, permitting discharge of tension.

As early as 1942 Szurek[24] described the psychopathic personality as being only a delinquent grown older, as an individual defective in personality organization, specifically in the individual's conscience. Szurek distinguished those individuals from the sociologically stimulated gang lawbreakers, and presented one of the earliest contributions to the dynamic understanding of these problems. He wrote:

> Clinical experience leaves the impression that the definition of psychopathic personality is no greater mystery than other syndromes in psychopathology. Almost literally, in no instance in which adequate psychiatric therapeutic study of both parent and child has been possible has it been difficult to obtain sufficient evidence to reconstruct the chief dynamics of the situation. Regularly, the more important parent, usually the mother, although the father is always in some way involved, has been seen unconsciously to encourage the amoral or anti-social behavior of the child.

As time has elapsed, we have observed that fathers are probably as frequently implicated as mothers.

## Conscience

It is impossible to understand the dynamic concepts behind the behavior of these individuals unless one has clearly in mind the development of the normal super-ego. One must understand the reaction of the well-integrated parent, and the subtle conscious and unconscious ways in which this behavior directs the development of the child's super-ego. Identification with the parent consists of more than

Downloaded from www.dbraulibrary.org.in

incorporation of the *manifest* behavior of the parent; it necessarily involves inclusion of the subtleties of the parent's conscious and unconscious image of the child. The healthy parent fantasies his child as capable of becoming law abiding. The well-integrated, mature mother does *not* immediately check on a child following an order or request; she unconsciously assumes that the order will be carried out. The neurotic mother, who immediately checks or warns that if the job is not done dire consequences will follow, merely conveys to the child that an unstated alternative exists in the mother's mind. It is frequently with this alternative image in the mother's thoughts that the child more strongly identifies. This is true because the child senses the peculiar parental emotional need conveyed in the anxious, vacillating tone of the parent's expression.

The child internalizes, then, not only the positive, socially consistent attitudes of the parent but also the frequently unexpressed, ambivalent, antisocial feelings. We cannot agree with those who state that the child identifies only with idealized aspects of the parent. The child identifies with all facets of the parent, repressing those parental characteristics which cause conscious confusion, anxiety, and shame.

## Individual Delinquency

### *An Etiologic Theory of Unconscious Individual Delinquency*

The patients with whom we are specifically concerned in this section are those manifesting what are frequently called "super-ego lacunae." The apparent "punched-out" aspect of this kind of super-ego is misleading except from the point of view of society.[10, 13] From the point of view of the patient, there is a positive, undeniable drive toward acting in the manner in which the parent unconsciously wishes, even though it is antisocial in direction. The conception of a deficit within the super-ego structure must be elaborated to include the overwhelming parentally determined dynamic push toward antisocial behavior which the child senses, and with which he necessarily complies. Although we are not here concerned with sociologically delinquent gang members, there is frequently overlapping of the individuals who act out antisocially, these latter often moving into gangs.

If the thesis is correct that parents unconsciously initiate and foster antisocial behavior in order to experience gratification for themselves, accurate documentary evidence must be defined in answer to two basic questions: (1) How is sanctioning communicated to the child? and (2) Why is one child implicated in a family in which all of the other children are quite conforming?

Not only is it possible by careful questioning and observation to define the process by which a specific child is chosen and the dynamic factors behind the choice of a particular form of socially disapproved behavior, but it is also possible to detect the highly personal technique by which the parent transmits the double talk, interest, permissive tone, or structured situation by which the activity is fostered.

During the process of definitive treatment, it is clearly seen why one child becomes emotionally chosen to be the outlet of expression for those forbidden impulses. An adopted child, whose behavior can be blamed on heredity, becomes a natural victim through whom to express antisocial trends, with simultaneous expression of hostile feelings in the parent toward this child. Sometimes the only son of a woman who is disturbed by unresolved, hostile, dependent problems with her own father, and permitted by her own mother to carry on petty stealing, may become the means of expressing both her unconscious anger and her poorly integrated stealing impulses through her fostering such socially destructive activities in her child. Ruth Eissler[6] has lucidly written of the scapegoat child in *Searchlights on Delinquency*.

Proper understanding of case material is impossible unless one is aware of the many innuendoes of communication which occur without conscious awareness between parents and child. Such communications take place by all conceivable means of approach—sometimes errors of omission, frequently ones of frank commission. Knowing *what* to listen for, and how, the diagnostician, listening to the spontaneous communications of the parents, de-

Downloaded from www.freebooks.org.in

fines these operations from direct quotations, double talk, facial expressions, and often through histrionic portrayal by some parents who dramatize the actual interchange between themselves and the child. In the more subtle cases the casuistic, disingenuous rationalizations of these parents can reduce the whole spirit of an ethical principle to a quibbling absurdity.

The specific manner in which, for instance, the truancy from home was handled on a particular day must be obtained; frequently, when this is done, one finds that the mother met the girl with the comment, "If you don't like us and our house, find another; we can get along without you."

The entranced parental facial expression apparent to the child describing a stealing episode, a sexual misdemeanor, or a hostile attitude toward a teacher conveys to the child that the parent is achieving some pleasurable gratification. No amount of subsequent punishment will act as a deterrent against the recurrences of the acting out. A child wishes to do the thing which he senses gives the parent pleasure, even though he may be punished. We frequently see parents who describe the child's delinquent behavior with obvious pleasure. Plainly, the child's antisocial behavior is stimulating that parent. Suspicious questioning often conveys the parents' unconscious wish that the child comply by doing the thing *verbally* warned against.

Frequently, parents verbalize evasions and deceptions such as, "Here is an extra quarter, but don't tell your father"; "You can get into the movie for half price, since you certainly don't look twelve years old"; "Fires are dangerous, but if you must get it out of your system, then we'll set some in the sink."

A mother can make such a suggestion, yet she would never recommend that her child take a trial run in front of cars on the street. The mother of a fourteen-year-old girl was not genuinely interested in prohibiting her child's stealing; she said to her daughter, "Why did you take the money from your *aunt's* purse instead of from mine?"

Children hear their parents gloating about shortchanging the grocer; naturally, they sense the parental pleasure. We cannot cheat a child or anyone else and expect the child to overlook it. Some parents do not follow through when the facts of stealing are perfectly clear. For instance, they hesitate to go with the child to the dime store to make proper restitution for a stolen trinket.

Paralyzed consternation may overtake a parent whose seven-year-old has just taken a dollar from the dresser or displayed a trinket pilfered from the dime store. Why this anxiety, confusion, or even undue hostility? Why not manage the matter firmly and directly? There is a reason. An impulse in the parent, alternative to complete honesty, compels vacillation and hedging rather than the establishment of a clear limit. That impulse may explode into a rage, with threats of the reformatory. Such a parental reaction suggests to the child that his impulses to steal really may get out of hand. In his unsophistication and dependency, he is inclined to accept the painting of Dorian Gray as a true image of himself.

The mature, normal parent neither anticipates impending disaster nor dismisses monetary transgression as trivial. Instead, the problem is resolved promptly without anxiety or guilt. The mother says, "Susie, you took the dollar from the dresser; please get it for me at once. No one may take another's money without asking permission." She insists that the money be returned promptly. Of the dime store trinket, she tells Johnnie firmly and without anxiety that it is wrong to take things without paying for them. She accompanies Johnnie to the dime store to return or pay for the article. Storekeepers are accustomed to parents coming on such errands and usually accept the proper restitution. Such a parent is neither the nagging, checking detective nor the permissive, lax condoner. She does not dismiss recurrent minor thefts with the rationalization "Oh, he will outgrow it," only to bring the child for treatment when the school complains of theft.

Many parents, whose own poorly integrated prohibitions permit them to overlook recurrent slight offenses, suddenly react with guilt and

Downloaded from www.dbraulibrary.org.in

alarm at the first suggestion of criticism from outside the home. They respond with righteous accusations and punishment. The child is confused and angry at what now appears to be parental betrayal. If the child is not too ashamed or frightened, he may give voice to his recollections of similar parental deceptions, initiating a vicious cycle of hostile blackmail and mutual corruption. A mother who has poorly integrated prohibitions concerning her own hostile sexual impulses may fantasy that her eight-year-old daughter will "get into sexual difficulties" as adolescence approaches. With her provocative warning accompanied by anxiety, she is a predictable stimulus to vacillating sexual behavior in such a child.

Truancy concerns everyone. How does truancy originate? Parental coldness and rejection are insufficient causes, contrary to some authors; these are nonspecific stimuli. The child of six, sensing coldness and rejection, may say angrily: "You don't love me—nobody loves me—I hate you all." Then, and not infrequently, the specific stimulus may be applied by the parent: "Very well! Why don't you just pack your bag and go live some place else if you think we are so awful?" We have observed some parents who even went so far as to pack the child's suitcase—a terrifying experience for the child. The suggestion to run away comes more frequently from inside the home than outside, for rarely do small children tell their friends that their parents are "mean," or get suggestions from other children to leave home.

How an adult can initiate running away is found in the illuminating account of Aichhorn[1] who deliberately resorted to such provocation as a technique of treatment. In managing the transference, he purposely used a simple suggestive device to provoke a boy to run away from the institution. His aim was to establish a positive contact with the adolescent, in which he had been unsuccessful. This very narcissistic boy, with no positive feeling for Aichhorn, constantly complained about the institution. Aichhorn made subtle suggestions about the attractiveness of the outside world, and an hour later the boy ran away, as Aichhorn had anticipated. In keeping with the therapist's predictions, some days later the boy returned, having found the outside world uninviting. He entered at once into a positive relationship with Aichhorn.

We frequently have patients whose parents tell the child to ask the physician for permission to do something they already well understand to be forbidden. Parents complain of *children's* breaking family rules when the parents themselves, consciously or unconsciously, break rule after rule and promise after promise without apology or comment.

The process of vicarious gratification now becomes clearer. The antisocial behavior of the implicated child becomes a means of parental expression by which poorly integrated antisocial impulses of the parent are expressed through the child. As Emch[7] lucidly stated it, the child is "acting out the caricatured reproduction of past parental behavior." In addition to this use as a mode of expression for parental impulses, such a child is the recipient of a hostile destructive drive in the parent; in close relationship lie vicarious gratification through the child and the wish to destroy this same child. Such family behavior, in the end, is destructive to both the child's ego organization and that of the parent, who is constantly being stimulated by the acting-out child. It is a mutually adaptive transaction.

In so complex a setting as family life, a multiplicity of variables operates, so that no single secondary cause for delinquent behavior can be isolated. As already mentioned, it is the contention of Johnson and Szurek[19] that unwitting permissive sanctioning by parents is a major and specific cause for children to live out antisocial impulses. Scientific proof of causation is not satisfied by demonstration of the invariable presence of the suspected cause (parental sanction) whenever the effect (antisocial behavior of children) is observed. It must be demonstrated also that the suspected cause does not occur unless the effect is also seen. This has been the experience of many students today. Johnson and Szurek[19] have never observed these parental permissions without antisocial behavior in at least one child

Downloaded from www.ebrary.org

who had been chosen as a scapegoat. The thesis is not merely reasoning based on *post hoc, ergo propter hoc*; the enmeshing interplay of parent and child in the affected area bespeaks more than a fortuitous time sequence.

## *Phenomenology and Treatment of the Individual Delinquent*

Many authors feel that they were never able to grasp etiologic factors in individual delinquency until they had treated and thereby studied the parents as carefully as the child. Similar collaborative treatment makes it more readily possible to understand what is going on phenomenologically. Because of research in the last fifteen years, much is known of the normal development of, as well as the pathology of, the super-ego in children.

One of the most lucid accounts of the normal child's moral development is that of M. Woolf.[32] Carefully developed are such matters as truth and lying, the sense of property, and sexuality in the young child in a normal family. However, there is a remarkable lack, so far, of research concerning the ego distortions in these children other than those facts well known to cause neurotic distortions. What is less frequently described are the ego distortions and adaptations closely related to the specific super-ego pathology and the hostility of the parents. Almost nowhere in the literature is there a *detailed* account of the psychoanalysis and treatment of an individual delinquent. The author has heard two recent papers of this nature, but they have not yet been published. Szurek[25] and Johnson[17] have published very briefly how some of these cases resolved their problems in treatment, but most of these were rather simple cases and not published in sufficient detail.

Confusion arises immediately when studying ego distortions in delinquents, for in early papers no distinction was made between the individual delinquent and the sociologic delinquent. Be that as it may, a few concepts seem current since the work of Aichhorn.[1] He always maintained that the first step in understanding and treatment of delinquent personalities was the establishment of an object-relationship, and he drew attention to the difficulty of doing so because of the delinquent's inherent inability to form relationships that can endure frustrations. Van Ophuijzen,[29] Friedlander,[9] and Szurek[25] held the view that in cases of antisocial behavior the treatment plan consisted in the establishment of a relationship with a child. Some workers speak of a process of re-educating the child by means of an emotional relationship to an adult who represents a parent substitute. All agree that treatment is more effective before or at the beginning of the latency period, regardless of whether treatment involves parents or child or both, or whether it is done with the child in residency outside of the home.

Pertinent questions arise relative to the above statements. Many of the delinquent children, individual or sociologic, can and have formed strong object-relationships. This too often, however, involves relationships with an object whose super-ego ideals consciously or unconsciously differ from those of society at large. The author cannot emphasize too strongly that great confusion exists from the telescoping of all delinquents together in one category. If we are dealing with the individual delinquent unconsciously sanctioned by permissive destructive parents, the phenomenology is special for that disorder, and treatment must be psychiatric and quite different from that child who is a sociologic delinquent.

Kate Friedlander[9] says, "We are familiar with the picture of the anti-social child during late latency period and puberty, with his narcissistic self-evaluation, his impulsiveness and his inability to establish object relationships which endure frustrations." This description cannot be accepted as evaluating vast numbers of delinquents. Many of them have established strong object-relationships with parents and other adults, but these are relationships which do not conform with society's codes. Many delinquents can endure frustrations having to do with those prohibitions long consistently demanded by the family, but they cannot endure frustration associated with what has been permitted by the family. We know count-

Downloaded from www.pdfmay.org

less individual delinquents who do not have the narcissistic self-evaluation observable in others. We must be discriminating in describing the character structure of delinquents as a total group. In each individual case a careful evaluation must be made of the healthy personality structure, conflicts, and defenses. Sometimes limit-setting has been excellent and effective in many areas but defective in another. To be sure, in certain cases, vast areas of limit-setting have been overlooked, and then we see the generally impulse-ridden child.

Much research is being done on the so-called predelinquent personality. There seems little doubt that, with careful study of the family, such forerunners in behavior should be detectable early, particularly in the individual delinquent. In sociologic or gang delinquency, the manifestations of impending difficulty may appear at a later age in the child. The soil for such sociologic outburst, however, is often well known in certain city areas. The child, neglected, mistreated, or subjected to overt misbehavior on the part of parents, may well move into a subculture group to resolve his insecurity, degraded self-esteem, and anger.

Once the diagnosis of individual unconsciously sanctioned delinquency has been clearly made, in *general*, treatment needs are now rather well known. If the child remains in the home, not only the child but the significant parent or parents must be treated by the psychiatrist as much or even more intensively than the child. Residency treatment for the child with little or no work done with the parents demands a long therapy if, when the child returns home, his treatment is to remain a stable integration. The availability of residency treatment of a dynamic nature is sadly lacking in America as well as elsewhere in the world. Depending upon the age of the child and the severity of the pathology at home, such residency therapy can be expected to run into years. Many times, parents are so disturbed and so destructive toward the child that they resist help for themselves in the dilemma. It has been the experience of the author and many others that treatment of the child in the home, without the parents in therapy, usually leads to greater acting out in the child. It appears that, with the child only in treatment, the unconsciously sanctioning parent feels he can shift the responsibility for the outcome onto the psychiatrist and is unconsciously motivated to act out his poorly integrated impulses even more so through the child. Ruth Eissler[6] has written brilliantly of the threatening of a family equilibrium by any therapeutic success with the acting-out member. This, therefore, necessitates concurrent help for parents.

Almost no intensive residency therapeutic cases of individual delinquency have been published. Rudolf Ekstein, then at the Menninger Clinic, gave, at a national meeting, a detailed partial treatment of such an adolescent boy, and it is to be hoped that this document will be published in great detail. In his paper on character synthesis in adolescents in general, Gitelson[11] deals with many valuable ideas on the therapeutic task and technique in treating the delinquent.

Many therapists have found that analysis of unconscious neurotic conflicts before the fairly good establishment of a solid super-ego led to disaster. As long as the child has no guilt about acting out in some area, such as stealing, anxiety aroused by uncovering an unconscious guilt about sibling rivalry, for instance, only leads to further acting out.

There are many valuable pointers on treatment of the individual delinquents by several authors in *Searchlights on Delinquency* that should be carefully scrutinized by all therapists in the field.

Hacker and Geleerd,[12] treating aggressive acting-out delinquents in a residency setting, found that there was a need for definite limit-setting in successful treatment. They showed that, lacking internalized controls, the children became victims of unbuffered drives: "His demand for freedom thus becomes a denial of vulnerability which he feels consciously or unconsciously."

Treatment of parents and child outside the residency setting, to be most effective, must be of a collaborative nature. Intensive analysis and close collaboration of all parties concerned

Downloaded from www.psychiatryonline.com

must be conducted in order for all participants to gain insight into the unconscious pathology and its genesis. This kind of therapy was the means through which Johnson and Szurek[19] arrived at their understanding of the genesis of unconscious, individual, antisocial acting out. In conjunction with an understanding of the genesis of the problems went, hand in hand, the necessary therapeutic changes. Parents are appalled as they gradually become aware that they are instruments in their child's misbehavior, and the greatest sensitivity and wisdom are necessary to help them analyze their role and conflicts. The author has treated many parents of very young delinquents (stealers, truants, fire setters, misbehavior in school) where the child was not treated at all. In such young cases it is often amazing to see the change in the child as the parents work through, in the transference, the problems associated with their poorly integrated impulses. Again we see parents whose destructiveness toward the child is so grave that it is easily apparent, from dreams and fantasies, that they can never be satisfied until the child arrives in reform school or prison.

There is not space in this chapter to discuss the multiple factors inherent in refined collaborative therapy. Szurek, Johnson and Falstein,[26] Johnson,[16] and others have written extensively of this elsewhere. Certainly, to see an adolescent five times a week and parents only once a week, the latter only in a supportive therapy, will never be effective. An analytic uncovering therapy for all concerned is mandatory. The parents who have poorly integrated antisocial impulses arrived at this level of operation with their child because of similar difficulties with their parents, albeit less blatant oftentimes. Necessarily then, their super-ego code and ego distortions must be meticulously analyzed in the transference. The author, with Szurek and other associates, has conducted such collaborative treatment over long years and knows that it is effective. Let us consider, however, the vast numbers of individual delinquents and the paucity of well-trained dynamic therapists. The only answer seems to rest with the earliest detection of difficulty, and we shall owe our gratitude to those research workers now engaged in such studies.

## ¶ Sociologic Delinquency

What differentiates the individual delinquency just discussed from that great mass of sociologic or gang delinquency? In the individual delinquency from "acceptable" families, we emphasized that there developed a conscience defect *unconsciously* fostered by the parents. This fostering is the specific stimulus, with a great variety of secondary stimuli. So far, there has been no evidence of such a one-to-one specificity of stimulus in the gang or sociologic delinquency. It is the author's impression that arrival at telling etiologic factors in sociologic delinquency is a much more complex and difficult problem than has been true with the unconsciously fostered individual delinquency. Time and great open-minded collaboration between all research groups will be necessary to solve this formidably baffling problem. Fortunately, men and women with such characteristics have been working for years toward a greater lucidity of understanding. This author, having studied the individual delinquent with collaborators for twenty years, feels on fairly familiar ground there. It is difficult, however, for me to do full justice with clarity to the problem of sociologic delinquency.

### *Etiology of Sociologic Delinquency*

Much has been written by way of explaining sociologic delinquents. It is safer at this time to suggest that only partial answers have been given, as most workers themselves would agree. A survey of some of the major views held to explain subculture sociologic or gang delinquency are the following: Some have asserted that the disorder is "traditional" and handed down from generation to generation. There is a hard core of truth in this, but additional factors seem to be involved, as will be reviewed. The so-called "social disorganization theories" maintain that sociologic delinquency flourishes in "interstitial areas" of

Downloaded from www.dbraibrary.org.in

our great cities, where not only is the area economically depressed but the population is mobile and never achieves a solidarity of community spirit or social organization. Observers with differing data in such areas maintain, however, that the social organization of the area as a whole may not be chaotic and without cohesiveness. As Cohen[4] says, "the social organization of the slum may lack the spirit and the objectives of organization in the 'better' neighborhoods, but the slum is not necessarily a jungle. . . . The qualities and defects of organization are not to be confused with the absence of organization."

The so-called theory of "cultural origin," which has enjoyed considerable vogue, is supported by a great deal of challenging data. A classic statement of the cultural-transmission theory of sociologic juvenile delinquency is that of Shaw and McKay.[23] Certain well-known delinquency areas in Chicago were described, with the persistence of the delinquency attributed to the persistence of a delinquent tradition. The principal conclusion of a monumental storehouse of research by Shaw, McKay, and their associates was that sociologic delinquency was a subcultural tradition in the areas of the city inhabited by the lower socioeconomic classes. Such delinquent groups were not correlated with any national group. Thus, regardless of whether Poles, Norwegians, or Italians had taken over the area, the rate of delinquency would continue. At no time did Shaw and McKay maintain, however, that economic factors were the whole answer to the problem. Hewitt and Jenkins'[14] studies found, like Shaw and McKay, that sociologic delinquents were likely to come from lower-standard homes. Many statistical studies tend to confirm the popular impression that gang delinquency is primarily a working-class phenomenon. This is not to say that gang delinquency does not arise in upper-class areas. It is, however, far less common, and, where it exists, as yet has not been subjected to careful study. Tannenbaum[27] and Ruth Topping[28] have also been serious exponents of the cultural-transmission theory.

Any areas of high mobility and conglomerate composition lack a unity of culture, or certainly one consistent with the codes of those representatives of the larger society. Some authors maintain that the adult world presents no clear-cut authoritative models to the child, and he is confused and lacking in respect for any code. Others maintain there is in his group a subcultural unity with codes, but that it is incongruent with the larger society. It is "their" world against our world. Their subculture avows it is all right to steal or betray the other world. In war our culture says it is acceptable to fight and kill the enemy. The gangs and subcultural groups from which they stem may have little guilt about stealing or manhandling those outside their culture.

Hirschberg,[15] speaking from much the same point of view, has said:

> In certain city areas, "the blighted areas," delinquent groups are a significant part of the social organization. Many of the people who live in these areas, regardless of their personal morality, have a strong subgroup sense of rejection by the larger and wealthier society on whose outskirts they live. Tremendous feelings of frustration and resentment ensue, and group attitudes condoning hostility, rebellion and destructiveness come into being. As a result, a mother and father in such a society may raise their child with the conventional emphasis on honesty, respect for property, etc., while they simultaneously express their bitterness, criticism and hatred of the larger society with which they struggle. As an individual the child *may* have no serious internal emotional problems. Again he may be deeply disturbed by personality conflicts. He then becomes a member of a subculture and freely joins with others into an aggressive group with whom he can identify and which is capable of anti-social activity. Nor is this problem confined exclusively to the poor. Many people who have struggled hard for years to accumulate a large fortune have powerful wishes for a hedonic way of life which they verbalize to the child but do not act out themselves, but which their children proceed to realize. Wanton indulgence of sexual impulses, of desires for "high living," or of "madcap" activity, may all be acceptable values in the parental culture, although as individuals these same parents may at times be reasonably conventional people. Their group anti-social ideal, however, achieves concrete form in

Downloaded from www.cbhlibrary.com

the behavior of their children when the latter come together and form a clique, a set, a club, or whatever. Fundamentally the subgroup phenomenon is the same and the outcome in either case, rich society or poor, is a delinquent group. From the point of view of our society, however, the major problems arise with the groups and gangs that come from the more marginal economic societies.

What makes the sociologic delinquent group is that it is largely moulded by community and home forces more or less *consciously* in opposition to the whole other social world. For example, a youngster growing up in a gypsy society might have certain values and standards about stealing which would be very different from those of the villagers among whom he wanders. He would have incorporated a conscience which was "defective" in at least one area, in that it held stealing to be an acceptable way of obtaining money. This would be both his family's teaching and the way of the group. Once having incorporated the values and images of his parents and his culture, this gypsy youngster would then not only be able to steal without conflict, but would steal as an activity of his sociological group. There would be no *conscious* pressure brought to bear on him when he stole. Nor would he have guilt about what he did. Stealing would be an easy and natural act. On the other hand he might have a great deal of fear of reprisal and he might experience much reality-based anxiety in connection with his act. But it is important to realize that the conflict he experienced would be a conflict between himself and external reality, not between him and his own conscience.

Albert Cohen[4] says of the culturist view that the delinquent is said to develop

> . . . no respect for the legal order because it represents a culture which finds no support in his social world. He becomes delinquent. . . . From the recognition that there exists a certain measure of cultural diversity it is a large step to the conclusion that the boy is confronted by such a hodge-podge of definitions that he can form no clear conception of what is "right" and "wrong." It is true that some ethnic groups look more tolerantly on certain kinds of delinquency than others do; that some even encourage certain minor forms of delinquency such as picking up coal off railroad tracks; that respect for the courts and the police is less well established among some groups and that other cultural differences exist. Nonetheless, it is questionable that there is any ethnic or racial group which positively encourages or even condones stealing, vandalism, habitual truancy and the general negativism which characterizes the delinquent subculture. The existence of culture conflict must not be allowed to obscure the important measure of consensus which exists on the essential "wrongness" of these activities, except under special circumstances which are considered mitigating by this or that ethnic subculture. Furthermore, if we should grant that conflicting definitions leave important sectors of conduct morally undefined for the boy in that delinquency area, we must still explain why he fills the gap in the particular way he does. Like the social disorganization theory, the culture conflict theory is at best incomplete. The delinquent subculture is not a fund of blind, amoral "natural" impulses which inevitably well up in the absence of a code of socially acquired inhibitions. It is itself a positive code with a definite if unconventional moral flavor, and it demands a positive explanation in its own right.

Cohen[4] attempts a new view of accounting for the delinquent subculture—why it is there in the first place, why it is located where it is, and why it has a peculiar content. In his theory of any subculture's genesis he maintains that people with similar problems tend to draw together in a community. Depending upon the problems, collective solutions are elaborated with mutual support and identification. He believes that being reared in social worlds quite different from the middle-class standards of schools which he must attend leads to status frustration and loss of self-esteem in the child. Sharing such conflicts, children tend to draw together in little groups or gangs. Depending upon their private needs and tailored accordingly, the delinquent subculture represents a rewarding of any who attack or assault the middle-class status system. In other words, the delinquent subculture is thus seen to be the logical response to the frustration inherent between their early rearing and the middle-class standards they encounter in school and elsewhere.

Downloaded from www.brainmaster.com

Many students accept such views only in part. For instance, in severely delinquent areas, we find many children who are well-behaved and stable citizens even though poor economically, because they are being reared in families where the parents are truly normal, setting limits effectively, guiding their children consistently and affectionately. A famous educator in this country told the author that he was reared in a highly delinquent slum area. Six of his early friends had already been sent to the gas chamber. The educator, however, had been reared by economically poor but affectionate, consistent parents who emphatically set limits about all behavior that tended to get out of line. Cohen himself says that the explanation he has offered assumed that the delinquent subculture stems from conditions of the working class. He suggests that, could such delinquency flourish independently of those conditions as found in the middle class, "it would strongly suggest that those conditions are not necessary even in the working class. It would suggest we may have overlooked some other constellation of circumstances." As with the works of Shaw and McKay, there is not the space here to do justice to the distinguished contribution that Cohen has made to the study of sociologic delinquency. Their theoretical formulations and data should be considered carefully by any student open to challenging inquiry and suggestion.

Many students feel that in sociologic delinquency a multiplicity of variables enter the picture, with no single one asserting itself as the specific stimulus. In sociologic delinquency, not only do clashes of class and poverty enter in, but there are child neglect, lack of consistent supervision, adult antisocial example, and all degrees of cruelty and rejection; they all create their own personality problems, the solution of which may be sought in identification with common problems of the gang. Fortunately, no one seriously concerned with such delinquency is satisfied with any answer, and excellent research continues on many fronts.

As has been said, many psychiatrists and sociologists have long confused the issues of etiology and treatment of delinquents by condensing them all into one group. The unconsciously fostered individual delinquent scapegoat child is seen by many students as being different etiologically and often phenomenologically from the sociologic subculture gang delinquent. There are students, however, who today do not agree on such a distinction, so further research, education, and clarification seem necessary. Long ago, Shaw and McKay,[23] in Chicago, recognized that the gang delinquents, in large part, could not be helped in the psychiatrist's office. Albert Cohen was careful to make the distinction as suggested above. He said, "Although the 'delinquent subculture' is not a category of delinquency statistics, there are a number of studies which distinguish group or gang delinquency from other delinquency." Cohen goes on, "These studies furnish us with an important kind of evidence about the distribution of the delinquent subculture, for it is a hallmark of subcultural delinquency that it is acquired and practiced in groups rather than independently contrived by the individual as a solution to his private problems." It is this latter group who can only be treated by the psychiatrist.

Because of the confusing condensing of all delinquencies as if belonging to the same category, there are no reliable statistics of the ratio of the individual unconsciously sanctioned delinquent to the sociologic group. Except for a particularly blatant or vicious individual delinquent case, we more frequently read in the press of the sociologic delinquents. Because of this confusion also, it is impossible to talk of the ratio of girls to boys in either group. Taken as a whole, however, practically all published figures from many sources conclude that male delinquency is at least four times as common as female delinquency. Authorities seem fairly well agreed that female delinquency is more likely to be sex delinquency than other forms. Although girls at times may be involved, as Cohen says, "'stealing,' 'other property offenses,' 'orneriness' and 'hell-raising' in general are primarily practices of the male." As one observes in a large diagnostic clinic, probably in individual unconscious delinquency, girls steal almost as much as boys. This is certainly not true of the sociologic group.

Downloaded from www.dbeulibrary.org.in

We come now to the overlapping of the two large groups of delinquency. Oftentimes, the lone individual scapegoat delinquent of the first group, with his deeply personal conflicts, gravitates to a gang in the sociologic areas. When such an individual, internally driven by antisocial impulses and the hostility of the parents, enters such a gang, he is often far more of a problem than are the others. He may be driven unconsciously to steal, destroy, or kill in a manner far more vicious than do other members of the gang that emerged in a culturally antisocial area. This is because of the generated hostility in the unconsciously aroused delinquent.

### *Treatment of Sociologic Delinquency*

To set about a rational treatment, certainly first we must settle whether we are dealing with individual delinquency, initiated as previously described, or sociologic delinquency. The individual delinquent and his parents, as discussed above, are problems for the psychiatrist. Treatment of sociologic delinquents demands a broader and frequently entirely different approach. To be sure, such children, in part, may have internal conflicts demanding psychiatric treatment, but the acting out, often in large measure, is the product of the subculture into which they have drifted and often of living with direct adult examples or lack of any guiding supervision.

In the years of the late thirties and forties at the Institute for Juvenile Research in Chicago, recurrently, social agencies and the courts referred children to us psychiatrists for treatment—children who were not the personally involved individual delinquent but rather the sociologic delinquent. These were not cases appropriate for psychiatric treatment. The sociologist, with his appreciation of group mores, of presence or lack of community leadership, of traditions of delinquency in an area, of economic imbalances and pressures, of community resources that lead to cohesiveness or its lack, is fitted for leadership in directing a therapeutic attack. Long ago, in Chicago, Shaw and McKay[23] and others gave impetus and direction to the multiple community approach that seemed pertinent to a basic modification of the pressures in a delinquent area. Not alone was economic improvement significant, but leadership that would bridge the chasm between the ego-ideal of the delinquent area and that of larger society was necessary. Individual leaders, religious resources, recreational opportunities, police and court cooperation, social agencies—all must contribute to a broad-base community therapeutic attack. All sociologists and psychiatrists interested in this problem should study the truly pioneering work of Shaw and his colleagues. This work not only portrays their data and theories of the inception of "area" delinquency, but it includes the therapeutic measures.

The sociologist, in his enthusiasm for a therapeutic attack on a gang area, should not overlook those delinquents who have internal conflicts not susceptible to the techniques of therapy drawn upon from the community. It is necessary, therefore, diagnostically and therapeutically, that the sociologist and psychiatrist work together very closely. Too often, one gets the impression that psychiatrists maintain that what we need are more psychiatric clinics and residencies—that this will solve the problem. Again too often, newspaper reporters at least get the impression from sociologists that their approach will resolve all delinquency. Both kinds of therapeutic treatment are necessary, depending upon the correct diagnostic evaluation. Many times, careful diagnostic procedures will indicate that, for an individual child or family, both approaches are necessary, possibly not concurrently but in time, to resolve the problem.

## ¶ Education

We cannot leave the problem of treatment of either category of delinquency without some reference to the possible efficacy of education. Many of us are often inclined toward pessimism on this score, but only time will show how much can be achieved through the avenue of bringing pertinent data to parents and adolescents involved in delinquency.

Whether parental sanction of antisocial be-

Downloaded from www.dbpublishing.org.in

havior is conscious or unconscious, it is legitimate to question whether widespread lay knowledge of the role of parents and other adults in delinquency promises to limit the phenomenon. Nothing can be lost by such an approach, and the thesis might be defensible that the mischief perpetrated by the poorly integrated parents under consideration might well be curbed if it were generally conceded that delinquent behavior should not, without searching scrutiny, be ascribed to heredity, bad companions, poor schools, or divorce. The poorly inhibited antisocial impulses of adults may not then so readily find expression in the encouragement of scapegoats. It is true that such adults might then become neurotic, evidencing emotional conflicts in which conscience has prohibited direct expression of an urge to antisocial action. Troublesome as such neuroses may be—in the form of phobias, compulsions, conversions, or a hundred other neurotic expressions—they are preferable to antisocial behavior, with its threat of perpetuation through generations. In most instances, a neurosis, with conscience holding the fort, is more amenable to therapy than is delinquency, in which the conscience is too weak or is in abeyance. The psychiatrist and sociologist apportion no blame but prefer to interpose a barrier of understanding that might divert conflicts of neglect or cruelty of parents toward their own individual neuroses rather than toward the misbehavior of children.

Educationally, we must consider the meaning of the juvenile court to parents and children. Both the general public and children continue to be unable to divorce the juvenile court from the criminal court and delay use of the juvenile court when it could be most profitably employed. Judge Nochem S. Winnet of Philadelphia points out that continental countries have tried to offset the criminal odium by placing the delinquency problems in the Department of Welfare, as in Sweden, or in the Department of Education, as in Russia. Judge Winnet[81] suggests that we use the designation "family court," which removes the emphasis from the child.

There is no doubt but that widespread knowledge among healthy citizens is the fundamental lever through which to enlist their aid and support for clinics, courts, civic therapeutic work, and an attack on a broad front for the amelioration of both categories of delinquency.

CHAPTER 43

# READING AND LEARNING DISABILITIES

Ralph D. Rabinovitch

Downloaded from www.dbraulibrary.org.in

CHILDREN'S LEARNING has long been a major concern of psychology and of child psychiatry, evoking the interest of both theorist and clinician. Theories of learning are numerous, divergent, and still growing in both number and complexity. They range through Thorndike's[44] early stress on stimulus response; Hull's[19] addition of intermediate mechanisms; Gestalt psychology's general principle of "pragnanz,"[49] elaborated in Lewin's[26] field-theory and life-space definition; the motivational approach of psychoanalysis;[33] Mowrer's[30] two-factor drive-induction and drive-reduction theory; and Hebb's[17] intriguing neuropsychological postulates. Psychiatry, faced with pressing service demands, has tended, in its training programs, to devote minimal attention to these background studies. While they often are more philosophical than experimental and are, at times, only tangentially related to the child's experiences, one can find in them numerous suggestions for clinical application. Among the critical review volumes on learning theory, Hilgard's[18] is particularly helpful to the child psychiatrist.

## The Learning Process in Children: Neuropsychiatric Considerations

The commonest single immediate cause for referral to our guidance clinics today is behavioral, academic, or social difficulty experienced by children at school. This fact, in itself, suggests the need for intensive study of the full meaningfulness of the schooling experience, the ways in which it affects the child and, equally important, the influence of the child's capacities and personality on the learning process. A further incentive to such study is the current national interest in our schools, a valid concern that has, unfortunately, tended to assume hysterical overtones in reaction to international fears and rivalries. The feeling that many children attending America's schools are not achieving their full learning potential is generating numerous re-evaluations of educational philosophy, teaching methods, and curriculum. Approached insightfully and with constructive motivation, such projects can lead to progress,

but there is the danger of the negative effects of oversimplification and overgeneralization. We find, for example, curriculum being blamed for all learning problems, with finger painting, home economics, and driver training incriminated as the arch enemies of science. Delinquency that interferes so markedly with learning is said to be due simply to coddling. Reading failure is described as routinely the result of inadequate early teaching. It would be comforting if the truth were so simple. In relation to the educational crisis that we are facing in America, child psychiatry has a major role to play in interpreting the multiplicity and complexity of causes of learning difficulties and in fostering a realistic child-centered approach in their handling.

The term "learning" has many meanings; in its most general sense it refers to the process by which experience leads to change. In this chapter we are concerned with a single type of learning, the acquisition of academic knowledge. The process by which this is achieved involves a wide range of factors. Impairment of learning may result from disturbance in any of these; as such it represents a symptom. There is, in fact, no validity in postulating a discrete diagnostic entity of learning disability. In recent years, as clearer concepts of the psychopathology of childhood have evolved, many other clinical problems (for example, mental retardation and juvenile delinquency), previously described as entities in themselves, have come to be recognized as part of a symptom complex reflecting a more generalized underlying disorder.[3,35] We can best approach our topic through a consideration of the multiple areas of the child's functioning involved in academic learning, disturbance in any of which may lead to the symptom of learning retardation or distortion. Most important are the following: (1) general intelligence, (2) specific capacities, (3) developmental readiness, (4) emotional freedom to learn, (5) motivation, and (6) opportunity.

Although we shall examine each of these factors separately, it is evident that they operate in an integrated manner in each child's learning experience, and, clinically, multiple etiologic components are often present. Because of this multiplicity of factors, no single disciplinary approach to learning problems is valid; neurological, psychological, psychiatric, and educational emphases must be brought together without preconceived bias in both clinical and research work.

## *General Intelligence*

Any evaluation of a child's level of academic achievement must be considered in relation to his intellectual potential. In general, we can expect competence to be commensurate with mental age, recognizing that, in the learning pattern of the slow child, capacity to deal with abstractions and problem solving lags behind rote learning. But this whole area of diagnosis is by no means simple. Despite advances in techniques of measurement, accurate assessment of intellectual potential remains a difficult task. One of the unsolved problems is how to differentiate potential from actual functioning, as measured on a specific psychometric test or series of tests. This is, of course, a crucial consideration in planning for children, and one in which bias and wishful thinking tend to run rampant in the absence of objective indices.

In considering the relationship of intelligence and academic learning, we have become increasingly aware, in recent years, of the need to move, at least clinically, beyond a unitary concept of intelligence to one that takes into account the possibility of wide divergencies in verbal and nonverbal capacities in the individual child. Experience with the Wechsler Intelligence Scale for Children, with its separate verbal and performance I.Q. scales, has provided ample evidence for the validity of this differential approach. The two aptitudes are used in different situations and involve different types of learning—verbal and perceptual-motor. Group and individual tests that measure primarily capacity to deal with language symbols may be poor indexes of total intelligence and, as such, misleading. On the other hand, formal school achievement is much more closely related to the single factor of verbal intelligence, which tends to be disproportionately highly prized in our culture. These issues have particular relevance to the problem of reading retardation, discussed later in this chapter.

Downloaded from www.dbraulibrary.org.in

From a research standpoint there is a pressing need for continuing work on these and related problems; detailed longitudinal studies investigating the meaningfulness of subtest variations on such tests as the Wechsler[47,48] should prove particularly fruitful. Meanwhile, in our clinical practice with children, all possible care must be used in the assessment of both intelligence and learning capacity, with major reliance on individual tests competently administered and interpreted by clinical psychologists, of whom, unfortunately, fewer and fewer seem primarily interested in evaluation and diagnosis these days.

### *Specific Capacities*

In order for the child to learn to his full potential in the normal classroom situation, intactness of other specific functions, beyond intelligence, is required.

The higher senses—vision and hearing—must be adequate; the diagnosis of hearing defect is often difficult, especially in the uncooperative, inattentive child, and may be missed in the more common search for primary emotional factors.[20]

Neurological integration must be sufficiently intact to permit attention and concentration. The brain-injured child, experiencing difficulty in filtering background from foreground stimuli, tends to be overreactive and uneven in his classroom functioning.[6] Special education, permitting repetitive activities in small, quiet groupings for a period, can often be effective in preparing the encephalopathic child for return to the regular class.[42] This group of children is much larger than many workers recognize, and facilities for both their diagnosis and appropriate schooling are sadly lacking.

Language capacity, in the broadest sense, must be unimpaired. This includes verbal comprehension, expression, concept formation, the processes required for the learning of reading (visual-auditory memory and association), and ability to calculate. Disturbance in one or more of these language areas is present in the various forms of aphasia now recognized in children.[15,22] Learning difficulties involving aphasia are common and often unrecognized. Confusion still tends to surround this whole important area of the neuropathology of childhood; this is probably due to the fact that diagnostic criteria have been borrowed from work with adults with insufficient emphasis on the developmental aspects so crucial in childhood.[40] Aphasia will be considered in some detail in its relation to learning in our later discussion of reading.

### *Developmental Readiness*

Educators have placed much stress on the concept of readiness as a prerequisite for learning. From the field of child development, the emphasis has been drawn on individual differences in maturational pattern, especially as they relate to children in the earliest school years.[14,31] Differentiated from intelligence and experiential influences, the factor of biologic readiness, which appears to be a reflection of specific integration patterns, plays a major role in the acquiring of speech and the learning of reading and arithmetic. While, for example, aphasia in the adult can generally be traced to known cerebral trauma in children, it is more often maturational in origin and represents a lag in the development of specific language functions. Usually, following the delay, spontaneous compensation occurs, although, on later examination, a residuum of difficulty may be diagnosed in the form of motor, sensory, conceptual, or mixed aphasia. A similar pattern is followed in older children in relation to reading. Differences in the development of such fundamental techniques as directional orientation and auditory discrimination may be wide in a group of first-grade children of comparable intelligence, and the influence of this factor on the learning process is crucial.

A vexing clinical problem for the child psychiatrist is suggested by these developmental considerations: In which cases can the early disability be expected to be overcome spontaneously through growth, and in which is specific help needed? Notwithstanding the validity of the developmental-lag concept, too often there is a tendency to wait too long for spontaneous compensation to occur, while the child is neglected, sometimes beyond remediation. We still see, in practice, a good many bright 16-year-old boys virtually illiterate, while work-

Downloaded from www.copyright.com

ers are sitting by, waiting for nature to take its course. At present, our differential diagnostic skills are at best spotty, and there is a need for much continued interdisciplinary research into these vital maturational factors in personality development and learning.

### *Emotional Freedom to Learn*

In order to acquire academic learning most effectively, the child must participate actively and must be free to invest appropriate psychic energy in his schooling experience. It is evident that emotional problems of any type may impair this freedom, and they therefore represent the underlying cause of learning difficulties.[33, 34] To discuss this large area in detail would require a volume in itself—in fact, a consideration of the complete psychopathology of childhood. Our present purpose will best be served by reviewing the general principles and relevant representative syndromes most commonly met in psychiatric practice with children and adolescents.

Along with the recognition of the relationship between emotional disturbance and learning disability, there has been a tendency to overgeneralize, with insufficient attempt to understand the specific ways in which the learning process is affected. In practice, it is difficult to predict when an emotional problem will undermine academic learning; many severely disturbed children, who, on theoretical grounds, might be expected to have learning impairment, do well in their school work. Such apparent paradoxes are sufficiently common to make definitive general cause-and-effect assumptions uncertain at best. Many factors that may not be germane to the specific emotional disturbance are involved, including the quality of gratification that schooling provides, the level of accomplishment possible, the degree of protection afforded in the classroom, the child's attitude toward competition, the family's expressed and covert attitudes toward school and learning, sibling relationships, and, most important, the relationship with the teacher.[29]

These and other analogous conditions of the child's total experience play a major role in determining whether an emotional problem, not primarily concerned with learning, will lead to secondary academic difficulties. It is these multiple interrelationships, unique in their qualitative and quantitative aspects in each case, that preclude facile generalizations. Further complicating the issue is the possibility that the emotional disturbance diagnosed in the child is itself caused by a basic learning defect such as a primary reading retardation (see p. 864) or a language disability. In clinical studies it is not always easy to distinguish reactive patterns from basic etiology, and there is a tendency to overlook the former. For example, the presence of relationship distortions in the life of a child, along with a learning difficulty, cannot lead to the a priori assumption that the distortions have *caused* the symptom. Whitehorn[30] has drawn attention to this important reality in his paper on the concept of "meaning" and "cause" in psychodynamics; he points out that, in any specific disturbance, a dynamic description of relationships may be accurate and yet have no reference to the basic cause. This caution takes on particular significance in our clinical work with learning problems in which biologic realities can be so easily overlooked in the often less-disciplined search for dynamic relationships. In this specific context Pearson[34] writes: ". . . at the present time there is so much emphasis on the importance of intrapsychic processes in all phases of medicine and education [that] psychiatrists tend to become over-enthusiastic about dynamic intrapsychic processes to the complete neglect of physiological and organic processes, for which they seem to have a psychic blind-spot."

These cautionary remarks, in the interests of clinical practice, do not imply that full, careful studies fail to uncover many cases in which a learning problem has its roots in the child's emotional state; Pearson[33] has, in fact, written a large volume on just such situations. Anxiety, depression, negativism, phobic preoccupations, and personality disorganization all may interfere directly and markedly with a child's functioning in the classroom. A number of common clinical examples will illustrate the various processes through which the impairment may occur.

#### REFUSAL TO ATTEND SCHOOL

This problem appears to be increasing in incidence and has a number of causes.[46] A

Downloaded from www.psychiatryonline.org

neurotic conflict may lead to a phobia displaced to the classroom.

Peg, 10 years old, developed feelings of inordinate tension and nausea when at school, so that finally attendance was impossible. Study indicated a severe oedipal problem, with separation anxiety based on the fear that the mother would be attacked in her absence.

Another frequent cause of school refusal is more characterological and may reflect a power struggle within the family.[18]

Joan, age 8, could not be persuaded or forced to attend school and responded with temper outbursts and direct attacks on her mother when any pressure was exerted. Clinically, Joan was minimally anxious, but she was involved with inconsistent nondirecting parents in a chronic battle for control, of sufficiently long duration to represent virtually a way of life for the child.

### Learning Block as Counteraggression

Children in whom a need for counteraggression is fostered within the family evolve various typical mechanisms through which, consciously or unconsciously, they express themselves. In the young child, feeding and toilet training are among the commonest media for dynamically induced oppositional behavior. Later, displacement outside the family tends to occur, with academic failure and delinquency the common symptoms; in the school situation, transference of negativism to the teacher, regardless of his handling of the child, may make learning almost impossible.

John, a bright 12-year-old, failed all subjects in the sixth grade. His teacher described him as unfriendly, uninterested, and unwilling to work. No remedial attempts within the school program or through tutoring had proved helpful. Later, psychotherapy revealed a fantasy of rejection by the parents on the basis of the younger sister's status, and an unconscious wish to strike back accomplished through total resistance to learning.

### Anxiety That Interferes with Concentration

Many children, faced with conflicts outside the school, are so preoccupied in the classroom that attention, concentration, and memory suffer to the point that learning is impaired. It is interesting to note that, while grades are poor when such interference occurs, basic skills are not necessarily affected. In such cases, both techniques and facts are learned but are not applied in a meaningful way.

Paul, age 16, in the eleventh grade, has a verbal I.Q. of 133 and performance I.Q. of 136, and on the Advanced California Achievement Tests both his reading and mathematics levels are beyond the fifteenth grade. Despite this very superior level of intelligence and skills, he is doing failing work in all subjects except geometry. In psychotherapy Paul indicates that he cannot study; his mind wanders, and he spends much time brooding about the fact that he feels different from other boys because his parents are divorced and he is ashamed of his father. He knows how to do the work but cannot apply himself to assignments; assimilation of learning is intact, application severely affected.

In other cases, anxiety affects assimilation of basic skill materials.

Steven, age 14, is doing failing work at school despite a verbal I.Q. of 134 and a performance I.Q. of 132. Achievement testing indicates that he is functioning at a sixth-grade level in reading, fifth grade in arithmetic, and fourth grade in spelling. Careful study indicates no specific disability; the learning problem is psychogenic. Steven feels inadequate, fears competition, and tends to withdraw when he is threatened. His anxiety has interfered with his basic learning from the earliest school years.

This differentiation between assimilation and utilization in academic learning is important clinically in that definition of the process disturbance will influence treatment recommendation. While psychotherapy may be indicated in both situations, remedial tutoring, often helpful in assimilation problems, will usually be of little avail where the prime disturbance is in application.

### Depression, Self-Denial, and Self-Punishment

Accomplishment at school involves a measure of pride and of self-gratification, bringing with it a sustaining feeling of success. The child whose inner conflict cannot permit such personal gratifications may experience the un-

Downloaded from www.dbraulibrary.org.in

conscious motivation to fail. Depression may lead to inertia, with inability to sustain interest. When the need for self-punishment has been internalized, the ego may, at times, deny even minimal satisfaction through new accomplishment. Such dynamic constellations underlie a significant number of school failures in children and are often unrecognized, especially in the preadolescent years.

Despite a full-scale I.Q. of 127, Ruth, age 11, was making little progress in her schoolwork and was described by her teachers as "dull and lazy." She tended to be inconspicuous in the class and gave little behavorial evidence of emotional disturbance. She was referred for psychiatric study after her superior intelligence was diagnosed through individual testing at school. History indicated that Ruth had been adopted in infancy, after having been abandoned by her unmarried mother. In psychiatric interviews she revealed that her adoptive mother, when angry, reminded her of her background in uncontrolled, hostile, verbal attacks. The child reacted by retreating from the adoptive mother to a progressively stronger identification with the negative image of the natural mother. Her super-ego strength precluded delinquent acting out; instead, she internalized guilt and feelings of total unworthiness. Her school failure was an expression of this inner life and accorded with her self-image, unrevealed at school.

### Symbolic Associations Affecting Circumscribed Learning Areas

In the cases described above, academic learning in general has been impaired by the emotional problem, rather than specific learning content being involved in the neurosis. This is the usual pattern; more rarely, a circumscribed blocking is seen. Here the particular subject matter invokes traumatic associations which the child's ego attempts to handle by avoidance.

Tommy, age 9, functioned well above his age level in all subjects except spelling, in which he was markedly retarded. He was referred for psychiatric help because it was felt that he was oversensitive and unduly introspective. During the course of psychotherapy, an interesting explanation for his spelling defect came to light. When he was 5 years old and beginning to manifest interest in spelling, two older boys in the neighborhood, as a ruse, taught him to spell a number of vulgar sexual terms without his knowing their meaning. At home he proudly repeated his new knowledge to his mother, who overreacted and punished him severely. To Tommy, spelling came to symbolize uncleanliness and danger, and his circumscribed learning block resulted.

Because cases such as this are dramatic and the explanation for the problem is comfortingly simple, and therefore particularly appealing to the psychiatric student, they have tended to be overemphasized in proportion to their incidence in the mass of learning problems seen in practice. Actually, they are relatively rare.

### Psychopathology Other than Neurosis

While brain injury, affectionless personality, and schizophrenia affect the learning pattern, each in a characteristic way, the presence of the disturbance in the child does not, in itself, inevitably mean that major difficulties at school will ensue. The many other relevant relationship, attitudinal, and educational factors to which we have referred in our discussion of the neuroses play an equal, if not larger, role in determining total adaptation in these illnesses. This recognition is important clinically, because there is a tendency toward unwarranted exclusion from school of some of these children on the basis of diagnosis alone.

In an earlier section of this chapter, we have described the importance of neurological integration in the learning process and some of the problems and needs experienced by brain-injured children. The major concern of the child psychiatrist and the teacher tends to be with encephalopathic children in whom the damage involves associational patterns affecting visual-motor functioning, the suppression of response to extraneous stimuli, and shift or smooth transitions in motor behavior.[6] In the classroom these neurological deficits lead, respectively, to disturbance in patterned activities, hyperactivity or short attention span, and uneven or repetitive motility. Anxiety tends to lead to disorganization in the brain-injured child's functioning, and his emotional state is often the crucial factor in determining adaptability.

Downloaded from www.dbraulibrary.org.in

Strauss and his coauthors[41,42] have outlined in detail the special educational needs of these children.

The affectionless child[5,9,36] presents, as his major symptoms, reduced capacity to establish depth relationships, inadequate social awareness and identifications, inability to control impulses adequately, and limited capacity for insight. In the thought process there is marked concreteness, with poor conceptualization that limits fantasy life and creativity; future goals cannot be envisioned. This clinical picture has a marked influence on learning. Basic skills and rote learning are much less affected than the incorporation of content in social context. Behavioral disturbance in the classroom is common to the point of presenting major management difficulties; in the absence of small groupings for special education, exclusion from school may, at times, be necessary. Treatment is extremely difficult because of the limitation or absence of relationship capacity; Bender[5] provides an excellent interpretation of the special educational and total treatment needs of this affectionless or psychopathic group of children.

As the clinical picture of childhood schizophrenia has been more clearly delineated,[4,21,28] the learning problems and educational needs of psychotic children have become a major concern of child psychiatry. The core problem in childhood schizophrenia is a dysidentity, an inability to establish a clear-cut self-percept and definitiveness in the appreciation of boundaries and identities. There is an amorphousness to the child's personality and thought processes that interferes with reality testing and leads to marked anxiety. Learning is frequently impaired by a tendency toward misinterpretation of stimuli, obsessive attention to insignificant detail, a limiting concern with orientational clues, and panic reactions when routine is disturbed. Some schizophrenic children have accumulated vast stores of relatively useless knowledge, frequently about numbers, dates, or locations; such orientational assurances gratify the child by lending comforting pseudo stability to his uncertain, floating world. The "idiot savant" is frequently a psychotic child displaying this restitutive mechanism. In long-term follow-up studies it has been encouraging to note, in some cases, a marked increase in learning capacity in adolescence. These studies suggest that even the severely autistic child may incorporate more meaningful knowledge than he can express; neglect of exposure to schooling experience is unwarranted. Among the techniques found most effective in the education of these children are small informal groupings, close contact with the teacher, simple repetitive programing, and reliance on music and rhythmic play; Abbate[1] has elaborated on these techniques.

## *Motivation*

The term "motivation," as used in psychology, has many meanings; we are using it here to imply incentive or desire to accomplish a goal, the goal being learning. Many of the emotional problems that we discussed earlier involve various aspects of motivation as a component of the disturbance. In this brief section we are concerned specifically with the attitude of children toward school and learning, recognizing that this is a crucial factor in the learning process. Two types of motivation concern us; extrinsic, in which concrete reward is the goal; and intrinsic, which implies inner satisfaction as the incentive. The fact that a large number of children in our American schools today seem to lack motivation of either type is a valid source of national concern.

In our clinical work with children, a number of reasons for this problem are suggested. These are students who have little interest in learning and whose application is minimal. In every aspect of responsibility, they do just enough to get by, or less. They study little and do not involve themselves in learning. Among the total group a number of subgroups can be recognized. There are those who have been raised by parents who make no demands on their children, avoid all possible frustration of their impulses, and sometimes permit a frank reversal of parent and child roles. Others have been offered no values by which to live, and they gravitate, herdwise, to the most superficial "hood" identifications which leave them sadly empty; they are truly lost children, but in their

Downloaded from www.brainlibrary.org.in

behavior, manner, and dress, they can demoralize an entire school. A third group, passive and uncertain of status, tend to follow the leadership of these more aggressively nonconforming adolescents.

There is more to the problem, however, than these individual factors in children; the cultural determinant is vastly important and has received far too little attention. At a time when expediency is at a premium, when affluence is more prized than integrity, and when the headlines are more gruesome than the comic books, it is not surprising that many children are having difficulty in finding motivation for hard work and devotion. The major crisis in education today (and child psychiatry is equally deeply involved) is to find ways to offer children personal relationships and community values that will generate at least some intrinsic motivation for learning, for the sake of the too-oft-forgotten inner life.

### *Opportunity*

The last factor to be considered in our survey of the multiple processes involved in academic learning is the opportunity for learning afforded the child. We can do little more than mention this topic in our concentrated survey, although it is a matter of much concern to child psychiatry. Involved are such issues as the educational philosophy that evolves in our schools, curriculum emphases, teacher training, and school design. Clinical study indicates clearly that a significant proportion of learning problems diagnosed in children have their origin in unfavorable circumstances prevailing at school. In our search for more complicated etiologies, we sometimes overlook the negative effects of overcrowded classrooms, lack of equipment, and unstimulating teaching. It is unfortunately true that the educational opportunity offered our children varies widely throughout the country, with primitive conditions not uncommon; the hazard of neglect is very real.

In regard to our schools, a number of issues are particularly relevant to the clinical concerns of the child psychiatrist. There is a great need for small-group special-education rooms for emotionally disturbed children who cannot function in the larger, competitive setting; the availability of such facilities frequently means the difference between a learning opportunity for the disturbed child and total educational neglect. Our inpatient psychiatric treatment centers for children are developing teaching techniques that may well be applicable in the public schools. We are interested, as well, in programs for gifted children and in retaining in the curriculum appropriate courses for the child who cannot handle academic work. Above all, we are interested in helping our colleagues in education in whatever ways we can to improve our children's learning opportunities.

## ¶ Reading Retardation

By far the commonest area of learning difficulty experienced by children is reading. Estimates of incidence vary widely but probably more than 10 per cent of children of average intelligence in our American schools are reading so inadequately for their grade placement that their total adjustment is impaired. Clinical and research interest in the problem date back many years. As early as 1843, Lordat described his own inability to read as a result of a cerebral accident. Through the years, many outstanding workers in the fields of neurology, psychiatry, pediatrics, psychology, and education have contributed a massive literature on reading disabilities. Bibliographic reviews can be found in papers by Bachmann,[2] Solms,[30] Hallgren,[16] and Rabinovitch *et al.*[27] The earliest descriptions traced etiology to a known, specific, focal cerebral lesion.[10] Later, numerous other etiologic correlations were described, including chronic illness, visual problems,[28] mixed cortical dominance,[32] developmental lag,[31] improper teaching, generalized neurologic dysfunction,[7] and emotional problems.[8] In the presence of these and many more etiologic possibilities, it is evident that inadequate reading, like other learning deficiencies, is a symptom rather than a discrete clinical entity in itself. Because of this, we[37] have suggested the term "reading retardation" to describe all

Downloaded from www.dbraulibrary.org.in

cases, specific etiology to be determined in each individual instance.

The term is used in reference to all children or adults whose level of reading achievement is two years or more below the mental age obtained in performance tests. It appears valid to use performance rather than verbal tests as the index of mental age, because functioning on the verbal portions of such psychometric tests as the Wechsler or the Binet is significantly affected by the reading inadequacy itself, whereas the performance subtests are much less so influenced. The two-year discrepancy between mental and reading age is arbitrary, but it has the value of limiting the definitive diagnosis to cases showing significant functional reading inadequacy that inevitably affects school adjustment.

While visual, general health, and other causes occasionally operate alone to produce reading retardation, the large majority of cases fall into three major groups:

1. Capacity to learn to read is intact but is utilized insufficiently for the child to achieve a reading level appropriate to his intelligence. The causative factor is exogenous, the child having a normal reading potential that has been impaired by negativism, anxiety, depression, emotional blocking, psychosis, limited schooling opportunity, or other external influence. We have discussed these cases in earlier sections of this chapter. They are diagnosed as secondary reading retardation.

2. Capacity to learn to read is impaired by frank brain damage manifested by clear-cut neurologic deficits. The picture is similar to the early-described adult dyslexic syndromes. Other definite aphasic difficulties are generally present. History usually reveals the cause of the brain injury, common agents being prenatal toxicity, birth trauma or anoxia, encephalitis, and head injury. These cases are diagnosed as brain injury with reading retardation.

3. Capacity to learn to read is impaired without definite brain damage suggested in history or on neurologic examination. The defect is in the ability to deal with letters and words as symbols, with resultant diminished ability to integrate the meaningfulness of written material. The problem appears to reflect a basic disturbed pattern of neurologic organization. Because the cause is biologic or endogenous, these cases are diagnosed as primary retardation.

In clinical practice it is not always easy or possible, at the present time, to be certain of the factors operating in each case, although in most instances the situation is clear. Research now continuing in many clinics both here and in Europe[24, 51] should, in time, provide us with more accurate evaluation techniques. In all cases there is a mutual interrelationship between biologic and experiential influences, and in some children primary and secondary factors are both prominent. Accurate delineation of etiology is important, because it determines the treatment program and prognosis. In regard to reading problems, Levy's[25] and Lowrey's[27] expressed concern about a prevalent "anti-diagnostic attitude" in child psychiatry is particularly relevant. Lowrey comments: "In recent years I have been puzzled by what seems to be a tendency to treat first, and then inquire afterward what was the matter." Failure to attempt accurate diagnosis, with all cases labeled indiscriminately as reading disabilities, has led to the many divergencies in reports in the literature, and, more important, has probably afforded many children inappropriate treatment.

Although definite statistics are not available, it is likely that the large majority of children presenting total or severe reading retardation have a primary problem, with secondary or exogenous causation higher in the less severe cases. There is a strong predominance of boys in the incidence of primary retardation. The proportion of boys to girls is probably greater than 10 to 1. Many workers have suggested a hereditary factor with which this sex incidence is related, and there is much evidence in support of such a view,[16] although further research in this area is indicated.

In an earlier report[37] we have presented the findings of a study attempting to define the specific process disturbances in the primary group and to differentiate these from secondary cases. Five avenues of approach have proved particularly fruitful: (1) psychometric evaluation, (2) achievement testing, (3) psychiatric

Downloaded from www.brainpad.in

evaluation, (4) neurological appraisal, and (5) specific remedial reading therapy.

### *Psychometric Evaluation*

The most significant finding in the primary cases, using the Wechsler intelligence tests, is a marked discrepancy between performance and verbal I.Q. The mean discrepancy is more than 20 points, with the verbal I.Q. lower than the performance by more than 40 points in some cases. There is a general verbal incapacity relative to intellectual potential which is much less marked in secondary reading retardation, regardless of the child's reading level. These data suggest how inadequate are verbal tests alone in assessing the intellectual potential of primary nonreaders. The fact that, in the past, such evaluations have been used has seriously clouded our understanding of the problem and has led to distortions in some reported studies. Statistical analysis of the 11 subtest scores on the Wechsler, although not conclusive in findings, suggests a greater difficulty with abstract or conceptual thinking, both verbal and nonverbal, in primary retardation, with greater relative impairment in social judgment in the secondary group.

### *Achievement Testing*

The level of retardation is higher in the primary cases. In a representative group of 20 children with primary retardation ranging in age from 10 to 16 years, the mean discrepancy between performance mental age and reading age was found to be close to 5½ years, with almost total illiteracy not uncommon. Contrary to a view often held, the deficiency in arithmetic is almost as great as that in reading.

Qualitative analysis of the functioning of the primary cases on testing and during remedial therapy suggests the specific areas of disturbance producing the severe retardation. Many factors are operative in the normal process of reading learning. Intact vision, including adequate fusion, is necessary. Visual memory, visual discrimination, and visual association are all utilized. Through visual memory, individual letter forms and combinations are recalled; through discrimination, differences in shapes, sizes, and forms are appreciated; through association, the forms in their combinations come to suggest words and concepts. Auditory memory, discrimination, and association are equally important. Through auditory memory, sounds of consonants, vowels, and combinations are recalled in response to visual stimuli; differences in the sound of letters and the many nuances of combinations in words are discriminated; through association, sound patterns suggest concepts. Another requirement for reading learning is directionality with capacity for consistent left-right orientation. In the normal learning process most children utilize both visual and auditory approaches, although usually one tends to be used dominantly. Visual clues are taught through the sight, or look-see, method; auditory through the phonic, or sounding, method. In our most severely retarded primary cases, we find major difficulties in learning through either modality; others demonstrate a deficiency in either visual or auditory memory-discrimination-association patterns. Where there can be no reliance on auditory clues, the child attempts to learn through memory of total word forms, and it becomes almost impossible for him to do so effectively past the third grade. When asked to write the word "woman," he may write "lady"; memory has broken down, and there is substitution of a word related in meaning but totally unrelated in sound. Similarly, the child who attempts to rely totally on a phonic approach cannot progress. He may learn the sound of each letter, but he experiences great difficulty in combining multiple sounds meaningfully. For example, his attempt to read the word "hat" may never move beyond the sounds "huh-a-tuh." Difficulties in directional orientation are expressed in reversals of letter forms, so that "b" may be read as "d"; total word sequences are reversed, with "no" interpreted as "on." These and other related deficiencies in the basic techniques required for the learning of reading are found in varying combinations in primary reading retardation; they are not typical of the secondary cases.

Downloaded from www.dbpublishing.org

### *Psychiatric Evaluation*

We have described the various neurotic and other exogenous problems that impair learning; the earlier discussion applies directly to our secondary reading-retardation cases.

The primary cases tend to exhibit a number of typical reactions. They show marked anxiety about their reading incapacity, are inclined to hold themselves responsible for the problem, and feel much guilt, inferiority, and frustration. They are often protective and defensive and may confabulate when asked to read. A most interesting finding, so common as to be considered almost pathognomonic, is difficulty in conceptual thinking in relation to orientation and such abstractions as time, size, number, and direction. Typical are such responses: A bright 12-year-old boy who lives 40 miles from the clinic is asked the distance to his home and how long it took to travel the distance by car. He replies: "Seven miles, I think it took 4½ hours." Sitting with two doctors, one 6 feet 3 inches and the other 5 feet 8 inches in height, a 14-year-old boy is asked which is taller; he correctly points to the taller man. Asked how tall each is, he states that the taller man is 5 feet tall and the shorter man is 9 feet tall; asked again which is taller, he points correctly, but he is unable to recognize the discrepancy in his number concepts. A 13-year-old boy, able to name the months of the year correctly by rote, replies that Christmas is in July and the hottest month of the year is February. In addition to these conceptual problems, various sensory or expressive aphasic difficulties are observed, although not so frequently. It is evident from these findings that the reading problem is only part of a larger language disturbance.

### *Neurological Appraisal*

Drew[37] has reported on the neurological study of a group of children and adolescents with primary reading retardation. He describes a characteristic pattern, with much variability from patient to patient, summarizing his findings as follows: "Right-left confusion, various extinction or inattention phenomena, cortical sensory disturbances, mixed hand-eye preferences, non-specific motor awkwardness, dissociated dysgraphia, and speech and spelling abnormalities are all variously combined with the reading disturbance." He interprets these findings to indicate disturbed spatial orientation, with many features suggesting similarity to the Gerstmann syndrome.[38] Gerstmann[12] has elaborated on some of these phenomena in a recent paper on disorders of the body image. Drew concludes that primary reading retardation results from a developmental discrepancy rather than an acquired brain injury, and that the dysfunction primarily involves the parietal and parietal-occipital regions. Studies by Critchley,[11] Gerstmann, and Drew are particularly pertinent in providing directives for much-needed further research.

### *Specific Remedial Reading Therapy*

There is a marked difference in response to remedial therapy on the part of the secondary and primary reading-retardation groups. Because basic capacities are intact, the secondary cases can progress rapidly, and results are generally gratifying. Psychotherapy is usually indicated because of the nature of the causative factor, but, when the reading level is low, it is often wise to add specific remedial work with a trained reading therapist.

The situation is very different with primary cases. Retraining is slow and unsteady, and the ultimate results are less favorable. Learning needs constant reinforcement, and numerous approaches—visual, auditory, kinesthetic, and others—have to be introduced.[45] Through careful diagnosis both the assets and the liabilities for reading are determined, and therapy is directed specifically to individual need. Training in directional orientation, visual memory, auditory discrimination, phonic recognition, sound blending, and numerous other techniques is called for. There tends to be little carry-over from day to day, and patients are often discouraged by their slow, uneven progress. Crucial to treatment is the relationship with the

Downloaded from www.duraunivers.org

remedial therapist, who must have infinite patience and ingenuity. At the present time, many adolescents with primary retardation leading to illiteracy may, with remedial therapy extending over several years, achieve a fourth- or fifth-grade level of competence, although some advance further. While this is less gain than we would hope for, it does represent functional reading capacity, so essential in our society. While there are large numbers of these children in our schools, there are very few available resources for their intensive retraining; this represents a major field for development and calls for much interdisciplinary interpretation and planning.

CHAPTER 44

# PSYCHIATRIC PROBLEMS OF ADOLESCENCE

George E. Gardner

Download Edition www.dbraulibrary.org.in

TO MY MIND there are four major tasks confronting the child as he enters the adolescent years. I shall not list them in the order of their importance, because they are all important. Nor would I claim for them an all-inclusiveness in respect to the problems of the adolescent years. Yet, it is safe to assume that many tasks of a subsidiary nature can be subsumed under the four which I now outline.[6]

## ¶ Tasks of Development in Adolescence

1. I cite, first of all, the extremely difficult task of adolescents in the necessary modification of their unconscious concepts of parental figures—both father and mother—necessary for them if many of the subsequent and consecutive steps in development as adults are to be achieved. This is not solely a "drive for independence," as it is sometimes called, but involves an extensive alteration of the frames of guidance in behavior that have been strong structural elements in the child's personality. It is not difficult for us to note that to the young child his very security is predicated upon the "all-knowingness" and the "all-powerfulness" of his mother and father. Such powers have been his strengths, his reliable guides, and his protection in respect to his own impulses and the actions of others. But faith and reliance on such alleged omniscience and omnipotence in parental figures cannot be maintained in the unconscious concepts of the child, in the face of evidence repeated through the child's many experiences within and beyond the home that such is not the case; thus the anxiety of insecurity besets him. And presumably it is well that such is not the case, as it could easily act as an immovable counterstimulus to the child's own growth and development. Nonetheless, it is difficult for the adolescent to modify these concepts—or rather, it is even more difficult for him to find other reliable sources to take their place. Usually, as a first step, he tries desperately, as many a harassed parent of an adolescent can attest, to

place other people (almost any other person) in the same role as the parent, as the supreme counselor. But this continued personalization of desirable figures of omniscience and omnipotence is doomed to failure, since no one can reasonably and totally satisfy when put to the test. This device is also doomed, because, in the last analysis, whatever "knowingness" or "power" adolescents ever are to achieve in order to become adult must be impersonalized and must reside within themselves—as a part of their self-concept and not as the concept of another, and as self-directed, not other-directed, choices and controls. I need not emphasize the episodic—or worse—sometimes disastrous devaluation of parents that takes place because of this necessary step in growth, nor need I emphasize (as has been demonstrated again and again in history) the extreme vulnerability of all adolescents (or of adults who are still essentially adolescent) to the cry and to the seductive voice of the false leader or the leader with the false ideology or intent. That adolescents (of whatever chronological age) are appealed to—and respond to—such leaders is accounted for by the fact that the latter always promise, among other things, an omniscient who can do their thinking and an omnipotent who will be their power.

This task of "de-authorizing" and impersonalizing the controls over one's behavior is formidable. It may, of course, never be achieved, and if achieved it must be thereafter repeatedly reachieved; but if it is achieved, the first and crucial steps are taken in adolescence.

2. A second task (which, like the others I shall mention, is really a specific segment of the over-all task just discussed) is the need for the assumption of standards of morality, of right and wrong, that are acceptable and appropriate in the adult society. We are all aware of the needs, from society's point of view, in this respect. What I would emphasize is the adolescent's needs for inner controls, and I am not referring only to morality or right and wrong in regard to sexual behavior. I mean social morality—the rightness or wrongness of acts in all the roles that the individual must play in his associations with all others in society. The adolescent wants and needs universally agreed-upon and universally adhered-to, fixed, and unchallengeable standards of social conduct. Even more so does he need agreed-upon standards that are "meetable," that is, that he can meet in the sense that they do not repeatedly tear his personality to pieces through the anxieties and insecurities attendant upon impossibility of attainment. To imply that the adolescent is faced with serious tasks and with serious conflicts in regard to both tenets and models as he tries to discern and to incorporate such standards is a gross understatement of the situation.

3. The third task of great importance to the adolescent, and one generative of most serious conflicts, is the identification with the sex role for which he or she was biologically determined. The pressures of all the societies that impinge upon him—from the "parental society" even to the "political society"—demand with varying emphases that this task shall be completed and be final and nonvariant. This identification is not limited merely to the biological role the youth must prepare himself to assume, without serious conflict, in adult life; it includes also all of the roles—dominant and subsidiary—that society insists he must have if the boy is to be a definitive male and the girl a definitive female. With all the dangers, actual or alleged, factual or fanciful, that have been outlined for youth by adults or by colleagues, and in the light of all the deliberately contrived or silently condoned ignorance in respect to these sexual roles, it is a never-ending surprise to all of us, I am sure, that the adolescent ever performs this task in development or ever becomes a reasonably conflict-free adult. That adolescents do so is, I am convinced, due more to their innate resilience, their dissatisfaction with half-truths or nontruths, and their curiosity than it is to the sensible guidance that they receive from others.

4. A fourth task of adolescents is in that area that involves permanent decisions and choices that must be made by them as to educational and vocational futures. I am not speaking here only in the narrow sense of picking a course of study or of the selection of a future particular or specific job, though these decisions in themselves frequently involve serious inner conflicts

Downloaded from www.dbtuniversity.ac.in

when one reflects that the final conscious choices ultimately arrived at are probably determined—again with attendant serious conflicts—by deep unconscious needs that insist on expression in one's lifework. These in themselves would be conflictive enough, but they are compounded in their effect by the multitudinous pressures and varying value ratings, in respect to occupations, that arise from the differing groups—ethnic, family, school, community, and peer groups—with whom the adolescent is in daily contact. One thing is certain above all others in the minds of adolescent youngsters in regard to education or occupation or both, and that is that some of the choices that are made are practically irreversible, and that with them they commit themselves along certain circumscribed life courses and forever forsake others. If it is true, as alleged by Freud, that adult adjustment and maturity can be in large part determined by two standards—the ability to love and the ability to work—the successful solution of this educational and vocational task selection is a major accomplishment of the adolescent and is comparable to the task previously mentioned, the assumption of roles consistent with his or her sex.

In the face of these four inner conflicts—plus many others that we might cite as normally expected phenomena of the development of adolescents as a group, just from the mere desirability of growing up—what is the most characteristic response that one would expect in these children, and indeed the one which we almost inevitably note? It is a temporary stage of role indecision, or, as Erikson has phrased it, "role diffusion." It is a stage characterized by the selection of shifting, fleeting roles; of variable ideas, ideals, and values; an age one moment of determined high idealism and resolute standards, followed by phases of the seeming abandonment of both. They are, these adolescents—again through normal impulses to go both forward and back—at one time normally obnoxious or even destructive in their independence and heedlessness, and at another flagrantly and unashamedly immature, dependent, and babylike.

By way of illustration of the emergence and demonstration of these tasks and their allied developmental stages in adolescence, I shall present and discuss an intake interview with a sixteen-year-old girl and the subsequent intake interview with the mother. In my opinion, these two interviews highlight most of the problems and anxieties (and defenses against anxieties) that one will meet in an essentially "normal adolescent." Furthermore, the two interviews, when viewed as a whole, throw considerable light and emphasis upon the persistence of, or the reactivation of, many of those tasks in the earlier development of this child that are now seen to have been totally unsolved or to have been incompletely and inadequately solved in infancy and in the latency period.

Frances, aged 16 years 2 months, a high-school senior living with her mother and father in a small town south of Boston, herself telephoned the Judge Baker Guidance Center and asked for an interview to discuss her problems. Because of the unusualness of self-referral to the clinic, she was seen the following day.

When she came into the office, she announced in quite a rush that she had been thinking over her problems and felt perhaps they were not important and that it was silly for her to be bringing them up here.

She is a tall attractive brunette girl who is quite reflective in her manner and who expresses herself very fluently, though she is rather shy. With some reassurance from me that I was interested in her problems, she began to talk of them.

She had heard about the Judge Baker Guidance Center from a cousin who was a social worker in a child welfare agency in Providence. She told her mother she was going to the clinic, and although her mother thought it unnecessary, she did not object to her doing so. She did not mention it to her father. The only other member of her family is her brother, Frederick, 29, a lawyer, who is married and lives in Detroit.

The first thing she mentioned was her inability to get on well with her parents. She feels that father, particularly, picks on her and takes the attitude that she can never do anything right. She gave as an example an occasion when she was attempting to help her father fix a radio. He had asked her to hold a bolt while he worked on

Downloaded from www.dbraulibrary.org.in

the mechanism inside the radio. He screamed that the radio wouldn't work and that it was her fault for not doing as he asked. She says this goes on all the time, and she feels that much of her activity in life is an attempt to prove to father that she can do things well. She started taking music lessons last summer against her parents' wishes, paying for them with her own money. She also makes very good grades in school and earns quite a bit working after school in a laundry. She feels all of these things, and many others she has done well in, have been done out of rebellion against her parents.

The second major thing she mentioned as troubling her concerned her inability to make and hold friends. Mother urges her to get into groups. Mother herself is quite a joiner and keeps up a furious round of activity in order to keep herself occupied, which makes her feel happier. Mother does all of these things by herself, not with Frances or with father. Frances hinted that there was marital difficulty between the parents. She remembers that there had been many serious quarrels between them when she was a small girl, and she was continually worried that her father might leave home. She seemed quite distressed that she had told me this and said that her parents would be awfully angry with her if they knew she had talked about these things, because they had told her not to.

As to her relationship with girls, she feels that she is always trying to please them and that, actually, she doesn't ever receive much satisfaction in having girl friends, because she is always the one to give in, and then she gets angry at herself for doing this. She said that she always tries to be liked and she feels that her tremendous efforts to be liked are rather silly, because maybe she would be liked more if she didn't try so hard.

Frances feels that boys don't like her. All the other girls have lots of boy friends, but she finds herself unable to interest them. She is sure no one will ever marry her. Frances feels that she is afraid of boys, and the fact that mother is very much the prude and will never answer her questions about sex contributes greatly to this.

In speaking of boys, Frances told me about her one boy friend, Louis, who is 26 years old. She met him two years ago when she was 14. She fell very much in love with him and her father and mother were very angry about it, but she now feels that if her relationship hadn't been forbidden by her parents, and if she didn't have this urge to defy them, she wouldn't have been this interested in him. He is of a different religion and her parents didn't approve of her going with him for that reason, and also because he is much older than she. Sometimes she sneaks out to meet him, and doesn't feel this is wrong because she has a philosophy that if you do something wrong, you will know it is wrong; and if she doesn't feel it is wrong to meet him this way, then it isn't wrong. In association to this, Frances also mentioned her boss at the laundry where she has a job after school. He is married and has two children, and yet Frances finds herself falling in love with him. She thinks the main reason for this is that he treats her as though she were an equal, which is something she never finds in her father. She worries about being attracted to older boys and men. Maybe it is due to the fact that boys her own age don't like her, but they are so silly and fresh. She also feels that part of the attraction she feels for these older men is due to the fact that they resemble her brother Frederick a little bit. It seems to her that in growing up, Frederick got all the breaks in life. He was allowed to go away to college and have more independence because he is a boy. This has always made her jealous.

However, she realizes that she is afraid of sex, and mentioned that she had an experience a year and a half ago that had frightened her. She didn't think she had been hurt by it, but evidently a boy had made advances to her and she had fainted because she was so scared. When she asked her mother whether she should let a boy kiss her, mother answered, "Later I will tell you about that; there's plenty of time."

Frances has applied for admission to a college in Boston, but would rather go out of town to college. However, father will not permit this because he feels that she would get into trouble with boys if she were unsupervised. This makes Frances very angry because she feels that all he thinks about is sex in this way, and her parents are continually harping on this and telling her of the dangers involved.

Frances brought up the subject of religion to emphasize the fact that father wouldn't admit that he is of his particular sect because of his business connections, fearing that his business would be harmed. However, her parents would be unhappy

Downloaded from www.dbraulibrary.org.in

if she didn't marry a man of this same religious group, and it makes her feel bad to be caught in this situation of not being allowed to admit she is of one religion and yet being confined to friends who go to the same church. She said quite pathetically that what she would really like very much is a kind of religion that would be really hers.

Frances also feels that her parents are so childish and petty that she has to be a parent to both her parents in many ways, and gave me an example of how mother had been up in the air about something. Frances had advised mother what to do, mother gave the suggestion to father, and father thought the solution was a good one and they adopted it as their own.

We discussed the clinic setup and how it works. We discussed the possibility of her mother's coming, and Frances said that mother had expressed a willingness to come if necessary. Frances, however, wanted to pay her own fee—she doesn't want to ask them for anything—and in discussing this, it came out that father's business had not been too prosperous during the past two years and she did not wish to burden him with this added expense.

She was again distressed that her mother might find out that she had talked of some of these things here, and I said if they came up in mother's interview, it would be because mother brought them up herself, and that Frances' confidences would be kept as such. We arranged tentatively that Frances would pay a fee of 50 cents. This would be paid out of her own earnings, which she applies mainly toward college savings.

An interview with the mother was arranged. She is a very attractive, well-dressed lady who immediately took command of the interview and tried to hold it throughout the hour. She talked of many of her activities outside the home and seemed definitely to be trying to impress the worker with her educational attainments and her efficiency. She did not feel that Frances had any very serious problems except that both she and Frances' father had found it increasingly difficult to give Frances advice. In short, they were willing to give Frances all the help and counsel that they could, but Frances seemed to wish to turn elsewhere for help. The mother states that when Frances was younger, mother was annoyed by Frances' total disinterest in things that girls should be interested in; but lately she has been annoyed because of her too great interest in boys, particularly boys much older than she.

Mother said that Frances was a full-term baby and the birth was normal. Mother was surprised when she became pregnant with Frances, as it had been thirteen years since the birth of her only other child. She did not wish to take up again the responsibilities of caring for a baby. Father, on the other hand, was delighted at the prospect of having another child. He wanted another son—in fact, mother says, she too probably preferred boys—and they were both so sure the new baby would be a boy that they had bought "all blue things" for "him" instead of pink, and had selected the name "Francis" for him. When the new baby turned out to be a girl, they gave it the same name, "Frances." Though he was somewhat disappointed in the fact that the new baby was a girl, father always spent a good deal of time with her until about a year and a half ago (Frances was 14½), when they seemed to grow apart, and quarrels were easily generated when they were together. Previous to this, however, father and Frances were always together; they attended many sporting events and movies together, and she helped father with chores around the house.

Frances' early development was normal and her health was excellent. She was not breast-fed, as the mother did not have enough milk. Frances was weaned to the cup at 9 months and was very fussy and irritable at this time. Toilet training was begun at 6 months and Frances was completely trained at 15 months, save for occasional bed-wetting; this stopped entirely at 3 years.

Mother said that Frances was never a feeding problem in early life, but at the age of 13 she placed herself on a very strict diet because she was "getting too fat," and in a period of 6 months she lost 20 pounds. Her weight had dropped, through dieting, to 90 pounds, and mother became alarmed by this. She took her to a physician, who warned the patient that she was harming herself physically by not eating enough. Frances stopped dieting immediately and soon gained back the weight she had lost.

Frances never had any serious illnesses in childhood, and except for a tonsillectomy when she was 5, had no operations. She menstruated for the

Downloaded from www.dbraulibrary.org.in

first time at 14½ years. Mother said that she had never been able to talk over sexual matters with her daughter, and whatever sex instruction Frances had, she received from her aunt, to whom she always went for guidance and advice. In this connection, the mother stated that probably she is old-fashioned in these matters because her father and mother were very strict with her and she was early led to believe that all things connected with sex were immoral or dirty.

Frances has always done very well in school and has had very good marks. In her early teens, she had insisted that she was going to be a physical education instructor, an ambition which mother feels grew out of her great interest in sports and her excellence at them. Mother again said that Frances never played with dolls or did any other "girlish" things but, on the contrary, was always out playing football and baseball with the neighborhood boys. She was a regular member of their teams. During the past year she has stated that she wants to be a physician, a nurse, or a social worker.

Mother emphasized again her own distress and the distress of her husband that Frances shows such interest in older boys, wishing that she would confine her attention to those of her own age group. Mother specifically mentioned Louis, stating that although he is a very nice boy, he is altogether too old and too "sophisticated" for Frances.

Mother described father as a rather shy, quiet man and gave the impression that she is somewhat dissatisfied with him because he has never shown enough push and energy to be successful in his business. In general, he is a very even-tempered man with quiet humor, but on occasion gets very upset and displays a "horrid temper" or else retires into a prolonged state of uncommunicativeness. Until recently, Frances was the one who could calm him down or bring him out of his moody spells, but lately she has seemed less interested in trying to do so.

Mother stated that she is quite willing to come to the Judge Baker Guidance Center for interviews with the social worker if we feel that Frances needs help. She did, however, list a fairly large number of afternoons when it would be impossible for her to come in town because of other meetings and obligations with which clinic appointments might interfere.

We may now use this case as a basis for our discussion in respect to the problems in adolescence. In discussing the case, I shall deal with the four main problems of adolescence that were commented upon above as they are exemplified by the material: (1) the problem of the drive for relative independence and autonomy; (2) the problem of the control of the sexual impulses and the establishment of an acceptable and accepted moral code; (3) the problem of a final and definitive identification of the boy or girl with that sex, and the sexual roles with which biology intended he or she should identify; (4) the problem of educational and vocational choices. In relation to each of these four problems of adolescence, I shall discuss the case material in regard to (a) the presenting problem itself; (b) the antecedents in early life that refer to unsolved or poorly solved tasks of development at various levels in childhood; (c) the present defenses used against anxiety created by the problem; (d) other defenses sometimes used by children other than this particular girl, Frances; and (e) case examples of extreme responses—responses leading to actual disabilities—that adolescents sometimes use in an attempt to solve these problems.

## ¶ Problems Relating to the Psychosexual Development of Children in Adolescence

As can be seen in the case of Frances, from the material which she and her mother gave to us at intake, she was, at the age of sixteen, finding it very difficult to allow herself to identify with the female sex with a view to later assuming the roles, sexual and otherwise, that would be required of her as a young lady.[8] Indications of this delay in maturation in these respects are seen in her anxiety about her relationships with boys and her reluctance to enter into close relationships with boys of her peer group. In addition to this, we can assume, from her own story and from the interview material with the mother, that she had been ill prepared in regard to the sexual information which should have been given to her in her preadolescent years.

Downloaded from www.dbraulibrary.org.in

Most striking are the evidences of this girl's continuation of the bisexual orientation, which is characteristic not of adolescence but of the latency period, and equally striking are the evidences of an unsolved oedipal relationship, specifically the acute reactivation of the oedipal conflict within her (and even within her father!) which resulted in various defensive maneuvers used by both in order to control or allay anxiety.

If we review the case material as it refers to this child's early life adjustments and adjustments in the latency period, we can see where and by what method this fault in psychosexual development was inculcated, and how at the present time it is being expressed in blocked development and in unhappiness. In the first place, there is the prenatal concept or image that both parents had of the coming baby, which played no small part in shaping the psychosexual development of this girl. For example, mother did not wish to take up again the duties of raising a baby, inasmuch as it had been over a decade since the birth of her other child. During those years she had turned her attention outward from the home and away from the role of the mother because of the very fact that her only child, Frances' brother, had grown into adolescence. Her interests were directed beyond the home, and she visualized correctly the numerous difficulties involved in withdrawing interests from these activities and again using her energies in the role of mother. In addition to this, there is a suggestion that this mother had many of the outgoing and aggressive tendencies of the male, with possibly a minimum of the maternal warmth that would allow her to derive her major satisfactions from the role of the mother.

It should be noted, too, that both the mother and the father preferred boys to girls, and that it was their wish that this child, when born, would be a boy. So strong was this wish for a boy child that they prepared for the baby's coming by buying "all blue things," as is usual in anticipation of a baby boy. Finally, as an indication of their desire for a boy, they selected the name Francis for the expected child. When the child turned out to be a girl, they merely altered this bisexual name and called the girl Frances.

As in all such cases where the parents have a strong preference for one sex and not the other in their children, it is very easy to conjecture (and probably correctly) that all these prenatal wishes and hopes of the parents were, from time to time, brought to the attention of our patient, Frances. To be sure, this may not have been done directly, nor was it necessarily done with a view to hurting the child's feelings or minimizing her importance; nonetheless, the young girl, knowing this intuitively, knew also (as do all children) that the best way to receive the maximum amount of love and security possible from her parents was to be the type of child (including the sex) that the parents wanted. There is no question but that she set about unconsciously (perhaps somewhat deliberately) to identify in so far as she could with the sex of the child that was most wanted by the parents. In other words, she determined to be as much of a boy as possible. As the case material indicates, she did not engage in any of the activities that would be expected of her if she were a girl. She did not play with dolls nor help with the housework, nor did she attempt to learn the rudiments of cooking. On the contrary, she played like a boy in boys' sports. She tended to dress as boys do, and later, in the preadolescent years, did not make attempts to change this dress to that of girls of her peer group; nor did she experiment in relation to feminine hairdos and make-up.

In addition to this, it will be noted that this girl became a "pal" of her father. They went to sporting events together and did the chores around the house together, and they did these things with the exclusion of the mother. In short, here we have a case of extreme tomboyishness, even boyishness, and subsequently we note a prolongation of this male identification, or at least strong bisexual identification, up to and into the adolescent years.

But, beginning at the age of fourteen and a half, and perhaps earlier, we have hints that it was becoming more and more difficult for this girl to maintain her identity with the male sex and more and more difficult for her to deny her femininity. Not only did the results of physiological growth make it increasingly impossible for her to assume that she was to be a boy, but also we can conjecture that there

Downloaded from www.psychiatryonline.org

were increasing pressures and demands by both her parents, and particularly by her peer group, that she take up the activities that are characteristic of girls in the teen-age group and give up those that are followed by boys of the same age or younger. It will be noted that the father, too, must have been assailed by the same pressures to give up his fantasy that this girl was really a son of his, and also to give up the fantasy that she would always remain close to him and afford to him whatever she was to give in respect to close relationships with people of the opposite sex.

The difficulties faced by this child, and the defenses employed in the face of these difficulties are quite apparent from the case material. In the first place, she found it very difficult to make relationships with boys in her own group because she was, as she states, "afraid of boys." It can be assumed that, because of her identification with boys in the preadolescent years and her minimal association with girls, she lacked the very practical techniques in respect to using proper attire, conversation, and behavior that are so necessary in the launching of even the most modest attempt in establishing relationships with adolescents of the opposite sex. This lack of techniques for identification with the girl's role is further attested to by her seeming inability to make friends among girls and to get along with them. It was only by extraordinary efforts to please them or to acquiesce in all of their plans that she was able to have any friends at all, and certainly she had no close friends nor any of the confidantes that adolescent girls usually have as valuable media for the exchange of questions, the discussion of problems, and the programing of their social life. Hence she attempted to be a boy as long as possible; but the facts of biology and physiological development, plus the pressures by her own peer group, made the maintenance of a bisexual status impossible.

In the face of all these conflicts, Frances attempted three defenses against anxiety, none of which were too successful. Because of the fact that many girls faced with the same conflicts carry these selfsame defenses to such an extreme that they constitute, in and of themselves, behavioral disabilities, I shall comment upon each of them at some length.

1. Both as a defense against her oedipal impulses and as an expression of the unsolved aspects of the oedipal complex, Frances found herself falling in love with older men. Her one boy friend, Louis, was ten years older than she, and she also found herself strongly attracted to the married man who was her employer during her afternoon work hours. Interestingly enough, she gives two reasons for her preference for older men: first, that they seemed to remind her of her older brother; and secondly, that the boys of her own age group were fresh and attempted to make sexual advances to her. The deeper reasons for falling in love with older men (of which Frances is unaware) are probably related to her still-strong unconscious wish for her father's love and the need to seek substitutes for this wish in the form of men somewhat closer to him in age. There is here, too, evidence of Frances' fear of sex and her inner realization that she was totally unprepared to cope with sexual expressions, however innocuous their aim, by any boys of her own age. There is seen in this mode of expression—that is, in her selection of older men as love-objects, a defensive response that is sometimes seen as a transitory stage in adolescence—the supposition that these relationships afford a greater degree of protection from sexual expression on the adolescent's part than is possible in the presence of members of one's own peer group. Unfortunately, many adolescent boys and girls learn that such protection is not forthcoming, and they become victims of seduction by men and women in the twenties or thirties.

2. It is interesting to note that, at approximately fourteen and a half, Frances placed herself on a very severe diet and continued this dieting until she had lost approximately twenty pounds. Dieting among adolescent girls is not an unusual occurrence, but it usually takes on the aspect of a fad, with temporary adherence to admonitions that may be voiced by parents or by their associates. Seldom, however, does one see the pronounced dieting and extreme loss of weight, as evidenced by this patient whom we are considering, without the reasonable conjecture that this need for extreme loss of weight is the result of uncon-

Downloaded from www.dbraincenter.org.in

scious motivations relative to the necessity not to assume the physical habitus and bodily contours expected of adolescent girls who are in the process of growing up. In these cases it is reasonable to suppose that this is another attempt, futile though it may be, to deny their femininity, and as in the case of Frances, to retain a sylphlike or even boyish figure as an indicator that female sexual development has not taken place. It is to be remembered, too, that excessive eating and the attainment of marked obesity in adolescents of either sex (but particularly in girls) can be an indicator that they are attempting to make themselves as unattractive to the opposite sex as possible. Finally, it is not unusual to see children who are struggling with the unsolved problems of early sexual relationships who alternate severe dieting and extreme loss of weight with periods of marked overeating and obesity.

Although Frances ceased her dieting and seemed to have done herself no irreparable harm by this curtailment of food intake, it is well to keep in mind that very serious excesses in this type of response to conflicts can lead to serious emotional and behavioral disabilities in adolescence, and, in fact, in the unusual case they can even lead to death through the physiological imbalances that may be set up by rigid and prolonged refusal of food. I am referring here, of course, to the condition anorexia nervosa, which is seen from time to time at this age level, and which is principally a condition to which girl adolescents are subject. (From time to time, one encounters an adolescent boy who exhibits the same extremely disabling and life-threatening response.) All intensive psychotherapeutic and psychoanalytic work with such adolescents would seem to indicate that the central and most powerful motivating force resulting in dieting to the degree that extreme emaciation supervenes is the desire on the part of these adolescents to stalemate physiological growth in the sexual sphere, and thereby to continue a denial of their identification with the members of their own sex. Coupled with these attempts at maturation arrest and refusal to assume the sex role for which they were intended, there usually is uncovered material that indicates persisting infantile notions of the possibility of oral impregnation, together with strong oral sadistic infantile fantasies.

3. A third mechanism, or rather technique, set in motion by this adolescent girl in her attempt to ward off or deny the persistence of her oedipal impulses toward her father was a deliberate attempt to set up a certain "distance" between them. From fourteen years on, she began to give up her role as a companion and pal to her father. She did not attend sporting events with him, and she refused to be his helper in the chore activities in the household. Furthermore, she was no longer his confidante and understanding counselor. She did not attempt to calm him down in his moments of anger at the mother, nor did she try to bring him out of his intermittent states of uncommunicativeness and moodiness. The father of this adolescent also seemed to follow this pattern of establishment of both spatial and psychological distance between them. It was as if he (owing to his own unconscious positive feelings of which he was, of course, unaware) was aiding and abetting, in so far as he could, his daughter's attempts to cope with both the unsolved and the reactivated elements of a strong oedipal complex—a task in development that should have been solved when the child was four or five. We can see, of course, in the light of the psychosexual history of the child as outlined above, why this solution to a normal task in development could not be found at that earlier age level.

Two frequently observed types of responses on the part of both adolescent children and their parents of the opposite sex are to be generalized from the material presented in this single case. The first is that, without a single word being spoken openly, the unconscious of the adolescent child "speaks to the unconscious" of a parent of the opposite sex, and vice versa. The psychoanalysis of adolescent boys and girls highlights this phenomenon repeatedly. Secondly, the behavioral response engendered in both, in the face of such oedipal conflicts, is this gradual but none the less definite establishment of "distance" between the child and the parent. This type of response is not referable principally to the mechanism of

Downloaded from www.PaulaHeimann.org

"devaluation of the parent" that is so large a part of the striving of the adolescent for independence and autonomy, but rather it has a specific reference to attempts at the solution of persisting and operating remnants of previously strong and powerful oedipal impulses.

## ¶ The Problem of Overcoming Dependency Upon the Parent and the Striving for Relative Independence and Self-Direction

A problem of great concern during the adolescent years is that involved in, and motivated by, the drive for emancipation and independence on the part of the child.[4, 8] Obviously, this is a drive for *relative* independence, inasmuch as the child, for a number of years, has to maintain a certain dependency upon the parent for care, protection, and sustenance until he becomes self-sustaining. As suggested above, a successful solution of this problem is dependent upon, and in large part influenced by, the solutions that have been made in earlier life to the problems involving security or insecurity, the freedom for exploration of the environment, and the affording to the child of opportunities for self-direction and decision making, in gradually increasing amounts during the latency period. In other words, if the earlier adjustments in regard to these items in the child's life have been faulty or inadequate, the problem of increasing freedom from parental control, the overcoming of excessive dependence on the parent, and the gaining of a state of self-sufficiency will be much more difficult. However, the internal pressures of the child, plus the pressures from colleagues his own age, from his parents, and from society as a whole, insist that he find a solution for these problems involving the attainment of independence in adolescence.

Nevertheless, the drive for adult status in adolescence immediately sets up certain conflicts within the child. On the one hand, the adolescent feels driven to be independent of his parents, to make his own decisions regarding his comings and goings, and to have a right to choose his own friends and to determine his own educational and vocational future. Everything about him and everybody about him insists, or seems to insist, that he shall assume these responsibilities. On the other hand, there are always many fears that contemplated independence brings to the mind of the adolescent boy or girl. Together with his drive for independence, the adolescent has a parallel or concomitant fear of losing or giving up the parents and all the material and emotional gifts that they can give to him. He fears also the possibility of making the wrong decision, of choosing the wrong type of friends, of selecting the wrong course of study, or, perhaps, of selecting the wrong intended vocation for his life's work. Adolescent children do their very best to conceal carefully all these fears in order to convince their parents and others of their competence, their all-knowingness, and their bravery. However, the elements of this conflict manifest themselves in that typical state of adolescence characterized by continual indecision and change in respect to needs, desires, intentions, and programs.[1]

The various aspects of this initial drive for emancipation from mother and father are seen quite clearly in the foregoing material relating to sixteen-year-old Frances, whom we are using as a paradigm and model for outlining the major problems seen at the adolescent age level. It will be noted that she makes her own clinic appointment; she refuses to have her parents pay for her interviews; she is unconcerned whether or not they wish her to come to the clinic for help, or whether they wish to involve themselves in the help that may be extended to her or to them. She refuses to take their advice and counsel and seeks others' counsel and advice from what *other* source is available to her. On the other hand, she complains that the parents do not give her credit for the good features of the counsel and advice that she gives them on matters within the household, and feels that in the eyes of her parents, or at least in the eyes of her father, "I can never do anything right." Furthermore, she takes music lessons over their protests and pays for them herself. She chooses a boy friend with whom they do not wish her to associate. She wishes to go to one college; her parents

Downloaded from www.dinamikilmy.blogspot.com

protest and insist that she go to another. She alleges that her brother, not she, has always been the favorite of the parents; and finally, she prefers a religion other than that followed by her parents. Coupled with all these indications of strivings for independence and self-decision, she works afternoons and Saturdays in order that she may not be dependent on the parents in a monetary sense.

It should be noted, however, that the parents of this girl, as is true with the parents of all adolescents, seem to be caught in the selfsame conflict.[5] These parents wish for Frances' independence and self-sufficiency, but they also fear and dread the loss of her love and the removal of her dependency upon them. It is very difficult for parents to accept or even contemplate the fact that they are no longer so absolutely necessary in the lives of their children at fourteen, fifteen, and sixteen years of age, and thereafter, as they were when their children were infants or in the middle grades. The complexities and complications in responses for ill or for good in the face of these two selfsame conflicts in the adolescent child and in the adolescent's parents are sometimes extremely difficult to clarify in the minds of either the parents or the child, and many times they are even more difficult to treat effectively.

Although it does not appear as a prominent factor in the case of the adolescent girl under discussion, there is one mechanism sometimes involved in the drive for emancipation on the part of the adolescent child that occasionally can lead to very serious or even disastrous results as far as the child's present behavior or future life is concerned. I refer here to the mechanism of "devaluation" of parents that adolescents seemingly must first make in their advance and progress toward adulthood. This mechanism is used by all adolescents, and in more than 90 per cent of the cases it is safe to assume that it is not used to the degree that a behavioral disability results. The origin of the need for this extreme devaluation of the parents as a stage or step in growth seems to lie in the fact that this is the one best way in which the child can modify his infantile pictures and evaluations of his parents as being both omniscient and omnipotent. This internalized image of the parent as being omniscient and omnipotent must be modified, and modified drastically, if the child's self-identity is to be assured and if he is to progress successfully to adult status.

Although these devaluations of parents are innumerable, and broad in extent, they usually include the areas of action, the various ideas, and the ideals and ambitions with which the parents have been vitally concerned in their attempts to bring up their children in a mentally and socially healthy manner. There is, at least temporarily, a repudiation of all that the parents feel is worth while. Although this overthrow of authority usually may be confined to authority as exemplified by the parents, in some instances there is a temporary tendency to overthrow all authority and to devaluate all authority figures in society, a maneuver that may lead to definitely antisocial behavior. At any rate, even in the normal child who remains relatively well adjusted in adolescence, his devaluation of the rules of conduct and the moral, ethical, and political principles enunciated by the parents, in large measure leaves the child temporarily with no certain values and leads to the intermittent, sporadic, and sometimes chaotic assumptions of values inherent in almost numberless other individuals or groups of individuals. This rapid, changing assumption of varying and even conflicting values leads, in turn, to that picture and status of "role diffusion" that has been commented upon so many times in the literature as characteristic of boys and girls at this stage of development.

As an example of the inherent destructiveness possible in the use of this mechanism of devaluation, I should like to cite some brief excerpts from another case, that of a fifteen-year-old boy. The material from this case is also important, to my mind, because it emphasizes the persisting effect upon adolescent task solution of poorly solved tasks of development which were present in the child at earlier age levels, notably in respect to (1) rejection by the mother, (2) unsolved oedipal wishes, and (3) sibling rivalry. It is equally important in that it demonstrates quite clearly the effects of previously established neurotic conflicts upon

Downloaded from www.dbraulibrary.org.in

the adolescent's choice of his educational future and his vocational choice. These will be commented upon below.

Allen, 15, was formerly an honor student but now refuses to do any work in school. In the past two years he has become increasingly antagonistic and sarcastic to both his parents. He seems to have developed almost a hatred of his father, and seizes every opportunity to belittle him—his work, his ideas, his interests, and his associates. Although at times Allen still evidences regard and affection for his mother, there are periods of a day or so when he shows open and marked hostility toward her.

Both parents have always worked hard and are very ambitious for the patient and his nine-year-old sister. They state that this is the second episode of such extremely belligerent behavior on Allen's part, the first having occurred over a period of months following the birth of the sister.

Allen was petted and fondled and given much attention by both parents—and in fact was "spoiled"—until his sister was born when he was six. Since that time, because of the demands of the new baby upon the parents, plus demands on their attention of activities beyond the home, Allen's needs and wishes have received much less consideration from them. He reacted violently to this rejection and began to show unabashed jealousy of his sister, did his best to come between her and the parents, and began to show open hostility and hatred toward both father and mother; and even though the parents were quite willing to grant him things about the house that he wanted, Allen began to steal food, candy, and money, preferring this method to actual gifts from them.

Allen's early development was normal. In fact, he was precocious in that he talked before he was a year old. He was breast-fed for five months; he reacted in a very antagonistic fashion when put on the bottle, which he hated. His mother forced him to drink from it, waiting until he was tired out and nearly asleep to accomplish this. In a six-month period, when he was 4½ years old, he went through the whole gamut of childhood illnesses.

Allen is of average height and weight, fair nutrition, with soft small muscles. He tells of occasional dizziness and car sickness. His vision is very defective, and he has worn glasses since he was eight.

Allen is in the eleventh grade, and for the first time is not even passing in some of his subjects. At present he shows a particular interest in the German language, Hitler, and other things German. The mother and father are particularly distressed that Allen is failing in school and that he shows little or no interest in going to college or in becoming a professional man—ambitions which they have had for both of their children.

On psychological tests Allen was found to have superior mental ability, with an I.Q. of 123.

Now what are this boy's scholastic and vocational ambitions? Our interviews with him are startlingly illuminating in the light that they throw on the subtleties involved in a child's determination of his career, and on how cautious we must be in evaluating our children's ambitions for school and for the years thereafter. Through a consideration of these, we can see to what degree and to what serious ends the mechanism of devaluation of the parents can be directed in adolescence.

In interviews with us, Allen tells us that he wants to become a professional fencer. He is not interested in ever going to college or entering any profession. Now in case you may feel that this ambition of Allen's (to become a professional fencer) is akin to the passing fancy of a very young child, it is to be noted that Allen is dead serious about this ambition, and in addition our patient is 15 years old and has long since passed the "fireman, cowboy, and Indian" stage of the 8- or 9-year-old. Furthermore, although this boy has refused to pay any attention at all to his school studies as his parents fervently wish he would, he has read everything he can find on all aspects of fencing and about swords and armor from ancient times to the present, and his knowledge of these subjects is astounding. To this he has recently added an interest in archaeology and geology and old Roman coins.

He tells us, "My friends call me a Germanophile because I like the Germans and the way they do things." He is interested in Germans and Germany because of their arms and the armor they wore (another interest), and the fencing that the Germans do, and he is interested in their guns and daggers. Germans and Germany go with

Downloaded from www.pdfbooksfree.pk

arms and armor because they are great fighters—that is, the Prussians are. He is interested in the militaristic Prussians, who, he says, are the best militarists in the world. At the time of his first interviews, he was voluntarily taking German studies with his Latin teacher, though he would not do his Latin lessons.

Another interest is riding. Riding goes with fencing, and they go together because you can use a long saber when you ride, and you can control the prancing horse with one hand, and cut heads off of people with the saber with the other. This led to his discussing his desire for a pair of riding boots. He would like a pair that come up to his knees because they look so well and sound so well as you tramp on the pavement with hard leather heels. If you are on horseback with a long saber and with the boots, you are practically invincible.

He has an enormous amount of information about pistols and states that the best gun today is a German gun, although he also likes some specific kind of ancient gun, a type unknown to the doctor. He needs to get more money in order to get more swords and more armor and more guns. He sees no end to his desire for more swords. "I'd like all the swords and all the armor in the world if I could have them." I said that that wish to have all the armor in the world must stand for something else, and he said, "Yes, for something all right, such as nicking somebody I don't like and defending myself. I should have been born six hundred years ago, Doctor, because if I had, and there were people I didn't like, I could kill them all outright, and it would be fair because they would have the same chance to kill me with their swords."

He thinks he may go to Heidelberg rather than Harvard, but then he doesn't know because if his saber breaks in a fight at Heidelberg, he might be killed.

In the next interview Allen has a new interest. He is learning the alphabets of various languages, and writes out the Russian alphabet for me and his name and mine in Russian. The Russians are proving to be more warlike than the Germans, and hence he is beginning to admire them more than he does the Germans.

In later interviews he discussed his newest interest, going hunting with his father. This is soon noted by the doctor to be a serious and precarious area of activity on this adolescent boy's part. Hunting with his father is by no means taken up by Allen on a pal-to-pal basis. He does it in order to demonstrate his superiority over his father in the use of firearms and in killing. He ridicules his father for his mistakes. He takes delight in telling me that father is stupid in his lack of knowledge about guns. He tells me father is going to get killed in the woods some time if he is not careful. "Somebody is going to get killed out there hunting." Again, long riding boots come up as an issue.

A week later he took up again the discussion about another proposed hunting trip with his father. "If that fool aims that gun at me again I'm going to shoot him." He told about father's buying a red and black checkered shirt to wear in the woods. "At twenty feet you can't see the red at all! *Somebody* will surely shoot him!" (Father is very careless when hunting, and according to Allen doesn't know how to handle guns.) There follows a dissertation about the gauges and calibers of guns, and about rules and regulations of hunting in Massachusetts. (We were somewhat concerned about this material in relation to hunting and suggested to the parents that perhaps the father and son should not hunt together for a while.)

Allen tells us later that he wants to take saber lessons because it is more dangerous, and he is eager to buy German sabers at $23 per pair and riding boots at $14 per pair. "You can get your head cut off, but of course you can cut off the other fellow's head, too, if you're fast enough."

I need not emphasize what this boy is trying to do through—and to express through—his educational, recreational, and even his vocational interests and intentions. I would emphasize, however, how seemingly unaware both the boy and the parents are of those drives and needs and of the repetitive, continual demands that are present to satisfy his extreme aggressive and devaluative impulses toward them. I think you can see, too, how terribly close to expression with dire results these devaluative drives seem to be. I shall not go into the intricacies of the treatment of this adolescent boy, except to state that the aims of treatment were to ensure that he gradually came to realize the meaning of this behavior; that is, that his life

Downloaded from www.dbraulibrary.org

as an adolescent was dedicated literally to fighting a sham death battle against his parents, particularly against his father.

It is to be noted also that, in contrast to our patient Frances cited above, the mechanism of devaluation of the parents in Allen has seriously involved the "work area" of the child, that is, the area of education. Every attempt possible is made by Allen to eradicate within himself the assumption of his parents' educational ambitions and hopes for him that he did assume in his earlier school years.

And finally, it is quite apparent that Allen's attempts to solve the problem of the necessary and expected independence demanded of adolescents have reactivated in full force the faults in the solution of earlier tasks in development which were presented to him in the oedipal period and at the time of the birth of his sister when he was six.

It is to be noted, too, that there was a definite "spread" of the personality developmental fault in the latency period to the extent that there was a faulty solution of practically all of the tasks of this period that relate to the control and sublimation of the aggressive drives.

## ¶ Tasks in Adolescence Relating to Educational Achievement and Vocational Choices

As can be seen in the clinical cases briefly outlined above, two of the major tasks of the adolescent involve the making of decisions (in many instances lasting and irrevocable decisions) relative to (1) present and future educational programs and (2) the choice of a lifework to be followed as an adult.

In both of these cases, the attempts at a solution of these tasks were influenced and altered appreciably by the neurotic problems and defenses not directly concerned with either education or vocation. For example, in the case of Frances, her attempts to continue in the "pseudo boy" role prompted her to hope to become a physical-education instructor, though she gradually but definitely modified these ambitions toward femininity, first by her hopes to become a physician (an essentially male profession), and later by her desire to become a nurse or social worker. But it is to be noted that her endeavors to devaluate the parents and their ideals did not lead to an abandonment of educational aims and aspirations, nor did they lead to a status of underachievement.

In the case of Allen, however, we see the disastrous effects of long-continued neurotic expressions both upon the work output in school and in his abandonment of all vocational aims consistent with his intellectual ability. His desire for revenge upon (even destruction of) his parents resulted in the choice for an ultimate vocation of a type of "work" (fencing) that should have become—and remained—the subsidiary expression of a hobby or avocation. He became, in essence, one of the very best examples of both the "underachiever" and the "deviate overachiever" that are seen frequently as single-behavioral disabilities in the adolescent-clinic population of any child-psychiatry unit.

These aspects of adolescent cases are valuable for us to consider because they do highlight the feelings and urges, and the fantasies based on these feelings and urges, that are present in many adolescents and, in turn, are directing their interests or lack of interest in their studies. I think you can see, too, how difficult it can be for the parent in his or her attempt to change such attitudes. It is difficult, in the first place, because the nuances of feeling are so subtle in their expression, and in the second place because the parent is usually involved, in some way or other, in the very problem he is trying to aid the child to solve.[2]

Up to this point I have emphasized those attitudes toward studies and jobs that are fixed by the earliest emotional responses of the child to frustration, insecurity, loss of love, and deprivations—all of which may be difficult to detect and even more difficult to alter to any degree. There are other things, however, which can occur in these interpersonal relationships of the child and parent which usually become formalized *later*, and about which we can do even more to eliminate or—much better—if forewarned, to *prevent* their becoming a harmful force in the child's life at all.

What parents need to do, of course, in respect to their adolescents' ambitions, is to see to it that their appraisal of their children is as

Downloaded from www.dbraulibrary.org.in

realistic as they can make it—realistic as to the child's innate abilities along intellectual, social, athletic, and even vocational lines. It is difficult for parents to entertain these realistic appraisals of their children and their desired expressions, likes, and dislikes. But there are certain difficulties which can get in their way about which I should like to comment:

1. In the first place, I shall comment upon a cultural phenomenon in our American life that seemingly has always bedeviled American parents and, even more, their adolescent children. This cultural notion is the desire (in fact, the feeling of necessity) on the part of American parents that their children should jump from the economic class in which the parents find themselves to the next higher economic class, if they are to consider themselves at all successful. Most parents feel this to be a necessity, and their need is transmitted to the children directly and indirectly in hundreds of ways. The laborer feels that his child should be trained for the white-collar class; the clerk's son, for business; the businessman's son for one of the professions. It is a subtle though powerful force in our culture. Many times this is harmful in that it keeps both the parents and their children from making the realistic evaluation of abilities and goals that is so necessary if either parent or child is to have any peace of mind. All children cannot be greater successes than their fathers or mothers, and some children (being much more realistic in the matter than their parents) recognize this as a fact and would be willing to accept it. But unfortunately many parents will not let them—such is the pressure of this centuries-old drive in our American society.

2. A second source of occasional parental lack of realism concerning their child's educational and vocational future is their tendency to identify their child inextricably with some other person, and act toward the child—and expect the child to act toward them in regard to his studies and his future—as if the identification really were true.

*a*) First and foremost is the parents' identification of the child with themselves. There are many unconscious motivations behind this sort of behavior on the part of the parents, and all of them must fight it. They must fight it because, by such identification, they try to thrust upon the child the ambitions and hopes that they had—or still have—for themselves, and they are as impatient with the child because he does not embrace them as they were with themselves because they did not fulfill the selfsame hopes and ambitions. The child may or may not wish to be what the parents (one or both) dearly wished to be, but, in the interests of his mental health, it is best for the adolescent to decide this point.

*b*) Another basis for unrealistic parental attitudes sometimes arises from their identification of their children, not with themselves but with someone—usually a family member—whom, for some reason, the parent or parents deem more worthy than themselves. Thus the boy soon learns from his parents that they consider that he is just like Uncle Joe and hence will, of course, be a lawyer—a very successful lawyer—like Uncle Joe. Or the daughter Elizabeth is exactly like—in speaking and in mannerisms—second cousin Alice, who is such a hit on the New York stage; or she is as intellectual as Aunt Nellie, who was a professor of philology at Vassar. The intricate and extensive struggles that adolescent children go through to live up to—or once and for all violently to deny—such identifications are frequently seen.

*c*) In the third place, there is the identification of the child with a class monopoly on one particular college, or one particular graduate school, or one particular profession, that makes realistic evaluations and choices on the part of both parents and children very difficult. For example, for generations no Snodgrass has ever gone to any college save Yale, so little Elmer shall go to Yale. Or for generations there has always been a representative of this particular branch of the Smythe family on the faculty of the Harvard Medical School and the staff of the Massachusetts General. So Jimmy Smythe soon—very soon—learns of his preordained identification. Again, such identifications make realistic choices for Elmer and Jimmy and their parents unnecessarily difficult.

3. There is sometimes, too, the parents' compelling need to have their child stand out as a unique individual—that he shall not be the *usual* youngster, but that he shall be *unusual* in his intellectual, vocational, and avocational

Downloaded from www.pbraintherapy.com

accomplishments. (Many times, the child's actual endowments prevent this.) The average child, even though he is happy and well adjusted, is sometimes not a source of contentment to the parent.

4. An associated phase of development of quite a different sort, but equally as troublesome to parents of adolescent boys and girls, is an assumed hyperintellectualization on the part of the child. By this I mean that the child may demonstrate an absorbed interest in theoretical abstractions and in intricate economic and social problems that either alarms the parents concerning the child's stability or leads them to assume that this proves the child is fitted for some highly intellectual vocation. It usually portends neither but, rather, indicates some attempt at solutions to problems regarding sex and morality by removing them from *that* realm and talking about them endlessly in the safer area of the abstract. Educational plans fixed with the child on the basis of such temporary developmental phases, too, can be unfortunate.

I have pointed out some of the barriers to parents of adolescents assuming such attitudes, in order that the parents can be helped to avoid them. But there are, in addition, other things which both the parents and the school can do to aid the adolescent child himself in getting realistic appraisals of himself and of his future. Both can be tolerant and can encourage in our adolescents a sensible estimate of themselves in physical and mental attributes, as they compare themselves to their associates of the same age group. They can urge them to be justly though quietly proud of their assets, and forestall, modify, and eliminate feelings of inadequacy that may temporarily arise because of unmodifiable liabilities or lacks. It is obvious that the schools can and should do more of a specific nature in this area than is now done. Definite attempts should be made in all schools, through courses in educational and vocational guidance, to acquaint adolescent children with the widest possible knowledge of the greatest number of study and job choices. Even though the adolescent may carry out his earlier life's wishes and fantasies in adult life, still society offers him—if he can but get a survey of them—hundreds of worth-while and satisfying ways of doing so. This material should be supplied him. This, in turn, is "realistic" in regard to needed information—needed by all adolescents.

## ¶ The Control of Heterosexual Impulses and the Establishment of an Acceptable Moral Code in Adolescence

The adolescent, in his attempt to establish and maintain a socially acceptable and emotionally satisfying code of behavior and attitude in relation to the expression of the sex instinct, finds himself confronted with a twofold problem, the varying aspects of which constitute the nuclear conflict in the throes of which adolescents usually find themselves at some time in the turbulent years of maturescence.

1. One aspect of this problem is the absolute necessity that the adolescent make an "identification" with the members of his own sex. This identification must be established in such a manner and with such rigidity that he overcomes, in so far as is possible, the inherent bisexuality with which all of us are endowed. Perhaps the subtlety of this identification makes it almost nonapparent, but it is a process and drive that best explains large segments of the adolescent's behavior. Particularly is this process involved in that behavior of the adolescent that seems to us bizarre and chaotic. However, in normal times and under normal social conditions, this establishment, through identification, of the orientation necessary for fulfilling the future biological role of the individual is accomplished without incident by the incorporation of the ideas, attitudes, and social and moral outlook of the parent or of parent substitutes, such as the teacher, the club leader, the family clergyman, or the physician.

This process is a gradual process of maturity, subject to acceleration, retardation, or even regression, and, as a matter of fact, the maturity or immaturity of the individual adolescent can in large part be judged by the degree to which this particular process has advanced. On the other hand, the failure of the child to "grow up," "become a man," "mature," in the

Downloaded from www.uraumay.com

sociopsychological sense, will, in turn, lead us to an investigation of the kind and number of "identification objects" that the child has had in his immediate environment—father, older brothers, neighborhood leader, and others. The adequacy of these objects and their relationship with the child have to be considered.

The point of importance for us, however, in our consideration of the sex behavior of the adolescent, is that the adolescent not only must make this identification with his own sex but also must demonstrate to elders and colleagues, by his actions, that he is no longer the shy, diffident, bashful schoolboy that he once was. The directness or indirectness of this expression of the instinct, or to what extent or limits the adolescent goes in this all-important "proof," or in what way he accomplishes it to his own and his comrades' satisfaction will depend on many factors, but the expression will inevitably take place. It might be well to note here, in the interest of tolerance of the adolescent, that as far as the expression of maturity goes, he is "condemned if he does and condemned if he doesn't" show evidence of maturity of sexual interest and outlook, and this even by his own parents. As stated above, the fact that parents wish their adolescents to grow up and be independent, and that at the same time they wish them to continue to be children and dependent upon them, has never made the task of the adolescent an easy one.

2. This, in turn, leads us to the second aspect of the twofold problem confronting the adolescent in his attempt to find an adequate and acceptable code of sex behavior. Concomitant with the cultural demands that adolescents become identified with members of the proper sex, and that they give evidence of readiness to assume the role of father or mother later in life, is the ever-present demand that the adolescent forego the expression of the sex instinct. That repression and control are necessary if the best interests of the child and the community are to be served is, of course, beyond argument. What interests us here is the manner in which this control of instinctual urges must be carried out, and the direction or source from which the control comes.

The hoped-for mechanism of control is, of course, an *inner* control—that the adolescent himself, by the time he reaches maturity, will have incorporated standards, repression mechanisms, or inhibitions of such kind and nature that, no matter what external changes take place, he will be able to hold in check his instinctual drives. The presence of this inner control, this ability to forego the pleasure of the moment for a later socially acceptable type of expression, in short, the strength of the ego of the individual, is, like our previous criteria of identification, also an indicator of maturity.

Needless to say, the ego strength of the adolescent is periodically weak, and the child gives evidence of his endeavor to strengthen these inner controls through external controls or external "consciences"—through his religious interests, club interests, and self-imposed codes and rites. Of equal importance is the fact that external factors can accelerate or retard this maturity. In the main, however, the most powerful controls that make it necessary for the adolescent to forego expression of the sex instinct are external ones—the supervision and prohibitions of parents and law-enforcement agencies, and the scorn and condemnation that such expression would evoke from families, neighbors, and colleagues. These forces, when present, properly insist on a mature attitude and a mature respect for convention, and they aid and strengthen, in turn, the inner mechanism of control that the child has already partially established.

Both aspects of this twofold problem of maturity can be accelerated or retarded by external factors, and it is my feeling that either a spurious retardation or a pseudo acceleration of development is apparent in all atypical, antisocial, or even pathological behavior in adolescents.

A further factor of influence in respect to the adolescent's identification needs to be mentioned. It is usually assumed that children identify themselves with the parent of the same sex, and that thereby, under favorable conditions, worth-while standards of behavior are inculcated. In regard to the deeper and perhaps more fundamental aspects of personality development, this is undoubtedly the case,

Downloaded from www.brainlibrary.org.in

but the more immediate objects of identification and patterns of behavior that the adolescent chooses are the members of the age group just senior to him, and he strives to participate in the activities and interests which they exhibit. Hence, if you would understand the atypical, asocial, or even antisocial behavior of *early* adolescents at any particular period or under any defined set of external conditions, it is well to study the behavior of the *late* adolescent group, for early adolescent behavior will always be an approximation of it.

I should like to present, at this point, some clinical material in order to illustrate the various struggles that the adolescent may have in respect to the control of sexual drives and to highlight the defenses employed to establish and maintain these controls—defenses that vary in nature and in intensity.

I have chosen for consideration an adolescent who has been subjected to both an overrigid ("overgood" if you wish) environment and a particularly loathsome environment, and hence the material will illustrate (in the extreme, of course) many of the problems, at least the sexual problems, that are seen in all adolescents in both types of environments.

Arthur, 16, is an only child who is living in a slum area in Boston with his mother, Mrs. W. The father and mother were divorced when Arthur was 3, and he went to live with his maternal aunt, a schoolteacher. Arthur lived with this aunt until he was 14 years old, when the aunt died, leaving her estate to Arthur. This is dispensed through her attorney. After her death, Arthur returned to live with his mother, who married for the second time six months later. Stepfather had had two admissions to a state hospital, and was recommitted there a few weeks ago. Arthur followed his aunt's religion, but since her death has gradually grown away from the church. Arthur and his mother live on the $15 a week dispensed by the attorney, plus the $3 a week contributed regularly by the boy's own father.

A family agency had known this family eighteen years before, and on referral a few years later. Home conditions recently were found to be utterly deplorable. Mother is epileptic and has deteriorated. Stepfather was at that time home from the state hospital but was unable to work. Arthur showed many alarming symptoms. He feared that he was going crazy, considering himself weak, puny, and run down, and for this reason was taking a muscle-building course. He often felt that he was being laughed at and talked about by all the people in his neighborhood. He was quite bitter about stepfather and resented his being paroled from the hospital to the home.

Practically nothing is known about the father except that he is supposedly of good family. Mother is the younger of two children. She is still having frequent petit mal and grand mal seizures, spends a great deal of time out in the neighborhood, is behind in her bills, and is a very poor housekeeper. She seems convinced that some of the men in the neighborhood have designs on her. Arthur's life from the age of 3 until he was 14, when he returned to live with his mother, was in great contrast to the present. The maternal aunt was an art teacher, a rigid person of high ideals. She owned her own home, gave the boy excellent physical care, was very religious and reared him in her faith, and imbued him with ideals for a college education and with an appreciation of good books and music.

Very little is known about his early development and childhood personality. He was a close companion of his aunt while she lived, and probably had no friends during that period. Since returning to live with his mother, he has not only been friendless but has often felt that other children in the neighborhood hate him and ridicule him behind his back. He is nervous, tense, lonesome, sensitive, and unhappy; spends a good deal of his money buying secondhand books on electricity; and paid quite a little for the correspondence course on muscle building. He attended camp this summer, and while his adjustment there was not too bad, he was unhappy, did not wish to remain, and came home after a few weeks. He says that he wants to attend a university and take up electrical engineering.

On physical examination Arthur was found to be slightly short for his age and ten pounds underweight. He has marked facial acne. Throughout the examination he showed marked concern about his physical condition and asked numerous questions about the various body systems examined.

On the psychological examinations Arthur was found to have an I.Q. of 111, with a Performance

www.freebookzone.com

I.Q. of 116 and a Verbal I.Q. of 102. He evidences no special disabilities.

I should like to summarize in some detail the material covered by this adolescent in his first eight interviews at the clinic. These can be divided into two parts, according to the material presented. The first, which includes four appointments, had to do with the following topics:

1. There was an almost continual condemnation, on Arthur's part, of Mr. W, the stepfather, still ill with an agitated depression. The boy was particularly distressed by Mr. W's going out on the street where everybody could see him, thereby bringing disgrace upon Arthur and his mother. Arthur openly wished for the man's death or wished that he would be taken back to the mental hospital, because of the effect that he was having on Arthur's mother. When Arthur was questioned about this, there did not appear to be any cruelty. On the other hand, there seemed to be a rather warm relationship between Mr. and Mrs. W. But the boy was particularly concerned with the effect on the mother through the alienating of her friends. In other words, the stepfather's "craziness" was going to be interpreted by the neighbors as craziness on the part of all three in the household.

Arthur was particularly angry because the money which came to him from his aunt's estate was being used to support Mr. W, and there is no question in the examiner's mind that Arthur would have carried this hatred and antagonism to the point of starving Mr. W if he quite dared to do it. As stated above, much of the hour at each appointment was taken up with this boy's open hatred of Mr. W. No amount of explanation on the examiner's part that the man was ill and needed attention and help, and that we would do our best to see that he got it, modified any of Arthur's feelings. The boy, himself, did not disguise at all that he was extremely jealous of Mr. W and wanted his mother all to himself. He covers these underlying feelings by a pretense of overt hatred of the mother.

2. The second important feature of his discussion with the doctor had to do with Arthur's physical condition. The boy complained bitterly of his lack of strength, of the fact that he was inferior physically owing to lack of proper food because his mother wouldn't feed him or because he had to go out to eat in restaurants. Arthur has had a persistent acne of the face and attributes this to his mother's neglect, her not giving him the proper food. At this stage of our discussions, he told us about the course that he was taking with Mr. Atlas to improve his physical condition, and was very much worried about his ability to carry out the provisions of this correspondence course in physical exercise. He did not wish to go to the YMCA or to any other group placement, not because he was not interested in such programs, but because they would take time from his own correspondence course in physical betterment. He asks many questions regarding his physical condition, carefully skirting the area of sex, but reaching out for some help in relation to fatigue, lack of concentration, and other well-known adolescent worries. No attempt was made at this time to interpret these meanings to him.

3. As stated above, much of Arthur's concern had to do with money matters. The boy is determined to control his money, to give none of it to Mr. W, and to give to his mother only such amounts as he himself deems necessary at the moment. This control of money matters extends to the paying of rent or the buying of some particular type of food at a particular time; and Arthur attempts to dole out the money piecemeal, always complaining that Mr. W eats too much. His attitude in this regard can be summed up by the statement, "Why is he allowed to eat when he doesn't work?"

4. Little is said by Arthur regarding his early life except that he veers from painting it in rosy colors, as a time when he had all the food and clothes he needed, and the house where he stayed was warm and there were no rats or cockroaches, to a condemnation of the aunt (who was a schoolteacher) as a very restrictive guardian who never allowed him to play with the boys in the neighborhood, though she might allow him to bring certain ones into the house, and who gave him many long talks about the evils of sex and of association with bad girls. However, Arthur states that at that time he was happy. He attended church with his aunt, went to Sunday School, and, even with the restrictions which she imposed, her death was a terrible blow to Arthur. He never speaks of his aunt without crying, and goes over and over the circumstances of her sudden death on the beach when they were spending Sunday

Downloaded from www.dbraulibrary.org.in

there. There follows always in his productions a contrast between that life and his poverty, destitution, and lack of love in his present home.

5. Arthur does not go out socially. In this early period of his talks with us, he emphasized the horrible conditions of the neighborhood in which he lived, the bad people who lived there, the fact that he didn't trust any boys or girls for fear of what they might do to him. He would have nothing to do with any suggestions that might be made as to his association with the Neighborhood Settlement, the YMCA, or his returning to his church in order to get allied with young people. He never ventured out of his house after school; and it should be added here that Arthur is determined that he will get a high-school diploma, and spends all his afternoons and evenings studying. His marks last year were average or a little lower than average, but he did manage to get promoted and is a junior in a technical high school at the present time. His ambition is to work in some field of radio.

During this first month of Arthur's coming to the clinic, our attention was directed to two things: (1) the necessity of hospitalization for Mr. W and physical care of the mother, and (2) possible camp placement for Arthur. Arthur accepted a placement in a caddy camp only after considerable worry and talk, and arguments with himself and with the examiner. It was very obvious that this boy did not wish to leave his mother and then take chances with associations with boys his age in camp, but he always replaced these possible positive feelings by stating that he was not going to leave Mr. W and his mother there to "eat up my money." However, he did go to camp, though he remained there only two weeks, and upon resumption of treatment this fall, which brings us to the second half of Arthur's discussions, he stated that he "could not stand the loneliness" at camp. He missed his mother and wanted to get back to her. He summed up by stating, "I would go for a walk in the evening, and I would take a long look at that empty lake near the camp, and I became so lonesome that I just had to go home."

In the second series of four interviews, Arthur's productions changed somewhat, and he gradually turned away from the external problems to problems and conflicts of his inner self. For example, he told that at 12 years of age, he first learned about sexual intercourse together with the evils of masturbation. He still was not sure that he knew about procreation and wanted us to help him with information. He was given a book to read, and upon completing it stated that it wasn't very satisfactory because it didn't answer his questions. The examiner told him that we had planned to have a follow-up session in these matters, and asked him what his problems were. He was unable to tell us for some time. However, he returned to it later in relation to his physical condition when he was complaining about his inability to gain weight, and the fact that he felt he was going to die. When asked what his fears were about dying, he said, "I didn't know that I was being poisoned mentally." On further questioning, which was done with great difficulty because of the boy's reticence, it was found that he had equated masturbation and gonorrhea, and he was desperate for a cure in order that he might not go insane. He had seen the word gonorrhea in an advertisement, looked it up in the dictionary, and found that it was characterized by (and these are Arthur's own words) "a mucopurulent discharge." He tried to find out what a mucopurulent discharge was, and the nearest he could find to it was a description of semen; and hence he drew the conclusion that masturbation and gonorrhea were the same. Arthur made a further erroneous elaboration that untreated gonorrhea became syphilis, and that he was going to die in an insane asylum because his brains were rotting. He said, "What can I do, Doctor, to get over this disease, this terrible disease? You are a psychiatrist. Tell me what I can do so that I can once more get control of my mind." The patient shouted this request in a panicklike manner, and it was some time before we could reassure him. He kept repeating that he did not want to go insane, that he didn't want to end up in an insane asylum like Mr. W. He wondered whether Mr. W had syphilis. He wondered if his mother's spells were caused by syphilis, because they were epilepsy, and she had been in a "mental hospital" for them.

(We then started a long and detailed re-education of Arthur regarding sexual matters and venereal disease, and in the course of these discussions many of Arthur's attitudes as to association with boys and girls became clear.) It was

Downloaded from www.pbookshop.com

soon apparent that he did not fear his neighbors because they thought Mr. W was insane, but because he was afraid they would begin to think *he* was insane because of his own "disease," and hence all of them would know that he and his mother and Mr. W probably had syphilis. He did not wish to associate with other children because of his fear of contaminating them, because he did not wish them to know he was diseased. (These thoughts he had had since the age of 12, and he very definitely dated it to his reading the dictionary at that time.)

Since this period of re-education, Arthur has been more and more concerned with trying to make contact with some boys and girls his own age in some groups in the neighborhood. His attempts, however, have been merely intellectualistic in that he continually goes over and over the ground with me as to why it is impossible for him to join the local church activities or to go back to his own church. He continually refers to the technical difficulties, his lack of sociability, his not knowing what to say; and he asks just what formula can be used when he goes to the minister or to the boys' club.

In the eighth appointment he came late for the first time. (He was usually ahead of time.) He immediately apologized because he hadn't gone to any group activities or to the church, and we told him that we expected him to get up his courage rather slowly, and that didn't mean that he had to feel that he had done wrong in our sight. Arthur felt greatly relieved at our not scolding him and then stated that Mr. W had finally been taken back to the hospital. We suggested that it must be nice to be with mother alone again, and he immediately entered into a long tirade against Mr. W, and the latter's effect on his own reputation in the neighborhood. We pointed out again that Arthur was really not so much concerned about the neighbors' finding out about Mr. W as about their finding out about Arthur, although what he was worried about didn't exist in him, that is, gonorrhea and insanity. Following this we told him that we thought it was only natural that Arthur should be a little jealous of Mr. W. We supposed that Mr. W did give companionship and sociability to mother during the years when Arthur wasn't with her and she was alone, that is, before she married Mr. W, and the boy readily admitted this was so and stated, "Well, Mr. W isn't so bad. That is, he isn't too bad when he's well, but you know he *should* work and support himself and my mother, and not leave it all to me."

He then spent the rest of this hour thanking me for helping him about sex information and about his fears of gonorrhea. He states that he still wonders if what I'm telling him is the truth, though he says, "I have no fear about your kidding me." We reassure him again that what we have told him is the truth, and tell him that we expect that from time to time his original fears will return; that when they do, we will talk them over again. He ends the hour again by telling us how difficult it is to be sociable, particularly with girls. He states, "My aunt used to tell me that all girls are bad, and it is hard for me to believe you."

It is possible, then, through a discussion of this material, to catch a glimpse of some of the most serious problems that many adolescents must solve—either alone or through help extended to them by parents, associates, or physicians. Paramount in importance in this boy's case, of course, are the problems relating to sexual expression and attempts to identify himself strongly with members of his own sex, with a view to assuming the role to be required of him at a later date.

In addition to the detailed problems of sex adjustment seen in an intensive study of this boy, I think the case is particularly pertinent in that it shows the evidence of, and the problems attendant upon, the retardation in maturity that was a result of his earlier markedly sheltered life in the home of his aunt. It is as if his environment had succeeded too well; even had his aunt lived and had he stayed with her, he still would have had a difficult time in adolescence.

But note also that side by side with these problems resulting from retardation and overprotection, we have in the very same case the demands for an accelerated maturity—the insistence by the disastrous breakdown of his "home" when he was fourteen that he assume an adult role and take care of himself, make his own decisions, outline his own future—his educational and his vocational plans. Even the problems of buying his own food and provid-

Downloaded from www.freelibrary.org

ing for the heating of his room were his to solve, and all this in a community setting that can be described at least as harsh if not actually vicious.

There are numerous points of interest in this boy's responses, a few of which I shall discuss.

This boy's information regarding sexual matters was woefully inadequate as he approached puberty; but more important, his first information (largely self-acquired), in addition to being erroneous and productive of many severe conflicts in itself, was acquired in a setting already destined to cause many serious mental conflicts. He desperately needed corrective medical information.

His aunt, who had protected him—rigorously and rigidly protected and supervised him in all normal boyhood contacts—died at the time that he entered puberty. His period of mourning and his return to his own mother (with the adjustments needed in regard to both) coincided, and both occurred simultaneously with his awakening interest in sex. From the information gained from him we can be sure that, like many adolescents, he never had a chance to learn even the rudimentary knowledge acquired by children brought up in more "normal" childhood settings; nor did he have a chance to have the customary and usual misinformation modified in the street-corner and curbstone consultations of which most boys avail themselves. Paramount in importance among the fears of adolescents regarding sexual expression are those that involve a fear of insanity, a fear of physical illness, skin diseases, loss of strength, and loss of the ability to concentrate. Our patient had all of these fears. In addition, he had a common bit of misinformation that chronic gonorrhea becomes syphilis, and the unfortunately truthful information that untreated syphilis may make for insanity. Hence, by association of masturbation with gonorrhea and both with syphilis, we have the ultimate in the adolescent fears of the consequences of masturbation.

What then are some of the defenses that this boy used that are commonly seen in adolescents whose problems (though they may be of less intensity) are patterned after those of our patient?[3]

1. Of extreme importance was his isolating himself as a retreat from any and all situations that might stimulate him sexually. What were some of the specific responses used to isolate himself from stimuli that created tension?

*a*) He went directly home from school without talking to *either* boys *or* girls, and, save for the necessity of going to the corner to buy his supper, he never left his room until he reported for school the next morning. In this way he was not forced to talk with any boys who might bring up the matter of sex, and he was not subjecting himself to temptation with girls. He attended a high school that has only boys as pupils and men for teachers, and though this set of circumstances may seem to have been mere coincidence and not at all the result of his choice, it is interesting that his first question, at the examiner's suggestion that possibly a preparatory school away from home might help, was (both fearfully and hopefully expressed) as to whether or not any girls went to such a school. He admits, of course, his strong interest in girls, but is afraid to trust himself; it was he himself who interpreted his isolation most correctly when he said, "I protect myself from them [girls], but I don't want to."

*b*) Within the home also, he protected himself from hearing or seeing the sexual activities that he imagined went on between his mother and stepfather by locking himself in his room away from them.

*c*) He always entered the house before dark, as he feared that he "may be attacked by the bad girls in my neighborhood," or that "if I am seen out at night, I may get blamed for all those things that go on in my neighborhood"; and he then added significantly, "I bet you think I'm a sex fiend because I worry so much and think so much about sex."

*d*) Even when he was alone in his room, this isolation was carried out further in that he refused to listen to comedy programs on the radio or any programs that had women members in the cast. He would not listen to mysteries or programs of crime. He listened only to the "Symphonic Hour" and the "Classical Album," and never to dance music or love songs.

Thus this adolescent, by the above four devices, kept sexual stimulation at a minimum in so far as his external world was concerned.

Downloaded from www.dbraulibrary.org.in

2. Another defense complemented that of restriction, because it enabled this adolescent better to handle his strong sexual strivings. I refer to the mechanism of reaction-formation. He continually repeated, "*All* girls are bad" or, when most angry, "*All* girls are bags." He added to this, "All sex is disease. All sex is weakness."

It is not difficult to suspect that an additional defense of adolescents was here in the process of formation. I refer to the defense through asceticism, which has been commented upon extensively in the literature. If such is the case, we would soon have had a more or less complete repudiation of instincts by this boy, and it seems to me that he was definitely on the road to such a protected and protective position in his attempts to handle his conflicts.

Finally, as far as this individual case is concerned, what this boy did *not* do should be emphasized—what reactions he did not have that are used frequently by adolescents in conflict, what defenses he did not employ. Why he did not do so, we cannot explain—any more than we can predict (or explain) the choice of a neurosis.

1. In the first place, he did not run away. Many adolescent boys, faced with conflicts involving the rivalry and jealousy of a stepfather acquired in or near puberty, will become chronic runaways. It should be noted that this may happen when the external situation (economic and social) is entirely adequate. It is a neurotically determined act, and one extremely difficult of solution. In adolescence such runaways usually entertain the fantasy of a later return to the home and mother—a return in triumph to rescue the mother or to care for her in splendor and luxury.

2. Our patient was not a truant. In fact, he has studied diligently and was ambitious for a college education. It is interesting, however, in the light of his educational interests, that he has never resorted to another favorite adolescent defensive device in that he has not used intellectualization as a solution and has not thereby evolved, as we might expect, some intricate and involved theoretical system of morality or of the social order as a mask and defense.

3. Finally (and this is perhaps quite beside the point in that it usually has no demonstrated direct reference to the sexual instinct but does have a bearing upon his well-established moral code), it should be noted that this boy has not resorted to any delinquent behavior and is unknown to the courts. He does not steal, and I would have you note that he does not steal even though he lives in the worst slum section of the city of Boston, and he himself is not only deprived of the little "luxuries" that a fifteen- or sixteen-year-old boy in his depressed neighborhood has, but he sometimes (together with his mother) is without food and without the money to buy it. Furthermore, other necessities—adequate clothing and housing, heat and light, dishes and bedclothes, etc.—are lacking. Again, it is traditional in his section of the city that boys his age do steal and are united in groups for that very purpose. But Arthur does not steal.

CHAPTER 45

# GENERAL THEORY OF COMMUNICATION IN PSYCHIATRY

Jurgen Ruesch

Downloaded from www.darulibrary.org.in

WE LIVE IN THE AGE of communication. Radio, television, newspapers, and circulars flood us with messages, as do invitations to attend cocktail parties, give speeches, or sit on committees. We all are haunted by slogans and clichés; and through the medium of advertising our professional concerns have been transmitted to the public. People on the street talk about the doctor-patient or parent-child relationship, and a term such as psychoanalysis has become part of the popular vocabulary.[20] But in spite of all this awareness of human relations and the availability of rapid transportation which enables people to see one another with the greatest of ease, modern man seems to feel lonelier and more helpless as time goes on.[33]

## ¶ The Contemporary Scene

The development of communication and transportation machinery, the control of the machine through information, and the impact of mass communication upon the individual have had a profound influence upon psychiatry. In former centuries, scientists took social relations for granted; today, they have made these functions the subject of pervasive study. This reorientation not only gave birth to the behavioral sciences but transformed the psychiatrist from an alienist into a personality specialist, social manipulator, community expert, and family doctor.[32]

The scientists' and doctors' growing awareness of social problems and the emphasis on communication in public life have been associated with a new approach to psychopathology. Every psychiatrist is familiar with the fact that when he opens one of his textbooks and runs across the description of a pathological phenomenon—be it hallucination and delusion or resistance and regression—the pathology is described in terms of the patient's communicative behavior. And in practice the therapist

meets the communicative process and its disturbances at every step of his work, perhaps as a difficulty in understanding the patient or as a management problem. All psychological therapies—and this includes psychoanalysis, psychotherapy, group therapy, hypnotherapy, and psychodrama—utilize the medium of communication therapeutically. Even the drug, shock, and lobotomy specialists are, by necessity, concerned with communication, and the only difference between their approaches and those of the psychotherapists is the locus of operation. Physical treatment methods impinge upon the patient's organs of communication whereas psychological and social procedures affect the functions of communication.[27]

The phenomenology of abnormal behavior, the therapist's role, and the choice of his treatment methods all are interwoven with the prevailing ecology and social structure. The contemporary trend toward the two-children system, the early separation from home, and the concomitant disintegration of the closely knit community structure have left the individual without an external source of human support to reassure, help, and sometimes threaten him. In the past, the individual was controlled from without by people who were personally known to him and with whom he had spent much of his life. This continuity and consistency in human contact resulted in the establishment of a sense of belonging and of responsibility, and it favored the development of controls from within. The vanishing of outside controls and the concomitant weakening of internal controls have left a vacuum which now is being filled by somewhat strange impersonal ties. Intimacy is being replaced by parapsychological relations;[12] the actor on the television screen sits in the living room, shares the family life, and inconspicuously sets standards as if he were a personal friend. And in urban as well as suburban living, families and faces quickly come and go, relationships have become impersonal, and real friendship or kinship groups are being replaced by casual, opportunistic, neighborhood, occupational, or recreational associations. The old-fashioned patriarch has been replaced by an impersonal authority called public opinion.

On an organizational level, this tendency toward impersonal relations is reflected in the accumulation of rules and regulations that are formulated by the state, the large corporation, or the labor union. We live in the age of highly organized corporate empires[16] which are distributed all over the globe and are interconnected by means of communication. Modern living is governed by a bureaucracy that controls everything from health to employment and from thinking to the choice of a marriage partner.[10] And the psychiatrist has become part of this social machinery—the trouble shooter of society, as it were. In the old system, people were either "in"—that is, they participated in the family and community life as regular members—or they were "out" and became adventurers, criminals, or insane. Today, this division is blurred, and the "ins" and the "outs" are almost overshadowed by the "in-outs"—that ever-growing array of marginal people, neither sane nor insane, neither criminals nor upright citizens, but persons who did not manage to get on or hang onto their respective band wagons. With this change in the social structure goes the disappearance of the classical syndromes of psychopathology and their replacement by an increasing number of borderline cases—immature and unidentified individuals afflicted by atypical or heterogeneous conditions. Theoretically and therapeutically, the interest of the psychiatrist has veered away from the study of the mind, or the soul, to the consideration of human relations, communication, and social interdependence.[21]

## ¶ A Psychiatric Theory of Communication

In spite of apparent technical or theoretical differences, a convergence of scientific thinking can be observed in the fields of communication engineering,[5] ego-psychology,[6] learning theory,[11] and action theory.[18] This similarity—at a higher level of abstraction, of course—comes about because scientists at a given historical period share many of the basic assumptions that are made about life, death, and health and about the human being's physical and social func-

Downloaded from www.ubiquitypress.org

tions.[32] But there is another and perhaps more cogent reason for this convergence of views. When a scientist has come to the end of his observations or experimentations, regardless of his personal philosophy, theoretical scheme, or technique, he must report his findings to himself or to others in communicable terms. This process of communication, in turn, alters his original ideas—even his findings—to such an extent that the processes of observation, recording, reporting, and interpreting become inseparably linked. Since, in the process of interpretation, the cultural heritage and contemporary views weigh rather heavily—particularly because language is culturally determined—the prevailing views of man and nature creep into the scientist's conclusions by the back door, as it were. But for psychiatry, things are even worse.

While in all other sciences the object of study is distinctly separate from the investigator, in psychiatry, object and subject of study merge into one. Since the subject of investigation is not a chemical compound or an anatomical structure but communicative behavior, the psychiatrist is called upon to pull himself up by his own bootstraps. He first observes communicative behavior of self and of others; then he records these signals in his head, on tape, or on paper by using certain signs and symbols; and finally he reports his findings to others by using another set of signs and symbols. Any psychiatric or therapeutic situation is so heavily determined by a multiplicity of symbolic transformations that inferences made about what really exists—for example, the inner psychic structure of an individual—usually turn out to be fiction. Therefore it seems wiser, safer, and less distorting to refrain from farfetched and abstract extrapolations and to limit the understanding of both pathology and therapeutic practices to simple empirical abstractions, This conclusion has two consequences: first, that more attention is paid to formal and quantitative characteristics of communication than to the signifying property of signs; second, that, when content is considered, it is confined to situations and persons that are familiar to the therapist. The therapist then can add his own experiences to the information on hand without relying too much on the signifying property of the patient's words.

In subsequent paragraphs a few principles of a psychiatric theory of human communication have been sketched.

1. People relate to each other through communication—a process which can be both observed and experienced. The intraorganismic functions[29] of men which include such phenomena as feeling, thinking, and memory at present can only be postulated. Their exploration is dependent upon a two-person or multiperson situation in which the individual communicates his experiences or performs a task.

2. The unit of study is not confined to a single individual but comprises all the people with whom a person habitually stands in communicative exchange. In such social systems, part functions are always functions of the system as a whole, and the chains of causation are circular, if not more complex.[32]

3. The artificial division of individual, group, and society, which formerly handicapped workers in the social sciences, need not be maintained. All messages originate in a human being, traverse human beings, and find their destination in a human being. Thoughts and feelings of an individual are as much the result of signals traveling along certain pathways as are interpersonal statements or broadcasts by a radio station.[25]

4. In order to be able to communicate, any organism or social organization must be equipped with the function of perception, that is, the ability to register incoming signals. Such an organism also must be able to evaluate, that is, to store previous impressions, to scan new impressions against the background of old ones, and to make decisions. Finally, any such organism must be able to transmit messages—to express the results of internal deliberations and to signal these to others. These three basic functions which characterize all living matter become, as it were, an organizing principle of nature.[27]

5. In order to be understood, signals must be phrased in terms which are understandable to others. The technical aspects of this process are referred to as codification. When the receiver understands the code, the signal to him becomes a sign. Language is a sign system by

Downloaded from www.uralinform.org.in

which people have agreed to abide. It is characterized by the fact that the significance of the language signs must be known to a number of interpreters and has to remain relatively stable, regardless of the situation.[17]

6. The accumulation of signs and their orderly arrangement is referred to as knowledge if it exists inside of a person, and as information if it is accessible to others. Knowledge and information enable people to predict events to come, to react in a meaningful way at the moment, and to recall past events. This usage of the term "information" differs from that of the communication engineer, who conceives of information as a purely quantitative notion.[34]

7. Regardless of what code or language is used and what kind of information is transmitted, specific instructions have to accompany any message if it is to be interpreted properly. These instructions are often referred to as "metalanguage," and the exchange as "metacommunication." In verbal speech the metalanguage is couched in the tonal qualities of the voice, expressed through gestures, and contained in patterning of speech. In written language it is conveyed through interpunctuation and spacing of the sentence and through the context within which it is written.[32]

8. When a person or group has expressed a statement, this action, when perceived by others, will have an impact. Eventually, the reaction of the other person is relayed back to the sender and serves to clarify, extend, or alter the original idea. Feedback, therefore, refers to the process of correction through incorporation of information about effects achieved. This function is basic to all learning, correction, and self-correction.[41,42]

9. In therapeutic communication the psychiatrist is interested not only in content and analogies—features which psychoanalysts have worked out in a superb way—but also in the form of communication. The matrix, the envelope, the mold of the feedback processes is the critical problem of therapy. It does not matter whether the discussion is carried out on the couch, in the chair, or standing up, or whether the subject is the collective unconscious, the oedipal conflict, or commitment; in all these situations and regardless of the content, feedback has to occur if therapy is to take place. Feedback is learned by the child first in the nonverbal mode, and only later does he become aware of the signifying property of words which then are fitted into this ready-made nonverbal bed.[24] The success of all of the communication therapies thus is determined by the extent and the type of the feedback processes that take place. If correction and self-correction do occur, the patient is back on the road to recovery.

## ¶ Popular Misconceptions About Communication

Theories and abstract principles frequently are in danger of being misunderstood. People who habitually deal with transcendental notions, for example, may conceive of communication theory as a mechanization of the human being. But those who use communication theory claim to advance neither a theory of ethics nor a theory of values. They merely purport to formulate and explain the processes that human beings employ to influence one another. Even the point that communication theory does not do justice to inner psychic functioning can hardly be maintained; all that can be said is that communication theory does not speculate about intrapsychic structures. After all, the inner life of another person is accessible only through verbal and nonverbal exchange, and, in a social situation, what is done or said is determined as much by one participant as by the other. Inferences about personalities, then, depend upon who is looking at them. In listening to a patient's report of past events, therefore, the psychiatrist does not assume that he gets an eyewitness report. On the contrary, he assumes that, although the patient may have participated in the events he mentions, his present expressions are designed to cope with a current situation involving himself, the therapist, and perhaps other people. This does not imply that the signifying property of the signs used is completely ignored; it merely means that, at the time an experience is reported, the reporting is treated

Downloaded from www.ibtlibrary.org.in

as a new event which has more bearing upon the "now" than upon the "then."

In discussing communication, communicative intent is frequently confused with communicative effect. Any action, be it word, gesture, or practical implementation, has an impact if it is perceived. Both sender and receiver are influenced by it, regardless of the sender's initial intention. To follow Shannon and Weaver's definition,[34] communication includes "all those procedures by which one mind may affect another. This, of course, involves not only written and oral speech, but also music, the pictorial arts, the theatre, the ballet, and in fact all human behavior." At no time, in face-to-face encounters, can the receiver separate the intentional from the nonintentional component of a message. The engineer's notion of noise[5]—the variable that accounts for interference in the transmission of signals—can hardly be applied to human communication, in which neither the channel nor its capacity can be specified. The context, a previous situation, or incidental events may shape the effect of a message as much as the intentional expressions of the sender.

Frequently, too, verbal communication is identified with intentional expression and nonverbal communication with unintentional expression. Unfortunately, this division cannot be maintained either, and the reverse is often true. The child or the very sick patient may express his statements in nonverbal terms, merely using words as modifiers. Verbal and nonverbal modes of expression are as intertwined as the content of a message is with the metacommunicative devices which serve to time, emphasize, or instruct. In practice, therefore, the therapist has to be content to watch the effect produced by a verbal statement or an action sequence rather than to speculate about intention. As a matter of fact, the only way to infer intention is to study the impact a message has had, because the conscious intention of the speaker may not have been his unconscious intention, and often the speaker himself discovers his own intention only after having observed the impact he has created upon others. Intention, therefore, can be determined by hindsight only.

Sometimes the engineers, statisticians, and natural scientists level another kind of criticism at the theories sketched above. They maintain that behavior has to be quantifiable. Without entering into a discussion of the merits of the scientific approach,[32] it is well to remember that, so far, quantification and measurement have not contributed to the understanding of individual behavior. The a priori assumptions that pertain to any kind of measurement—nonparticipation of the observer, difference in time and space scales between observer and observed, anonymity of particles studied, and stability of the yardstick—do not apply to the study of inner experience.[19] Paradoxically, scientific measurement or the appreciation of mass effects is successful only when the observer is not too well informed about the subject of his study. If the physicist were to know atoms and molecules personally, each labeled by name, age, and place of origin, and were he to take their individual life histories and follow their fate over millennia, he would realize that measurement of mass effects would tell him little about the individual particle. Likewise do the circumstances and actions that provide for therapeutically effective experiences occur in patterns which are destroyed when quantitative analysis is used to dissect them. In the field of human communication, quantification is, at best, useful for the assessment of the extraorganismic components of the process—channels, signals, codes—but not for the most essential component—the impact of a message upon the participants and its evaluation. Reaction to stimuli and interpretation of messages depend upon earlier experiences, and since these are not the same in every person, not even in identical twins, the prediction of outcome will remain limited except for very special situations.

Most measurements are time-consuming, but communication and psychotherapy are processes which rely upon immediacy. The therapist cannot wait for the results of a test, and he cannot delay for hours or days his responses to the statements of his patients. When a person makes a statement, the reply or lack of reply on the part of the doctor acknowledges, amplifies, contrasts, or contradicts. In tying state-

Downloaded from www.dbraum.org

ment to statement within the mind of the patient and from person to person, reorganization of disturbed communication becomes possible. The human fields of endeavor that cope with learning, skill, and experience rely upon patterning and timing. Time-consuming analytic and reductive methods which break behavior into component parts have proved ineffective and nonsensical. The scientific fallacy is obvious: Because certain assumptions and methodologies have helped to master the material environment and physical health, and because they have been successful in improving plumbing and transportation, it does not mean that they are applicable to the universe of human experience. We therefore have to accept the fact that present-day scientific methodology has not as yet elucidated many of the problems inherent in human experience, communication, and psychotherapy. And perhaps it never will.

## The Communication Expert's Contribution to Psychiatry

Perhaps one of the most significant advances in psychiatry has been the clarification of the role of the observer. Observation at a distance by a neutral observer yields different results from inquiry undertaken in close participation with the patient. To have been exposed to the manipulations of the patient, to have been lured into the maze of a neurosis, and to have been the subject and object of transference and countertransference leave an imprint which is quite different from that experienced by a man who observes behavior through a one-way screen. The description of pathology, therefore, is dependent upon the roles of the participants and the nature of the system in which the observations were made. The idea that the information obtained depends on the position of the observer in psychiatry was first expressed by Sullivan[35] in his concept of participant-observer, and later was amplified by Ruesch[31] within the framework of a theory of communication. For the development of a general system theory of behavior, it is relevant to remember that the attributes of the naturally existing system (patient) are complementary to the attributes of the observer system (psychiatrist), and that both cannot be stated with accuracy at the same instant. The more we know about one, the less we know about the other.

In practice, this results in essentially three different ways of reporting behavior.[23] When a psychologist talks about personality structure, he acts as a somewhat distant observer who minimizes his own characteristics, the situation, other participants, and the place and time of observation, and maximizes the time-enduring properties of the subject. The patient thus is described as if he lived *in vacuo*. This procedure is useful in understanding and predicting behavior if the specific participants and the context of future situations are unknown. But in psychoanalytic and psychotherapeutic situations in which the therapist engages in two-person communication, the picture is quite different. Here the other person is being tested in an ongoing exchange, and many of the generalities listed under the heading of personality study have to be qualified, modified, or entirely discarded. The picture obtained is time- and context-specific, and generalities about other people, situations, and contexts are boiled down to specific incidents. What is said and done within the period of the two-person interaction is weighted more heavily and used as data more than is information about what happened before or will happen afterward. Here the patient is experienced as an individual who responds to the therapist's operations, and vice versa; and it is this knowledge of the other person's response that enriches the therapist's picture and comprehension of the patient.[23]

The observation of the patient in a group emphasizes different aspects again. Role distribution, teamwork, timing, and sensitivity to context matter more than the over-all features described as personality structure or the dynamic, ongoing interchange experienced in two-person situations. The individual here is seen as a member who either furthers or interferes with the task of the group, and his expressions are weighted with regard to the benefit the group derives. The report will vary, depending upon whether the investigator acts as an

Downloaded from www.brainvalley.in

in-group or as an out-group observer; thus it is obvious that a crime appears quite different from the prosecutor's viewpoint as opposed to that of a family member.[23]

Another contribution of the communications approach to psychiatiry has been to point to the fallacies inherent in verbal communication. We owe primarily to Whorf[39] the insight that the manner in which we assign words to the various parts of the universe influences our ways of thinking. If we have created a word to denote a quality or part aspect of an event, we eventually come to treat this verbal unit as if it really existed independently in nature. The world of verbal unreality thus becomes a danger to all disciplines in which a one-to-one check of word against natural event is difficult if not impossible.[24] This danger is particularly prominent in science when words denoting hypothetical constructs eventually enter the general vocabulary. People then often attribute body and substance to such words and may argue about the super-ego and the id, for example, as if they were bodily divisions of the human organism. Awareness of the vicissitudes of communication in scientific procedure may help us to avoid this pitfall. Particularly if theoretical formulations are restricted to the empirical level of abstraction, any generalizations made can be readily referred to the operations from which they derive.

Familiarity with the characteristics of nonverbal denotation is another bulwark against verbal unreality.[33] The symbolic function of gestures, actions, and objects cannot be dissected, and their impact is immediate. Much of the distortion introduced by words is due to the time it takes to describe a short-lasting event, whereby the organism has to combine words that were heard half an hour ago with words that are perceived now. This combination and recombination of verbal symbols in an individual's head is stimulated and governed by nonverbal factors. When nonverbal perception and expression do not function, verbal communication becomes difficult if not impossible. While the psychoanalysts have worked out in detail the relationship of content and verbally related memories to therapeutic effect, it was left to those therapists who dealt with the psychoses — notably Sullivan,[35] Fromm-Reichmann,[9] and Rosen[22]—and the child specialists—Szurek,[36] Redl and Wineman,[19] and Levy[18]—to point out that attitudes and responses of a nonverbal nature are an integral part of therapy. In the psychoses, and this includes many borderline cases, feedback is disturbed in the nonverbal mode. The patient, not having mastered response and interaction in terms of movement, emotional expression, and gesture, is incapable of engaging in meaningful verbal exchange.[1] Therapy in the psychoses, therefore, has always employed doing (occupational and recreational therapy) and utilized skin stimulation (continuous baths, wet-sheet pack, proximity of nursing personnel, insulin therapy); in other words, unwittingly, psychiatrists long ago chose to approach their psychotic patients in the nonverbal mode, with emphasis on the stimulation of the proximity receivers. Among the psychotherapists, those who are nonverbally skilled are particularly successful with the very sick, and only when the patient has mastered, with their help, simple feedback functions in the nonverbal mode is verbal exchange likely to improve.[24]

Another effect the communications approach has had upon psychiatry is to shift the emphasis from theory to procedure. Patient and doctor actually use words, gestures, and actions to influence each other. These communicative operations so far have received little, if any, attention. Under the concepts of transference, transference neurosis, and countertransference we find some references to the actual exchange;[30] others are included in case reports;[8] and again others in the description of dream interpretation[7] or hypnosis.[43] But on the whole, the actual communicative exchange and, particularly, its nonverbal components are described in global terms such as interaction, support, working through, etc. The lack of a vocabulary to describe nonverbal action is in no small way responsible for this shortcoming, but at least the foundations for the evolvement of a special language have been laid.[3] This involves the study of both disturbed communicative behavior[23] and the therapeutic methods used to cope with it.[24]

Another innovation introduced into psychia-

try is the notion that although only one patient may have symptoms, the group in which he lives is the seat of the disturbance. Every individual is part of a communication network, and his malfunction can often be understood by studying this larger system. Furthermore, it has been discovered that the individual needs to be a member of a group and needs the support as well as the criticism of other group members. Under the influence of child psychiatry and social psychiatry, it has become common practice to take various members of a group into treatment, and the results seem to be better than if one individual alone is subjected to therapy.[37]

Studies of experimental communication[15] and of communication in animals,[38] although removed from psychiatry, have certainly raised a number of new questions. The study of special networks, the capacity of channels, the amount of information, the redundancy of language, the physical characteristics of speech, the role of phonetics, content analysis—all of these topics have come under critical scrutiny and, directly or indirectly, are bound to help the psychiatrist in his work.[5] But these scientific contributions cannot be taken over wholesale. They first have to be sifted, reinterpreted, and adapted, and, inasmuch as therapy is an art, it depends on the therapist's skill to convert knowledge into therapeutic action.

## ¶ The Nature of Psychological and Social Pathology

Elsewhere[23] the author has elaborated and illustrated the hypothesis that abnormal behavior is associated with physical or social interference with communication. Just as the metabolic functions serve the purpose of tying man to his material surroundings, so does communication connect him to his social surroundings. Interference may take the form of injury or disease affecting the instruments of communication—that is, sense organs, nervous system, or effector organs; it may appear as a genetically determined disturbance such as mental deficiency; or it may take the form of functional interference resulting in personal or social pathology. Clinically, such interference is manifested in emotional states such as alarm, anxiety, anger, guilt, shame, fear, or depression; in disturbances of thinking such as dissociation or flight of ideas; in attitudes such as the tendency to be suspicious, aloof, or dictatorial; or in social approaches such as withdrawal, argumentativeness, or mutism.

Any form of interference not only elicits momentary responses on the part of the individual but also leaves traces inside the organism which continue to exert an effect upon his behavior. In dealing with pathology, therefore, we have to consider not only the results of direct impact but the symbolic representation of such impact inside the human being as well. The more intense and repetitious the interference becomes, the more significant are the traces left in the human being. By the time an individual reaches the age of twenty or thirty years, traces of past experiences determine much of his behavior. It is a well-established fact that in all adult psychiatric patients, the symbolic processes are disturbed, and, although current difficulties with other people may be at the root of the trouble, internal obstacles derived from previous experiences usually prevent the patient from successfully coping with the current difficulties. The various forms of communication therapy not only aim at improving the patient's ways of communication but count upon the fact that a successful exchange will leave traces within the individual and be superimposed upon the memories of the past that are disruptive to communication. Thus it is obvious that social and intrapsychic processes are inevitably linked together.

Functional interference with human communication is frequently related to deviations in intensity. Since the capacity of the organism is limited, overload or underload which affects the sense organs, the central nervous system, or the muscular system may exert a disruptive effect. In ordinary language we call the result of such interference stress, strain, overstimulation, or exhaustion. Deviations in timing—messages that arrive too early or too late and which therefore have lost their relevance or are threatening because the individual is not prepared—are responsible for another host of dis-

Downloaded from www.pbauhaus.org

turbances. A third group of disturbances results from messages that, in themselves, are perfectly respectable but which do not fit the physical situation or the social context, or do not reach the right participants—a misplaced call, a lost letter, a secret message that reaches strange ears. The phenomenology of these disturbances can be summarized in a little verse:[23]

> Too much, too little,
> Too early, too late,
> At the wrong place
> Is the disturbed message's fate.

Almost all functional disturbances of communication can be traced historically to the fact that one person impinges upon another and produces frustration by ill-timed, badly quantified, or inappropriate messages. In children, these circumstances can be verified by direct observation. For example, devious acknowledgment by selectively disregarding or emphasizing certain aspects of the message may produce intolerable frustration for the child.[28] Or an individual may receive a message the content of which is threatening; or he may continuously be bombarded with hostile action, as in warfare. Regardless of the nature of the quantitative or qualitative deviations, it is well to remember this salient point: Since man needs a certain amount of gratifying communication in his life in order to learn, to grow, and to function in a group, all events that significantly curtail communication eventually will produce serious disturbances. When communication becomes too frustrating, man finds ways to protect himself by withdrawing, screening, or otherwise controlling the exchange. But through this control the feedback characteristics frequently are lost, so that the purpose of communication—correction of information and performance—is defeated. If an individual discovers that communication does not work at all after having tried it over and over again for many years, he is likely to withdraw from the nonfunctioning system altogether, without being able to establish himself in another well-functioning network. This latter condition is referred to as functional psychosis, in which the feedback circuits progressively are confined to the organism of the patient.[23]

In individuals, pathology of communication is often kept alive by others who unwittingly reinforce it. How can a young man give up his dependent role vis-à-vis his mother if the significant experience and contact with her are based upon her making decisions for him? If this young man were to make his own decisions, he would temporarily or permanently alienate his mother, whose existence was built around control of her son. The anticipated unpleasant breakdown of communication and his lack of skill in making decisions prevent the son from asserting himself. The same applies to the girl who cannot relinquish her self-destructive seduction as long as she acts on the assumption that men will perceive her only if she offers herself as a target for their mental cruelty. Communication pathology which develops over the years may, at times, remain dormant until a specific stimulus triggers it into existence. Weaning a person from his pathology is difficult, because either its intensity is so great that all other experiences in contrast appear flat and unfulfilling, or the withdrawal symptoms are so unbearable that the patient prefers to stick to his pathology. But if the therapist can keep the trigger stimulus muted until the patient has developed new and more fascinating patterns of experience, a desensitization does occur. Control over the trigger stimulus may be achieved when the significant relatives and friends of the patient are taken into treatment.

A discussion of the nature of communication pathology would be incomplete without mentioning that no fundamental difference exists between normal and abnormal communication. All the elements found in ordinary communication are present in pathology, and vice versa, so that the criterion of abnormality is not related to the presence or absence of a certain ingredient. Instead, abnormality must be conceived of as a pattern that ceases to be functional. When the feedback devices do not bring about a much-needed correction, and when behavior has become stagnant or repetitious, then we are entitled to talk about pathology of communication. Freud considered repetition-compulsion as the core of the psychoneuroses; we now refer to this phenomenon as

Downloaded from www.unilibrary.com

feedback. Pathology can be conceptualized as being maintained by processes which, instead of correcting (negative feedback) often increase its extent and direction (positive feedback). The art of therapy thus is to break into this circuit and change positive feedback into negative or corrective feedback.

If abnormal communication is viewed as a quantitative deviation of normal communication, how then can one explain such emergent phenomena as hallucinations or catatonia? The answer is simple. Today we know that when external input is suddenly reduced, it is replaced by an imaginary internal input. The less the pressure from the outside, the greater the activity of the fantasy, even to the extent of creating hallucinatory experiences.[14] Catatonic states usually are triggered into existence by a heightened reactivity to some minor stimuli producing anger or threatening coercion, or by a lessened reactivity to very powerful stimuli threatening exclusion or isolation. The emergent nature of these phenomena is only an apparent one, and careful observation will reveal that, under stress, tendencies that existed before are reinforced. The novice observer's attention then is drawn toward the features he did not perceive before, and he believes that something new has been added.

## ¶ Therapeutically Effective Processes

If we attempt to explore the secrets of psychotherapy, we invariably fall back upon its first and most important requirement—that, in addition to the patient, there must be another person present who is accessible and visible, who can be talked to, and who is ready to understand and to respond. Once interpersonal feedback is established, the exchange elicits in the patient the sensation of pleasure. To be acknowledged is pleasant; to be understood is gratifying; to be understood and to agree is exciting. This gratification becomes the driving force which induces the patient to seek further improvement.

Understanding is not to be confused with agreement. Agreement involves decision-making and commitment; understanding does not. Agreement means that the information supplied by one person corresponds to the information held by the other person, whereas understanding does not imply a correspondence of information. Since the first step of therapy is to achieve understanding, the therapist, to the best of his ability, attempts to establish in his head a model of what is going on in and around the patient; and once he has succeeded in doing so, he imparts his understanding to the patient. By establishing as correct a relationship as possible between the model in the therapist's head and the events in the patient's life, and by validating this model consensually, the patient himself becomes aware of contradictions and inconsistencies between his private views and his actual behavior. As the exchange continues and the therapist perceives behavioral features which are not represented in the patient's model, he can, by feeding back to the patient the observations he has made, further correct the inaccuracies in the model.

The second method open to the therapist is the mobilization of information which is available inside the patient of which he (the patient) is not aware. This information does not necessarily represent repressed material, but, because of lack of communicative exchange, the patient may not have been able to organize certain pieces, and they may have been left unused.

The third method which the therapist uses is to add, out of his own wealth of knowledge, some pieces of information which the patient may juxtapose to the old information he already holds. In so doing, the therapist conveys to the patient facts which have been ascertained by other people, and the patient is given an opportunity to compare his own experience with that of others.

Interpersonal feedback, therefore, produces three results—mobilization of unconscious information, utilization of nonintegrated information that the patient already possesses, and acquisition of new information. Correction of the patient's old body of information thus occurs when the patient is exposed to a picture that is somewhat different from the one he has held before. But the magnitude of the difference determines the outcome. If the dif-

Downloaded from www.dbraulibrary.org.in

ference is too great, the patient will reject the new version; if it is too small, the patient will not see any difference at all. Corrective feedback, therefore, is bound to differences in views which, in order to be effective, have to be of optimal magnitude.[26]

A second determinant of effective correction is related to the "what," or the topic under discussion. In most instances the therapist cannot work through all areas of experience of the patient, and therefore he has to make a strategic selection. This will depend somewhat on the school of thought he follows and the theory by which he abides. But by necessity he will have to concentrate on, among other things, those aspects which interfere with the communicative functions of the patient. This would involve: (1) sharpening the patient's social perception—the behavior of self, of the other participants, and of the context in which his daily communications take place; (2) correction of the procedures of evaluation and decision-making, involving the scanning of memories, the combination of newly received information with old information, the abstracting of conclusions, and finally the initiation of action in accordance with these conclusions; (3) clarification of his emotional reaction to things, people, and situations—current as well as of the past; (4) development of the language and symbolization systems which the individual possesses, thus helping him to use modes of expression which are appropriate for the general context, the number of people involved, their roles, and their personalities; (5) appraisal of the appropriateness of knowledge and skill relative to the type of occupational and recreational activities in which he is engaged; (6) correction of his metacommunicative processes—that is, of those devices which serve, both in expression and in perception, as instructions for the interpretation of messages; and (7) training the patient in observing the effects of his actions upon others and helping him to include these observations in his future actions.

Once the groundwork has been laid for correction of part functions, the more difficult task of integrative rehabilitation moves into the foreground. Integration means to coordinate word with action and feeling with thought, and, in turn, to synchronize internal experience with outward-directed activities. The aim is, of course, to help the patient mobilize all his resources for a given task and use thinking, feeling, and action in unison. This is achieved by painstaking work in which the emphasis is not on pathology but on experiences that are felt as full. By comparing his satisfactory experiences with the disjointed ones—engaging in love-making without feeling, or making plans for tomorrow without carrying them out—the patient is made aware not only of what is disturbed but also of what he misses.

The tracing of a disturbance to its historical roots is valuable in that it adds to understanding, but this understanding in itself is not therapeutic. To spend hours in exposing the patient to a study of his pathology is justifiable only if it also leads to an understanding of those functions that operate satisfactorily. Understanding the past does not shift the balance to make pathology unrewarding and healthy functioning rewarding. This task is implemented by therapeutic operations which reflect the therapist's orientation to the present—the now. By minimizing the past and the future, the patient experiences the feeling that the therapist is with him in what he does, thinks, and feels today. The present, in all its ramifications, then becomes something the patient can learn to focus upon and eventually to accept. Communication with another person about matters which are currently active becomes rewarding because the patient discovers that whatever change may occur can only occur in the present. Manipulation of the past or the future is an illusion which prevents people from coping with their existence.

If one agrees with the existentialists that experience is the basic datum of psychiatry,[2, 4] one has to add that therapeutic communication is an experience in itself. The sharing of information and the pooling of knowledge give a person a sense of mastery. Anxiety is diminished, obstacles are overcome, and the limited power of one individual is amplified through the support of others. The result is a feeling of security. The experience that, in ordinary liv-

Downloaded from www.dbraulibrary.org.in

ing, behavior is censored in action rather than in fantasy provides for relief; the facts that the therapist will not destroy and damage the patient and that the patient's fantasies cannot annihilate the therapist contribute toward a lessening of feelings of guilt and frequently toward more independent thinking and action on the part of the patient. After much work, the patient usually discovers that communication provides for an experience of shared concern which eventually may facilitate action. In the therapeutic situation the slogan of symbolic freedom and limitation of action seems to produce therapeutic results.

Of course, this does not mean that, in therapy, the basic personality structure of people changes. Rather, attitudes, social approaches, and skills that are already established can be redirected to be used in a more productive way. The narcissist can be helped to communicate through creative production; the paranoid may find a worth-while cause to fight against; and, by associating with each other, marginal people can be made to accept their deviance without feeling strange and separate. If, at the beginning of therapy, the patient was motivated to seek help because of anxiety, fear, anger, guilt, shame, or depression, he gradually learns to seek more fundamental gratifications. One of these is the pleasure of communicating, and the exchange between patient and therapist may become one of the major incentives not only to continue therapy but to extend gratifying exchange to other people as well.

But therapy does not progress satisfactorily unless, concomitantly, certain daily life situations contribute toward gratifying experience. A man who has never dated a girl in his life will have to take this step once, and no amount of talking to the therapist can substitute for it. However, the pleasure found in the interchange with the therapist may have given the patient enough security to undertake this anxiety-provoking first step. And after the first date he may then elaborate his experience with the therapist in order to prepare himself for the next step. This close integration between life situation and therapeutic communication has to occur if the patient is to improve. Only when the patient lives as nearly as possible a full life does therapy progress satisfactorily. But if therapy is used as a defense against living or as an end in itself, the patient has to be given vacations from therapy until such time as he begins to participate in extratherapeutic situations. The strategic moment to take therapy out of the center of the patient's interest has arrived when the patient is about to enter a new phase of his life—change of domicile, the arrival of a child, a new job. Once the patient is able to experience these events and manage them alone, then therapy will become as it should be—a side issue only. And then progress is rapidly made.

In any discussion of therapy, the psychoanalytically oriented person will raise the question of the role of transference. The answer to this question is that what was said about therapeutic communication constitutes, in effect, nothing else but a detailed study of transference phenomena.[30] But, while in classical psychoanalysis the patient is left to his own fantasies and associations until such time as he himself comes face to face with his distortions and then perhaps experiences a sudden insight, in therapeutic communication, distortions are not permitted to grow to such magnitudes and are corrected little by little as the opportunity arises. If, at the beginning of an acquaintance, every person must make assumptions, assign roles, and act on the basis of past experience, nonetheless the image of the other person has to be rectified and adapted to the newly acquired information as time goes on. This slow rectification is the process that the patient has not learned to undertake. In the ambulatory therapeutic situation, unfortunately, the limitation of activities favors the establishment of distortions which can only be reduced if more aspects of existence are shared by doctor and patient. In an inpatient setting where the doctor can play, walk, or even eat with the patients, the distortion of role is somewhat less prominent. The more varied the situations are in which doctor and patient have contact with each other and the more there are other people involved and present, the more the realistic

Downloaded from www.dbraulibrary.org.in

aspects of the relationship will dominate the picture, keeping transference and transference neurosis within bounds.

CHAPTER 46

# SPECIFIC PROBLEMS OF COMMUNICATION IN PSYCHIATRIC CONDITIONS

Rose Spiegel

Downloaded from www.dbraulibrary.org.in

WE HAVE A DOUBLE CITIZENSHIP in the universe of communication: Communication concerns us as part of the human experience, as the *sine qua non* of all experience, and even of life itself. And in our specialized concern with psychiatric patients, communication is a prime tool of therapy. All psychotherapy—that is, all those therapeutic endeavors which use the interaction of personality as the essential tool and which meet the difficulties of the patient directly and in terms of his psyche and his personality—revolves around communication.

## ¶ Communication and Personality

Communication deserves to be an essential goal of therapy rather than the incidental achievement it often is. The psychiatric patient often is incommunicado—cut off from relatedness to others both by his disorder and by the impaired understanding of him by his family and community. Not only is the psychiatric patient's communication with others seriously impaired; so also is his relatedness to himself—his intrapsychic communication. As part of therapeutic achievement, he is to be helped to communicate better with himself and with others; consequently, those in psychiatry and the allied professions require a particular sensitivity, skill, respect for communication between people and within themselves. Certainly the social and professional communities can better understand the psychiatric patient as they become more receptive to the possibility of communication with him, as they extend themselves in an inner listening.

There are numerous approaches to communication. It has its physics and mathematics;

its biology, physiology, and psychology; its techniques and skills; its philosophy, its anthropology; its relation to art and entertainment. Though we tend to assume that communication is singularly a human achievement, it can be defined in terms ranging from the interpersonal to the inanimate and mechanical. Before we center on our own psychologic and psychiatric concerns with communication, let us take note of several definitions.

Weaver, who attempted to apply Shannon's mathematical and engineering theory of communication to "the broad problem of social communication," presented the following definition. Communication, in its very broad sense,

> . . . includes all of the procedures by which one mind may affect another. This, of course, involves not only written and oral speech, but also music, the pictorial arts, the theatre, the ballet, and in fact all human behavior. In some connections it may be desirable to use a still broader definition of communication, namely, one which would include the procedures by means of which one mechanism (say automatic equipment to track an airplane and to compute its probable future positions) affects another mechanism (say a guided missile chasing this airplane).[25]

In an over-all biologic sense, communication involves all the processes setting up the two-way relatedness of the organism to its animate and inanimate milieu; narrowly, it is the transmission to the organism of a datum from a field of its relatedness—external or internal to it—which affects or conditions or touches off its responsiveness and/or responses.

In psychologic, human terms, communication is the establishment of psychologic relatedness between the person and an experience or field of experience, and includes the various processes involved in setting up this relatedness.

Speech and verbal thought are the crowning, specifically human achievement of communication. Our end organs and special senses are in the service of communication with the physical cosmos. At the opposite pole, communication involves the fundamental interaction with the refined and cultural subtleties in civilization.

Communication is a dynamic process—experience in itself and also the gateway to other experience. Communication not only is a psychobiologic means, it is also an end—a process whose fulfillment brings its own gratification.

Innate in all living beings is the drive to communicate. We have our being in a universe of communication. We are at the center of our physical cosmos, of a social and cultural world of people and ideas, of a direct, immediate interpersonal world of varying closeness and distance. And within us is the intrapsychic world.

When we think of communication in interpersonal terms, it appears as a brief encounter between persons involved in a specific transaction which is delimited in time. On further reflection, we recognize a continuous, long-term process. Indeed, we recognize the synthesis of various kinds of communication processes on various levels in the person himself, and between him and the other communicator.

In the first version, communication is an event occurring in "time the present"; the person is viewed on his presenting surface in the interaction. If we consider his inner communication processes at all, it is cross-sectionally. In the long-range view, we relate to communication as the flow of experience that has patterned the person to communicate as he does—his psychologic experiences, particularly those bearing directly on communication, the maturation pattern of communication, the cultural contributions affecting communication. Communication in this sense has some of the quality of growth and maturation. In the episode of communication, the whole person enters the transaction; furthermore, he has been shaped as a personality by his specific life experience in communication. Lastly, there are fairly characteristic patterns of communication for the various kinds of personality disorder that fall within the province of psychiatry.

## *The Communication Circuit*

In an operational sense, every person is in a communication circuit, consisting essentially of the *sender of the message, the message,* the *receiver* (and *integrator and interpreter*) of

Downloaded from www.ibrarian.net

the message, and his *response* to the message. The communication circuit has a pattern reminiscent of the familiar one of the reflex arc.

Every person is a communicator; he plays various roles, with different and varying intensity, whether at various times or at the same time. Indeed, in some senses, the person himself is the message.

The message, of course, is not necessarily verbal. It may be a feeling state or a construct of meaning. It may be a datum of the outside world on which the receiver builds his meaning. The sender of the message, indeed the receiver of the message, is not necessarily a person, but, by and large, we shall consider the communication circuit in its personal sense.

The message to be communicated may be directly interpersonal or it may be intrapsychic, with the message from one part of the personality transmitted to another. The communication may be between the person and his society, and may even influence the culture.

The communication circuit may be fulfilled or may be attacked even to the point of annihilation. Either the fulfillment or the attack may be directed by a person toward communication with himself, with others, or toward some facet of the outer world. In short, communication may be conjunctive or disjunctive.

### The Message

The relationship between communicator—whether sender or receiver—and the message is many-faceted. The message, in one sense, is an extension of the sender, and how it is received is a measure of the recipient. It may, indeed, be a connection between them, part of a continuum from one to the other. Yet the message has its own identity. What gives the message its essential character depends on four dimensions: (1) the psychologic modality that enters into the communication, (2) the means by which the communication is effected, (3) the reality to which the message pertains, and (4) the meaning contained in the message.

The message conveys both a psychologic modality and a meaning. The psychologic modality may be a feeling state, sense datum, or construct of meaning. The meaning is contained in or elaborated from the psychologic modality. If the psychologic modality is an idea—that is, a construct of meaning—the meaning is contained in it. If the psychological modality is a mood, say depression, the receiver may empathize the mood and only as a subsequent step derive the meaning from it, recognize it for what it is, or attach an interpretation and significance to it.

Sometimes the impact of the modality is so direct and intense that the experience is delayed in any cognitive sense. In early infancy the feeling states which a young infant empathizes from others occur before his development permits cognitive extraction of meaning, although he is profoundly affected by the experience.

The means by which the message is conveyed are surprisingly important. They are intrinsically connected with the psychologic modality of the message and help shape the message. On a psychologic level, the message may be communicated seemingly directly, as by empathy, or clearly indirectly, by the mediation of signs and symbols. Feeling states are often conveyed empathically, constructs of meaning by sign and symbol which permit elaboration and precision hardly attainable without them.

Meaning comes close to being the datum of the message, its explicit content sense. The term "meaning" is also used to indicate the fuller, richer significance outside the tight package of explicit content sense. For simplicity of terminology, however, the term "significance" is suggested, to indicate what the message "really means."

"Significance" would relate the message to the human reality from which it arises. "Significance" would show the connection between what is intended and what the message states, in spite of any disparity between them. For instance, the meaning of the words or the gesture of a message may be explicit derogation; the significance may be that the person is reacting in this way to anxiety evoked from outside the communication situation and displaced onto the other communicator—as often occurs in transference in psychoanalysis; or, the significance may be a counteraggression to hostility, and so on.

It is quite apparent that both explicit meanings and their fuller significance ought also to

Downloaded from www.dbraylibrary.org.in

be ascertained in communication relationships in the world at large, for significance is the encompassing denominator for the message and its communicators.

## *The Role of Signs and Symbols in Communication*

Of the several modes of interpersonal communication, our focused and conscious awareness generally is on the play of symbols. The symbol-using and symbol-making processes are related to mentation. The evidence at hand is that this functioning begins early in infancy, but later than the modes of body-language and empathy which function almost from the time of birth. The role of symbols, however, reaches far beyond the interaction in interpersonal communication and is based on fundamental physiologic and psychologic functioning, namely, on symbolic process. This process involves meaning, which, in its highest sense, encompasses conceptualization and our attempts at understanding.

Related to the use of symbols is the use of signs. How symbols and signs function for us is significantly different, but they have one important operation in common—they convey meaning and they both are involved in the basic psychologic operation of the quest for meaning and understanding. Indeed, they may very well have a linkage in their evolutionary roots. Symbols and signs depend for their qualitative difference not so much on what they are made of as on the uses put to them by our minds, for the same entity or phenomenon may now be a sign, now a symbol.

The sign essentially is directed to giving information, the symbol to conceptualizing. The loose definition of symbol, as something that stands for something else, turns out to contain some of the most challenging problems of thought, reality, and experience. More specifically, a symbol is a representative of an entity, phenomenon, occurrence, or conception, and serves as the vehicle for conceptualization of the referent.

### Signs

Signs clearly are of elemental importance for creature survival in a universe of dangers and beneficences. Signs enable a reading of danger before the event, or a pursuit of food or mate after indication of its existence. Time is gained, by means of some signs, for a kind of foresight, for choice and decision. Functioning through symbols is a much later biological development which permits such psychologic luxuries as thought for the sake of thought.

In operational terms, a sign indicates the existence or presence of something, or the occurrence of an event, of which the sign itself is a part or accompaniment, a foreshadowing or residue. A sign, in being directed to giving information (though it may be misleading or inept), has a certain practicality. Some signs command.

In our lives, we have two kinds of sign experience—those which we read to our uses, over which we are the authority, and those to which we are subject, which exact a response from us directed by others. The latter include our man-made signals, epitomized by our bells—from alarm clock to fire engine. Such signs go beyond giving information of necessities and dangers—they command. In our context we are most interested in the first kind of sign, from which we read and learn.

In our interpersonal world we depend on signs of emotion, behavior, and attitude, from others, to inform us of the state of being behind these signs. We even read signs of ourselves, part of an "objective" relationship to oneself—contributing to self-appraisal.

Though we are quite fallible in our reading of signs, we proceed on the basis that they are genuinely indicative of a correlated condition—the blush of embarrassment, the timbre of the voice in rage, the disarray and dilapidation of an extreme of schizophrenia, the rigid self-contained movements of the extremely obsessive person. These signs do not necessarily depend on the intended design of communication by the person whom we read by these signs. We read them in a kind of behavioristic human-animal psychology. Professionally, we observe physical, emotional, and behavioral states—signs that we read and interpret and which enter into formal diagnosis.

The communicator in interpersonal situations may use what ordinarily are signs of a condition to convey specific intended mean-

Downloaded from www.naturalhealth.org.uk

ings to the other person and to evoke an emotional and behavioral response. The easiest and extreme example is that of the beggar displaying his sores as a plea for alms, as well as the subtleties employed by hysteric personalities; that is, signs may be used manipulatively or with intent to deceive, mislead, or influence.

Signs introduce an important modification of interpersonal communication. The very quality of objectivity in their use tends to deflect the relatedness which has the quality of being *between*, to the quality of being *about;* that is, the relatedness is less an open person-to-person fluidity, a rapport, and more a reading of information. The message conveyed by the sign may lead to other kinds of relatedness, and the information may be reacted to with an immediacy of emotion, but relating to the sign introduces some detachment. Signs, when reliable, validate or prove the existence of the entity or condition which is its referent. All the functions of the sign are derived from the theme of the existence of its referent.

### Symbols and Symbolization

Through various functionings involving symbols, we are enabled to relate conceptually to our several worlds. Within the psyche, by means of symbolic process, we transform experience into symbols, into hierarchies of symbols. Some of this symbolization goes on outside of awareness, the evidence of its functioning having been obtained through subtle observations in psychoanalysis and child study. In other words, symbolic process relates us conceptually to experience, even though some of the links are unconscious.

Symbols and symbolic activities function not only in the utilitarian exchange between persons but also contribute to the soaring reaches of the human mind, the building of constructs of thought and imagery which add to the culture. Symbols and symbolic activities, when pathic, bring down grave disorders in our personal life or even large-scale human tragedy.

Symbols enable us to think about an entity or phenomenon when it is absent or even intangible, and to conceive of the physically nonexistent. Symbols enable us to imagine. By means of symbols we express intricate states of being, we can exercise foresight, we remember and recall; that is, symbols serve us in the experience and functioning which are centered within us and also in our relatedness to others. The inner and outer worlds of symbolization communicate with each other. Our thoughts, dreams, and fantasies are often communicated to others; our symbolic activities in patterns of movement and behavior also speak.

Symbols may exist in the outer world and have outer form or concreteness, or they may exist entirely within us as an expression of symbol activity and process. The basic symbol modes of our inner life are *sense percepts, logical constructs* of thoughts, and *sense imagery.*

Sense percepts relate us to outer reality on the creature level. We process experience with physical modalities into perceptions which actually are representations of reality. Sense percepts—what we "know" we see, hear, touch, taste, and so on—are actually a symbolization of the perhaps unknowable outer reality.* In consequence of some kinds of organic damage to our bodies, these symbolizations of physical reality are not achieved. In some psychologic disturbances, the perceptions of outer reality are disturbed; that is, the symbolization does not bear a normal relation to outer reality.

Both in the intrapersonal activity of thinking and in the exchange of thoughts and ideas with other people, symbols typically are logical constructs. In dreaming and reverie, another variety of intrapersonal symbol activity, symbols typically are sense images. However, people may dream in logical constructs and think in sense images.

The symbols we use in the exchange of ideas are intended for cognition by others and so are agreed upon, accepted as convention. These are the consensually shared meanings which contrast to the private, often unshared meanings, the so-called autistic meanings. We are most familiar with, or rather, most focused on word language as a carrier of meaning, but word language is just one variety of symbol.

* We are dangerously near the philosopher's playing field of what is outer reality and what is our sense experience of it. As Langer puts it succinctly, it is a "surprising truth that our sense-data are primarily symbols" (Ref. 18, p. 16). We may say our sense percepts are symbolizations of signs of reality.

Downloaded from www.dbraibeo.net

In the exchange of ideas, the receiver of the communication has his own inner processing to do with the symbols sent him, or else the communication fails. To the sender or initiator, the symbol serves not only as vehicle for thought, in the sense of passive transfer, but as embodiment, container, and representative of the thought or experience for which he dynamically selected the symbol. These inner experiences are part of the process of conceptualizing by means of symbols. The use of symbols for the exchange of ideas is, then, an interpersonal and intrapersonal process and also culturally determined communication.

We recognize the symbols of sense imagery as belonging to the vast undersea life of the unconscious. Besides the private symbols from our autistic life, there are those more or less private symbols which are processed into art forms. All these symbols of dream, fantasy, and art form re-present experience.

Sense images are rooted in three kinds of basic experience, which give rise to three kinds of symbols—the universal, the individual, and the cultural.

The universal symbols, as Fromm has designated them in *The Forgotten Language*,[13] are related to the intrinsic and fundamentally human condition, both in the present time and as far back as we can stretch our knowledge, and therefore are more likely to be shared intuitively and empathically. Universal symbols include also the basic sexual symbols of Freudian symbology.

The second root of experience relates to special circumstances of time, place, person, and event which affect one's life. These more circumstantial experiences and their derived symbols are less likely to be communicated empathically or intuitively than are the universal symbols. Symbolization derived from special circumstances may properly be designated as individual symbols (what Fromm terms "accidental").

The third root of experience concerns the interplay of the person with his culture. Culture in the large and in the family subculture provides us with some of the materials for thought in the form of word language. The culture makes its impress on us through the symbols and symbol activity of art, entertainment, and prestige—symbols which we share with our society.

The impress of the culture on symbol formation begins in our early upbringing. Sullivan [26,27] has traced this influence, which operates partly through the mothering person, in the growing child's development of the self. Socialization of the child involves the superimposition of symbolization on such physiologic events as eating and excretion. This symbolization is in terms that are partly shared and partly highly individual, and they vary in their availability to his consciousness.

#### Symbolic Activities

We engage in a variety of operations which either are the equivalent of symbols or which produce symbols. These are symbolic activities. Artistic expression, scientific pursuits, and religious rites are symbolic activities of large significance through which we communicate with the culture and, indeed, in some ways with all mankind. Other symbolic activities are on the smaller scale of the individual's functioning, for instance, speaking and gesture, and the inner events in thinking and the reverie process.

Still another range of these activities is related to personality and to its disorders. We express ourselves symbolically through our actions, behavior, and interests, by which we are read and misread. Our choice of occupation is not only a practical matter but a symbolic expression of ourselves. Some actions of an obviously instinctive nature have a symbolic dimension; for instance, sexual intercourse is not only a basic creature event but a highly symbolic and communicative experience. We attach symbolic significance to one or another event or interpersonal situation, and our symbolic significance may be at variance to the intrinsic meaning of the referent.

### *Interpersonal Communication*

#### Rapport

When communication is consummated between persons, the experience is of an almost incommunicable, buoyant sense of openness, at-homeness, and acceptance—a sense of the flow of thought and feeling in a shared

Downloaded from www.culturalarchive.org.in

rhythm. It may transcend the specific verbal language or include it as a component. Loneliness is transcended. Meanings are understood. Verbal and nonverbal communication fuse. There is a sense of "being on the same wave length," "in tune with each other," "in touch." Rapport has this quality; most intensely, "being in love" contains this sense of open relatedness, or the illusion thereof.

Most interpersonal communication is more pedestrian—a grinding exchange of words whose meaning and significance is more laboriously achieved.

Some of the difficulty and unfulfillment of interpersonal communication is attributable to the misapprehension of the empathic mode.

### Empathic Communication

Empathic communication occurs through the reading of subliminal signs of another person's behavior, emotion, etc. It is an open question as to whether there are still other avenues of communication that enter into empathic communication. Through it we apprehend affect, emotion, body feeling, and attitude. What the sensory channels are in this kind of communication is not known, but it does require the bodily presence of the persons in the circuit. Perhaps better than the circuit, as the figure of speech, is the image of a magnetic field of force.

Empathic communication is not verbal, does not depend on statements of the feeling state, but may accompany language, for instance, through the ring of the voice. The apprehension of feeling states, which provide one kind of meaning, is through the immediacy of the feeling itself. The receiver of the message experiences the feeling state itself, whether consciously or unconsciously, as a similar reverberation of feeling in his own psyche. This message we may relate to in quite a number of ways—from identification, to anxiety, to repression—but the first experience of the receiver in empathic communication is the *felt* meaning which may be outside of cognition.

### Body-Language

Body-language includes the sense of the basic physical presence of another person, the sense of the impact of another person, his quality of movement. It includes gestures, the body attitudes, that the person does not intend but which reveal him, and also those which he does intend and by means of which he communicates. The former are signs by which he is read. The latter, in some respects, are equivalent to his word language and so function as symbols to convey his meaning.

The body-language of another person is apprehended by direct observation and also by our predilection for taking on the movements and body tensions of another in our mimetic responsiveness (which may be one of the reasons for the pleasure in watching a dance recital).

The complexity of sexual relatedness includes all modes of communication, verbal language being the least, and interpersonal relationships in the usual sense being only a part. The "message" is the person himself. The partners carry high symbolic significance for each other (not to be confused with esteem or love). The intensity of sexual intercourse depends on empathic communication and the immediacy of direct body relatedness, to which symbolic value is added.

### Spoken Situations

The spoken situations generally contain a great deal that is mutually understood, both of meanings that could be made explicit and of deeper, empathic, inarticulable moods and meanings. For we carry with us the aura of our life experience, both as outer events and inner thoughts. Shared meanings of the culture and subculture are recognized intuitively by how they have molded us. These implicit meanings reach the other person by the subtle signs from which we can be read—from the clothes one wears to what makes one smile.

Entering into spoken situations are the shared, consensually defined meanings which are set up by the culture, as in the established symbolic meanings and significance of language, of gesture, of certain forms of behavior and activity. Another range of such symbol meaning which enters into interpersonal communication is derived from family and group definitions. In addition, private and autistic meanings cast their aura on a spoken situation, often to obscure it.

Downloaded from www.dbraybooks.org.uk

Spoken communication depends a great deal on the readiness to communicate, on the expectation and the availability for verbal relatedness. These enter into the sense of consummated interpersonal communication in the experience of rapport.

#### SILENCE

In interpersonal communication, there are occasions when silence occurs—with varying significance and varying comfort and discomfort for the participants. Silence has its eloquence. Silence may express noncommunication in a deep sense, inarticulateness in spite of the wish to communicate, or fatigue. It may be due to a person's absorption in experiencing himself to the exclusion of the outside world. There may be the companionship of a shared mood, needing neither words nor gesture. Or silence may be indicative of hostility, may actively convey belittling operations to the other and be intended to evoke disquietude in him. It may arise out of a profound negativism about communication, which we encounter in a wider range than, for example, the disorders of schizophrenia and depression.

People differ in their need for silence. For some, there is a premium on filling the air with sound. For many, silence is anxiety-provoking and evocative of childhood ostracism by an angrily silent parent. But silence may also clear the way for empathic exchange, for deeper communication. Thus silence may well be considered a mode of communication.

### *Intrapsychic Communication*

#### ORGANIZING ACTIVITY

Intrapsychic activity organizes the messages received from the inner world of emotions and body states, and from the outer world. The organizing psyche is derived from all the experiences up to that point in time at which the new experience occurs, as well as from predispositions that we cannot accurately assess as isolated factors. As an example of the latter, we recognize that we have our personal inclination toward one or another sense modality of symbolization. For that majority of people who are eye-minded, not only language but visual images are the means of recording and storing messages.

Communication from within includes messages from the side of us which rarely comes to explicit word formulation—not only from emotions but from affective states and bodily conditions that contribute mysteriously to our general sense of ourselves. How these are symbolized, how they affect other symbolization, is still uncharted territory. However, it appears to be a reasonable assumption that at some point symbolic processes within the receiving person act upon these messages.

#### SYMBOLIC PROCESS AND SOME DISTORTIONS IN RESYMBOLIZATION

Intrapsychic communication involves the recognition, interpretation, creation, and expression of symbols, symbolic activities, and meaning—all of which enters into our mentational activity and into the experience of the self which give the sense of "I am a person."

Resymbolization of the message received ultimately transforms it into the interpretation that enters awareness, or, in emotionally significant experience, the interpretation that is forbidden to awareness. The interpretation may be a genuine comprehension of the symbol meanings, may be quite remote, or may be a distortion. The epitome of the comprehension of meaning, significance, symbolism, and reality is manifest in intuition, which is the consummation of understanding in depth.

An interpretation is utilized, whether or not it corresponds to the actual understanding of the symbol and its meaningful content. For instance, in rationalizations, significance has been reformulated, resymbolized conceptually, and cast into a language form acceptable to our consciousness. In conversion hysterias the process of resymbolization turns away from what is consciously verbal and into somatic expression, with subsequent resymbolization into awareness.

We may ask ourselves the difficult question about a person: Does his interpretation of the symbol and its meaning match the reality behind the symbol? This is a way of appraising his apprehension of reality.

#### RELATEDNESS TO THE SELF

The relatedness to one's self and one's organism clearly includes the Socratic prescrip-

Downloaded from www.chiraltrust.org.in

tion, "Know thyself," and the full self-knowledge of ideal psychoanalysis. It includes insight; that is, an intensity, depth, and fullness of self-knowledge with a sense of the roots of one's behavior and experience; a recognition of one's motivations and emotions and of the forms in which they are expressed.

Experience of oneself on the level of self-knowledge and self-awareness depends on permitting awareness, feeling, and recall. Experience of oneself as fulfillment includes not only hearing but listening to and heeding the messages from affects and bodily states, from reverie processes. It involves their consummation and their transmutation to thought. It involves not only permitting messages but seeking them. It involves focal attention. It has its linkage with interpersonal experience in terms of emotional gratification and values.

Intrapsychic communication may be cut down and turned off its true course in the prosaic and everyday denials of the self which do not form the clinical syndromes of psychiatry, but which deplete the experience of living.

## *Psychologic Aspects of Verbal Communication*

Verbal language is, by and large, our favorite form of conveying messages, particularly interpersonally. It is part of the collection of skills whose continued competence is a function of one's consciousness and thought, of emotional fluxes, of somatic and psychologic health. Verbal language becomes disturbed in the not-unusual experiences of fatigue, stress, and anxiety. It becomes characteristically altered in such clearly psychiatric disorders as the schizophrenias and depressions.

Though language is a specific mastery for every person, its emergence depends on three root processes which are derived from our biologic and cultural heritage, namely:

1. Man "instinctually" is a symbol-making creature.
2. The verbal language of the culture directs the individual's thinking along the thoughtways of the culture.
3. Communication, including verbal language, is subject to a process of maturation in each person's life, beginning in infancy and affected by his earliest interpersonal experience.

The existence of speech and language for all human beings seems to be bound to the human propensity for symbol making. That we are "instinctually" symbol-making beings is the keystone of Cassirer and Langer's hypothesis concerning the origin and function of language for mankind. In effect, they point out that language is both the proliferated outer form and the consummation of the psychologic process of symbol making. From the innate necessity for symbol activity, they derive the corollary that the gratification of this drive is an end in itself and its own reward.[7,18]

### Language, the Culture, and the Individual

Word language offers the prime demonstration of how the culture acts on the person from his earliest infancy. The culture begins its use of language as a tool through the sanctioned, explicit verbal meanings and forms whose mastery begins in childhood and is a continuing challenge.[30] Language provides the culture with a channel for the transmission of its attitudes and meanings. More tenuously, a specific language reflects its culture through the experiences it names (and those it doesn't), in the identified (and unidentified) abstract qualities, in what's proper to talk about.

Most subtly and elusively, the specific language, per se, in its intrinsic structure, exerts a molding force, presses thought into direction by the meanings implicit in its own structure. Whorf, from his researches on the great language clans of the world, adduced evidence for the thesis that a culture patterns the thoughtways for the individual through the conceptions implicit in its language. Concepts of time, space, and movement are conceptualized differently and characteristically for the respective great language clans. For instance, the Hopi language (American Indian language clan) recognizes, in contrast to syntactical English (Indo-European language clan), an experiential dimension of time which we lack. "The Hopi realize and even express in their grammar that the things told in myths and

Downloaded from www.dbraulibrary.org.in

stories do not have the same kind of reality or validity as things of the present day, the things of practical concern."[31] Such implicit conceptualizations embedded in a language are, according to Whorf, even more powerful than explicit word meanings.

Within the same linguistic family, the member languages not only have their respective verbal idioms but their characteristic emotional tone. The earthiness of one language is the vulgarity of another. The emotionality whose verbal expression is good form in Italian is suspect as oversentimental in English. The courtly verbal forms that still are currency in Spanish would be an artifice in English. It is quite an achievement to master the thought-ways of a second language and culture and learn to live in them psychologically.

The obstacles to communication—in social encounters, in psychotherapy—which arise from linguistic differences can surely be diminished by awareness of their existence and by the wish to communicate, by the attempt to have a meeting of minds and personalities. In contrast to the communication problems of the denizens of Babel, people sharing a language have a sense of relatedness to each other. Though many of their shared meanings are derived from other factors in the culture besides the language, the community of language is a prime factor in establishing this feeling of relatedness, of being at home with others speaking the language.

### INDIVIDUAL EXPERIENCE AND THE FUNCTION OF LANGUAGE

When we focus on the person himself as the unit, we see that verbal language meets certain subjective inner necessities for intrapsychic and interpersonal communication. Compared to the other symbol forms, words possess great precision (though the analytic philosophers are more impressed with the vagueness and condensed meanings in ordinary language.)

In the domain of intrapsychic activity, words symbolize reverie, thoughts, and emotion in a form that has great mnemonic advantages. Words make convenient packages for memory, both as long-term mnemonic devices and in the swift transition from one thought to the next. Language helps focus consciousness on subjective experiences that tend to be elusive, particularly when inarticulate. Thus word language enables us to stabilize experience, whether to think about it, talk about it, or recall it. In none of these respects, however, is verbal language the only means of capturing experience.

Word language helps to stabilize meanings. It is opposed to autistic meanings. Of course we know, from the rapidity of change in American English, that meanings won't stay pinned down to words; and, as we know from our subjective experience, autistic meanings attach themselves to words.

Word language permits building hierarchies of meaning, from image for a concrete object to abstraction of a quality or meaning. Thus it organizes thought and experience, one level of organization forming the floor for the next. Word language makes interpersonal communication of thought easy. It fills in what the empathic mode of communication, which essentially serves the affects, can hardly accomplish.

These very functions of language lend themselves to misuse and misunderstanding. Verbal communication is often considered to be antithetic to empathy, and, indeed, verbal language is often used to din out empathic perceptivity. A challenging problem is: Is this antithetic relationship an intrinsic necessity? Verbal people are particularly prone to assume: no articulate verbalization, no thought; no thought, no intelligence. We tend to disregard what we know very well—the structuring influence of emotion on thought, the truth in the proverbial "wish is father to the thought."

Another misuse is overabstraction, by means of which one becomes divorced from the reality underlying the words. Indeed, one of the marvels of language is its relationship to deep processes and experiences without which it could not function.

Words serve not only to express and communicate emotion but also to drain off emotion. Emotions, when inarticulate, may express themselves in behavior and deed directed at the environment or may be repressed. Breuer and Freud's first contribution to psychoanalysis was the concept of abreaction—the discharge of the repressed emotion into verbal emotive

Downloaded from www.pbalibrary.org.in

expression. The channeling of emotion into verbal expression instead of into action on the environment has been one of our major socializing forces—not without unfortunate by-products in terms of overrepression and constraint of emotional experience.

Some of our subjective experiences, when our use of language fails us, show up its functioning when it is "normal" and integrated. A language experience familiar to most of us is the sense of distress when we are at a loss for words to name a feeling state. Having a word for a thing or for an observed phenomenon is a great convenience; having a word for a subjective experience is a great comfort. The naming and identification of a new and disquieting emotion reassures one of emotional kinship with one's fellows (unless the recognition of the feeling state is self-deprecatory). Indeed, sometimes any label is preferable to no label, a fact which has important implications for psychotherapy.

Words built into sentences can convey a whole thought, in contrast to isolated words. But single words can carry a sentenceful of meaning, depending on the contextual situation, on the associated nonverbal communication. Single words with the force of sentences are part of the experience of each of us, submerged generally in deep memory. It first occurs as a step in the maturation of the young child in dealing with language and meaning. We occasionally encounter it in ourselves when we are greatly fatigued, or when coming up from deep sleep. With some creative people in the press of accelerated thought and imagery, the words come tumbling out in phrases indicating ideas but not expressing them in the smooth verbal order that is their later form.

Discourse in words is something volitional and learned; something that has become second nature. Nonetheless, like all learned processes, it may become disorganized under great stress or privation, and it has characteristic patterns which enter into psychiatric disorders.

### Symbol Forms of Verbal Language

There are two great subjective modes of symbol activity which correspond to the two great categories of symbol form into which verbal language falls. These modes are thinking in logical constructs and fantasizing in imagery. The corresponding modes of verbal language have been designated by Cassirer as "discursive logic" and "creative fantasy." The term "creative fantasy" does not exclude the fact that both kinds of symbol activity have their creative aspects.

It is essential to understand the characteristics and the distinctions—and the rivalries—between these two basic styles of language and mentation in order to get a better sense of their role in different patterns of personality and mind-set. Indeed, they are particularly pertinent in the communication disorders involved in obsessional thinking, in schizophrenia.

Discursive logic operates by means of what may be called "denotational symbolism." The meanings of the symbols are precise and sharply defined and within the range of cognition. Discursive logic is often considered to be a close indicator of reason.

The symbolism of myth is metaphor, which deals with connotations, with analogies seen in the phenomena occurring about us, and with imagery arising from fantasy and the unconscious. The meanings of myth are not easy to pin down but shimmer with elusiveness and paradox, and sometimes with the challenge to reason that characterizes dreams. Myth has significance rather than precise meaning in the semantic sense. The symbolism and significance of the mythic mode are communicated in imagery, narration, or the dramatic form. More often than either camp would acknowledge, discursive logic is a hidden partner under the final polished form of the mythic mode.

Often the mythic mode is called "prelogical," with the implication that it is qualitatively and chronologically the rudimentary precursor to logic, with the further implication that lingering in the myth-making mode indicates a kind of retardation of the psyche, an emotional arrest in the "golden age" of childhood.

The writer subscribes to the view that the mythic mode has a logic of its own, often a logic about human nature, a logic of the psyche, whose relation to discursive logic is paralogical rather than prelogical, and with which it is not necessarily incompatible.

Downloaded from www.dbraulibrary.org.in

The division of language symbolism into discursive logic on the one hand and into metaphor and myth on the other is paralleled by the inclination of different personalities toward one or the other of these vast congeries as the most natural way of experiencing thought and intellection. Some persons verbalize their experience in highly metaphoric form or in dramatic style, which often is suspect to the person who favors the logical, abstract pattern. It is astonishing how difficult communication between these two mind-sets may be, particularly if embodied in psychiatrist and patient.

## *Communication and the Child*

We have noted that the emergence of language for the individual depends, in part, on the human pattern of maturation of communication. The child's experience with communication subsumes a number of impressive facts which are pertinent to our interest in psychiatric disorders:

1. The culture, both through its language and through nonverbal means, has an intricate action on the child's communication.
2. The role of the mother is fundamental to the emergence of communication in all its modes.
3. Many difficulties in interpersonal communication and many disorders of communication as skill derive from disturbed communication in childhood.
4. Some kinds of interpersonal disturbances of communication in childhood as well as in adulthood evoke anxiety and even panic.

### Communication Between the Culture and the Child

The culture communicates with the child; it reaches into his cradle and molds the patterns of his behavior, his thinking, and his feeling. It injects meaning; it shapes his symbolic operations. It prescribes the kind of cradle he lies in, how his mother holds him; in short, it steps into the communication between mother and child in the earliest nonverbal and preverbal modes.

Through the language itself, the culture affects how the child conceptualizes even such elemental experiences as relate him to the physical cosmos (the Whorf hypothesis). Shortly after the child enters the symbolic mode of language, the culture begins to communicate with him concerning interpersonal behavior. The culture molds not only the thinking but what emotions are acceptable, and defines the "proper" way of showing emotions and moods, of communicating emotion.

### Broad View of Communication from Infancy to School Age

The newborn's potentiality for communication is realized under the sun of parental affection, tenderness, communication, teaching, and encouragement. The most striking achievement is speech, a miracle of development. Though the emergence of speech and language is responsive to good parenting, nonetheless it is subject, in its progression, to the general human pattern of innate order and timing.

Speech is but one element in the child's communication. From the beginning, communication is enhanced by other functionings and experiences which converge on it, such as vision and the other special senses, the competence of arm and hand movements, etc. However, the child himself is greater than any one sense or ability, as the experience in teaching physically handicapped children demonstrates.

Communication is indissolubly bound to the learning process. Indeed, the learning process is one indication of competence of communication. In the first two years of life, a phenomenal development of one mode of communication after another proceeds, beginning with the newborn's total receptivity and culminating in the rudiments of verbal language. In the next phase, between two and four years, words become organized into syntactical form. After language has become a rather competent tool for the child, he not only uses it interpersonally but carries on extensive audible private monologues for his own gratification. The meanings are often uniquely his own. By the

Downloaded from www.vidyarthiplus.org.in

time he enters school, social language exchange, with standardized accepted meanings, overshadows his inner language.

### The Emergence of Spoken Language; the Role of the Mother

Communication progresses from the presymbolic phase in the newborn state to the symbolic mode of language and gesture in early childhood.

**The Neonatal Period.** In the neonatal period, the first month of life, the infant is essentially passive-receptive in communication, as in his other relatedness. He may be said to be *subject* to communication. He receives communication from his mother, predominantly through the closeness of direct body contact and also through empathy. Some inarticulable impress of her becomes incorporated during this presymbolic period in what is to be deep body-memory.

Nursing is his one focused activity. We might say that the nipple is the only "sign" that is meaningful to him in this phase of *protocommunication*.

In his first two weeks his vocalizations are not recognizably correlated with situation or stimulus. Between the second and fifth weeks, specific sounds correspond to specific discomforts and are read as signs. These first vocalizations are communications of affect and are outside of consciousness as we know it.

**Early Infancy.** In the next period, early infancy (two to four months), the baby becomes more active in communication, more participant both as receiver and sender. He receives his information through direct body contact, empathy, and the emergent special senses. To the newborn's receptivity he adds two modes of operation—responsiveness to the signals coming in from the outside world and the beginnings of volition in sending forth messages.

With the development of the distance receptors—in the order of smell, vision, and hearing—his apprehension of the physical and personal world about him increases in range and precision. He begins to reach out, with hand and attentive vision, to the objects and the world that he apprehends. A most important innovation begins later in this period—eye-to-eye communication between baby and mother.[11] He has begun to vocalize, with indication that he enjoys it, and to respond to the human voice—an expression of the drive to communicate. Toward the end of this period he imitates sounds.

The messages he sends early in this period still are of affect. Whole-body movement is his expressive language, the forerunner of gesture. He protests and cries with his whole body as though to thrust away what offends him, and he gurgles and expresses delight with his whole body. At the end of this period he begins to indicate his wishes by what he reaches for with his hands, by what he turns away from in avoidance.

Mother has begun to enter his dawning psyche not only as the deep introjection of the presymbolic phase but as an image which takes form cognitively, that is, in early symbolization.

For understanding her baby, mother still depends on reading the signs of voice and cry and body tone and movements. His cry is the prime sign, with its range of intonation and meaning. Parenting includes respect for the cry.

Latif[10] points out that it is the mother's responsiveness to the baby's whole-body expressive movement that helps narrow it to gesture, since his movement is read and anticipated. His response "thus becomes merely symptomatic, i.e., symbolic."[10] In the maturation of communication, gestures are among the earliest symbols understood, imitated, and exchanged by the infant.

**Mid-Infancy.** In the next period, mid-infancy (five to eight months), his range of vocalization and of syllabification widens. Mother re-enforces selected sounds from his vocalization which are in the range of her language, and appeals to his imitativeness in their affectionate interplay. She reads the first meanings into his syllables—da-da, ma-ma; she structures little situations to which the word is appropriate, and the learning of speech begins.

The infant gives indications of direct messages, addressed to mother—of fear or anxiety.

Downloaded from www.dbraulibrary.org.in

He gives evidence of other meanings—recognition, command, refusal; information as information is a later achievement, whether with gesture or in words.

**Late Infancy.** The period of late infancy (nine to twelve months) culminates with the achievement of words. The baby's gesture of "bye-bye" is established. Between the tenth and twelfth months he responds to commands of various sorts, including pointing to parts of the body. Two words or more are reported quite uniformly at the twelfth month. Infancy, etymologically without speech, is drawing to a close.

**Second Year.** In the second year the vocabulary increases, and the child enters the naming stage and can identify objects pointed to in pictures. The first phrases, sentences, pronouns, and prepositions occur in the twenty-third and twenty-fourth month, the peak of achievement.[20]

### Socialization of Language; Autistic Meanings

The child is next involved in the complexities of language and, soon after, in communication situations centering on verbal discourse. This encompasses the preschool period, up to about six years of age.

The child acquires considerable skill in vocabulary, syntactical form, and above all, in meaning. Both shared and private meanings settle around words (Sullivan). In later childhood, in Sullivan's view, the child's enlarging world of school and people presses on him to relinquish or submerge his private meanings. Thus the mastery of shared language meanings enters into the child's socialization and acculturation.

In *The Language and Thought of the Child*, Piaget,[22] reporting on two six-year-old children in a nursery, observed the distinction between private monologue in the presence of a person and true conversation. The first variety he designated as "egocentric," the second as "socialized."—

Egocentric language is hardly restricted to children. Certainly our verbal ruminations, whether or not voiced, are egocentric in Piaget's sense. And we all have experience with people who require the presence of another person as a backdrop for their verbal performance.—In socialized verbal communication, the child engages the other person in conversation with intended exchange. The egocentric language behavior precedes the socialized in the development of the child and is gradually supplanted by it.

Vigotsky,[29] in his discussion of childhood speech in "Thought and Speech," gave a different interpretation to Piaget's observation of "egocentric speech." His view was that egocentric speech is really private inner speech, a reverie process which is not the forerunner of socialized speech but is on another track of development and function. The speech is still audible because the child has not yet learned to be silent, to internalize speech.

We may conclude that language serves the child in several functions—as exchange in interpersonal communication, self-expression to others, and self-experience in reverie and thought. That is, the functions of childhood language are communication with the self as well as with others.

### Where Mothering Can Go Astray in Communication

We have seen how the emergence of language is integrally bound to mothering. The interplay between mother and baby is essential not only to his learning but to the structuring of his personality, which depends very much on interpersonal communication. Without this interplay, the damage is overwhelming—even to life itself.

There are, of course, other destructive modifications which involve the child's communication besides its absence:

In the long period of their relatedness by direct body contact, does he receive the jarring physical impact of an unconsciously hostile, anxiously tense, or overefficient mother; or is there gentleness and tenderness in the handling of his body?

Is he empathically flooded by parental moods of depression, commotion, anxiety, and rage?

Downloaded from www.libtool.com.cn

The preverbal child reaches out for affection, for body contact, cries out in flicks of anxiety or distress. Is his mother available for nonverbal communication?

Is he given—and asked for—more massive "love" than a baby or child can take or give?

Is there a disparity, a "double take," between verbalized affection and the feeling tone which the baby and young child empathize? Perhaps the mother can neither give nor take physical responsiveness, and the disparity between her withdrawal and her affectionate verbalisms confuses the child.

In the period of language learning, is he subject to excessive pressure, by either parent, because of a high premium on performance and language precocity?

Is the emphasis on reason and logic such that the child is pressed to make up reasons—in effect, to produce rationalizations to meet his parents' queries?

Perhaps the child is not granted adequate psychologic privacy for his reverie processes and his developing relatedness to himself. Are his explorations into the physical world about him hindered?

## Traumatic Experiences in Childhood Communication and Later Personality Disorder

The following are instances of disturbed communication in childhood, viewed from the adult side of the bridge.

### Respecting the Cry.

Ellen S., age twenty, in psychotherapy for an acute schizophrenic episode with hallucinations and mutism, recalled mother's stated position concerning an infant's crying: "I will not have a spoiled child. No child of mine cries."

And the baby had been allowed to cry herself mute. The classical open safety pin found jabbing into the crying baby did not invalidate mother's rule; and the pediatrician who maintained that little Ellen was crying because of hunger was a sentimental weakling.

In early childhood Ellen had asthmatic attacks. Now the lack of respect for the cry of babyhood was replaced by a lack of respect for verbal self-assertiveness. In adolescence, Ellen learned what would work—a brooding silence would invite mother's prodding to find out what was troubling her. By this means, mother's controllingness was outmaneuvered into a modicum of effective communication.

"If I say something," said Ellen, "it won't be respected; only if I seem to withhold. Any wish was met with a logic about why I shouldn't have the wish; and I gradually let the logic seep in and replace the wish."

### The Unavailable Parent.

Marvin G., a young engineer twenty-six years old, was incapacitated from functioning in his profession by fluctuations of rage and depression, and he was churned with open anxiety over his impulses to violence. His rage dated back to the birth of his brother when he was two years old. What for him was proof of being unloved came from his mother's seeming indifference to him, and his father's preoccupation with newspaper politics. Marvin responded with empathized depression to mother, and sometimes with rage. When he wasn't wistfully reaching to father, Marvin experienced distructive rage toward him, who communicated only with arguing and formulating.

"Mother was depressed when I was a kid, and she would sit and stare out the window and turn away and shrug her shoulders when I spoke to her or touched her. I felt mother cut contact; I was like a ship cut from moorings with no one at the tiller. I was in a depression and waiting for someone to take the tiller . . ."

### Affection Through Words Instead of Body Closeness.

Anne H., thirty-two years old, came to psychotherapy following a suicidal attempt during a postpartum depression. She was extremely obsessional, in her thinking and in her household activities, and teetering on a knife-edge between anxiety and depression. She was given to long, tense, sulky silences in psychotherapy. Apropos of her "resistance" she said, "What's the use of talking? It's futile. All I got from my mother was praise, words, for giving up to my sister. Never a touch, never a hug."

In contrast to her experience of limited communication with mother was her sense of excessive

Downloaded from www.brainlibrary.org.in

transparence with father, a lack of psychologic privacy between them.

"We understood each other too well. He was transparent to me; there was a frightening sense of communication. He would say, 'I know, I know,' and I would feel that I had to flee."

**Disharmony Between Words and Affect.** Marian O., a young woman in an anguished depression following the death of her father, came to analysis with a congeries of distressing symptoms—a sense of confusion and of alienation from herself, a cynical probing for hypocrisy, a provocative teasing of authority figures, including the analyst. Her communication in analysis was baffling. She was given to verbal pyrotechnics; though her words as language were meaningful, there was a quality of unrelatedness to what she was actually experiencing at the time that, nonetheless, gave a sense of meaninglessness.

Both her parents had been talented people: mother aloof, controlling, and overintellectualized; father moody, brilliant, and divided in his numerous interests, of which his daughter was but one. In the high value put on language performance, Marian was precocious. She had always felt lonely, first from her parents and later from her less "special" schoolmates.

"I doubt if I ever communicated with anyone, if it means having the feelings and words coordinate. No one communicated at home."

**The Child as "Captive Audience."** Avery R., twenty-seven years old, had a learning block which had seriously interfered with his accomplishment in college in spite of high intelligence and even originality of ideas. He was inarticulate in the interaction with verbal people but expressed himself fully and maturely to those to whom he felt protective. He had difficulty in concentrating, in listening to any prolonged discourse by anyone.

"Mother doesn't want any comment. Any comment I make is an interruption."

["Even agreement?"]

"She wants agreement, but more than that she wants to prove it to herself aloud, so when she talks I don't quite listen. I daydream, I make plans, and just listen to her sometimes here and there and nod."

Should this example be captioned, "The mother with 'egocentric speech' "?

## *Faulty Interpersonal Communication*

### The Spectrum of Faulty Interpersonal Communication

The spectrum of faulty interpersonal communication covers a wide range. Its nodal stations are shown in the diagram below.

These may all be accomplished by discourse itself, or without words. Nonverbally, the means may be any of those which we have already mentioned—nonverbal symbolism, direct body contact, body-language, empathy, of affect. A communicator in the faulty interaction may or may not be aware if the process is in himself or in the other person.

**Grossly Destructive Communication.** This communication may be imbued with hostile intent, consciously or unconsciously, or may be inadvertently destructive without hostile intent. For instance, exposure to a person who is consumed by rage or hatred is a negative experience, even if an absent person is the target; that is, emotions which have a destructive force make an impact on the receiver even if he is only a bystander.

The message of the verbal discourse may be hostile in its literal content, as a vituperative or derogatory attack on the other's self-esteem or on his good values. The literal content may be nonhostile, but the significance may be hostile—for instance, some techniques of ridicule. Or verbal discourse may be an attack on reasoning, as some incredibly destructive kinds

| Grossly destructive communication | Authoritarian communication | Disjunctive communication | Pseudo-communication | Noncommunication |
|---|---|---|---|---|

Downloaded from www.dbraulibrary.org.in

of arguing are. The hostility may address itself to distorting the relationship of symbols to reality, to introducing gross error.

The attack may be on interpersonal communication itself, by shouting down the other person to din out communication, or by silence. Silence may be a refusal to communicate or a refusal to permit communication. It may be an attempt to imbue the target person with a sense of ostracism, unworthiness, loneliness, disrelatedness, or confusion. Destructiveness with hostile intent may be conveyed by body-language (brusqueness of physical contact, a shunning avoidance), by rejection or disparagement in voice quality, or by facial expression and gesture in subtle eloquence.

Hostile communication may introduce stresses into the other person in his relationship with himself or with others as part of the direct hit of hostility. By attacking the other person's meanings, values, and significances, one reaches into him to attack his sense of self and disrupt his intrapsychic communication. Hostile communication may break up his natural rhythm, tempo, and patterns of communication.

**Authoritarian Communication.** The most blatant examples of authoritarian communication are the "brain washings" with police-state techniques.[15] In the authoritarian-communication situation, one person or party commandeers and controls communication so that production is exacted from the sender, without respect to his wish to participate, with heavy pressure on him to structure the verbal message in the form insisted on by those in control—not necessarily in terms of fact or truth—with repressive hostility for nonverbal responses.

Questioning, with the intensity and persistence of inquisition, is one of the destructive tools. Another is the pressure on the sender for unending production of messages which are recurrently annihilated by either oblivion or disparagement.

Communication of this kind occurs in miniature in our most prosaic experience, as exemplified by the person whose attitude is, "You are not to talk. You are to talk when I tell you to," and by attempts at thought control by authoritarian parents.

Another variety of authoritarian communication is by means of heavy formulations, in which the speaker is the overweening intellectual authority.

One patient in a frenzy of arguing and of collecting bits of information in the futile attempt to prove his father wrong to his father, had hoped, by getting into technical studies, to get away from his father's indoctrination.

"I felt that I wanted a little sphere of my own. One thing I liked about my technical studies was that I could do my own thinking, and my father couldn't."

**Disjunctive Communication.** In disjunctive communication the predominant purpose is confusion, disruption, or divisiveness. Either sender or receiver acts to make the communication disjointed, literally "unhooked," in the direction of breaking down communication, changing authority roles. Sometimes it is playful teasing or a skirmish of wits, employing the disjunctive techniques but without destructive intent or effect. Sometimes the apparently playful skirmishing is defensive, arising, say, from anxiety, reflecting or spiraling into a state of confusion in the communicator. Disjunctive communication, when it is defensive, really signifies, "Don't annoy me, don't ride me; let me be." It may be one of the operations of resistance during psychotherapy.

The techniques involved tend to break up the line of reasoning or the flow of language. Introducing semantic confusion is a favorite method. Another time-tested means is the question—the "irrelevant, immaterial, impertinent" question which is curbed in the law courts, the pseudo-logical, heckling questions that are rampant in quarrels.

Gestures and mannerisms—crackling of the cellophane cigarette wrapper, jangling of a charm bracelet, etc.—may be used disjunctively in psychotherapy as an expression of resistance about an oversensitive area.

**Pseudocommunication** is a composite of dissimulation, simulation, and limitation of communication. Communication is seemingly, but not really, going on. There may be a sense

Downloaded from www.dbraunbooks.org.in

of "double talk," of disparity amongst the several levels of communication.

Pseudocommunication is to be differentiated from noncommunication and from phony communication. In contrast to the former, a sense of relatedness to the other person persists, although communication may be guarded and restricted. In contrast to the latter, the intent to deceive or to set up a meretricious image or message is lacking. Pseudocommunication may or may not be sincere. Of itself, it is not hostile or destructive, though it may occur in a hostile context. Indeed, in some situations pseudocommunication is a kindness.

We all engage in pseudocommunication occasionally, sometimes out of respect for another when there is neither wish nor necessity for him to get involved in our personal feelings. Some of the social forms of gesture and conversation serve in pseudocommunication.

Pseudocommunication is often defensive. For instance, an anxious person, in his initial psychoanalytic interviews, may have recourse to social chitchat before feeling ready to get to the purpose of his visit.

**Noncommunication** may occur in an ostensible communication situation. A communicator experiences a sense of the other's lack of relatedness, in spite of a continuing verbal exchange whose explicit content makes sense. A not-unfamiliar and often distressing experience of noncommunication is the sudden sense that the listener is absent—that the interpersonal wire has gone dead.

Noncommunication may be experienced by a straining listener, whose attention is not relieved by a message, with a feeling of the most overpowering doped drowsiness—most distressing if the listener is an analyst and the noncommunicant a reclining patient!

This is to be distinguished from resistant communication in which the communicator sets up a sense of impasse by verbal or nonverbal means. With resistant communication, there is a vivid sense that communication is being pressed back, that there is an active rejection or denial of the free flow in the exchange.

The word "resistant," of course, brings to mind the problem of resistance in psychotherapy. The usage in the present context is denotational. In the usual clinical sense, resistance concerns a wider range of communication difficulty occurring between therapist and patient and entails consideration of the following elements—each participant's personality and communication pattern, the patient's specific anxieties and their origin, and the specific operations in the communication transactions.

## Personality Disorders and Communication

### *The Hysterias*

With *Studies in Hysteria*, published in 1895, Breuer and Freud[6] made two major contributions to communication in the field of psychiatry: first, symptoms have meaning; second, communication is the therapeutic operative force in psychoanalysis. The symptomatology of hysteria was a language to be decoded and translated back into words. The translation itself, and the release of affect associated with the translation, was the therapy. As Breuer said, "The excitement which is produced by very vivid and irreconcilable ideas finds adequate reaction in verbal communication."

#### CONVERSION HYSTERIA

In conversion hysteria, emotional disturbances are expressed by disturbed functioning of a part of the body in terms of its body-image; that is, the disturbed functioning is expressed in a resymbolization conceptualized as to how it functions. The sufferer himself does not recognize that the body experience is linked to affect and the affect to a contextual experience. The sufferer does not recognize that the symptom is a direct expression in body-language of a full interpersonal event, relationship, and experience, presented in the form of a charade. All that seemingly remains is its somatic symbolization. The force toward repression, some profound necessity for alienation from the self as an experience, is the powerful operative impetus.

Download from www.cbalibrary.org.in

The steps between the original experience and the clinical picture of conversion hysteria are: (1) interruption of intrapsychic communication by repression; (2) some deletion of meaning from the unfortunate affect-situation relationship; (3) a persistent somatic symbolization of the affect-situation relationship; and (4) reinterpretation and reformulation of the somatic symbolization in terms of a local illness of the body; that is, there has been a series of resymbolizations. The meaning, as experienced in the sufferer's awareness, is not consonant with all the relevant facts. In other words, the meaning in awareness is false to the reality and the significance.

The symptoms in conversion hysteria may also operate for the sufferer in interpersonal communication. They are signs which are not only observed and interpreted by the therapist but are to be read in a certain way. The symptom also bears its own intended message, by nonverbal means, by the charade. Such interpersonal messages may be reproach, accusation, an appeal for pity, forgiveness, or help—these intricate operations all going on outside of full awareness of the patient. It is likely that the sometimes hostile response of those close to persons with conversion hysteria (including the baffled physician) is due in part to resentment of the manipulated message, the operations in the other communicator also going on outside of awareness.

The conversion of an unfulfilled emotion and desire for action into a symptom whose meaning and affect-content could be returned to awareness is illustrated by the following report of a patient seen by the writer in consultation and for brief psychotherapy.

Mrs. Tessie T., aged thirty-two, was a recent arrival to this country from Poland shortly after the Nazi occupation. She was the sole survivor of her family, having leaped from a freight train with destination Buchenwald. After her escape back into life, she spent eighteen months of the Nazi occupation lying cramped under the kitchen floor of her Gentile benefactors. She would emerge in the depth of night for her bodily needs, except when it was sensed that a search was imminent.

Beginning in the last months of this period, the symptoms for which she later came for therapy declared themselves—paroxysms of severe cramping pain in the hands, transitorily relieved by slow and full squeezing together of the hand muscles. The cramping pain persisted after her liberation and emigration to the United States.

No physical basis was found for the pain, which interfered with household duties, let alone gainful employment. In addition, she had severe occipital headaches and sleep disturbed by screams of terror.

The early goal of psychotherapy was to ascertain whether there was a clear personal meaning in the hand pain. She was encouraged to make movements with her hands which would relieve the pains. In the course of this somatic expression the patient recognized that she was strangling Nazis, that she was expressing her consuming rage and visualizing the Nazis with whom she had had experience. With the affect expression and the recognition of the symbol meaning of the hand pains, the symptoms did, indeed, greatly diminish, but not the screaming nightmares.

### Anxiety Hysteria

In anxiety hysteria, anxiety is projected onto an outer circumstance—an object, situation, or event—which is believed by the afflicted person to account for his distress and becomes the object of his phobia. In other words, the basis for the anxiety is resymbolized by a reinterpretation of outer reality. The new symbol serves as a rationalization for the anxiety.

### Hysterical Disturbances of Consciousness and Hysterical Dream States

These conditions may be considered a replacement of the reality of here and now by another world of time and place—and perhaps person—as what has existed either in past reality or only in fantasy. This switch-over is an autistic projection, which differs from what is generally included under the rubric of schizophrenia in the following two respects—the intactness and effectiveness of the hysteric personality, and the retention of adequate verbal and ideational performance.

In the hysterical switch-over, the "as if" takes over as a well-integrated play might do.

Downloaded from www.orientalpsychology.org

It is as if life were resymbolized *in toto* by the other role which is played with the consistency of another self, and which replaces another constellation of traits and operations which, in turn, seemingly form a functioning self. The patient is able to manipulate fact, meaning, truth, interpersonal relationships and his (generally her!) own self in a full, integrated role.

#### THE HYSTERICAL CHARACTER

The hysterical character comes close to what is considered hysterical in common parlance. This personality type is remarkable for the use of emotionality and histrionics in interpersonal communication, and for the highhanded bending of fact and truth to her own purposes and to the distortion of meaning and significance for the other person—all of this very often with verisimilitude. Sometimes the histrionics carry over into acting out—beyond drama into deeds.

These devices have high communicative intent and make a powerful impact on the appointed audience. They become a method of expressive communication more important to the person than direct verbal literal communication. The kind of language favored may have great dramatic and emotional import, though the nonverbal expression by gesture, facial expression, and behavior may be preferred. The person of hysteric character doesn't linger on logic and verbal thought and formulation, for these would slow up the full sweep of the dramatization. In these respects the person of hysterical character is qualitatively opposite to the person of obsessional character.

If one can retain one's sense of oneself in the presence of a person operating in terms of her hysterical character, one may note in oneself a lack of empathic responsiveness, though the manipulations may be surprisingly effective in the hands of an expert.

The common factor in the hysterias appears to be the resymbolization of emotional experiences containing meaning, which is potentially within awareness, into somatic form.

The sequence of inner processes basically involved in hysteria is the progression from an intolerable emotional experience, with meaning which is potentially within awareness, to resymbolization of experience and meaning into other terms: in conversion hysteria, into somatization; in anxiety hysteria, into phobic resymbolization of anxiety; in hysterical alterations of consciousness, into resymbolization of one's sense of self; in hysterical character, into resymbolized acting out in the form of a whole, different, integrated personality. All these changes generally occur to the complete mystification of the afflicted person.

### *Obsessional States*

#### PHENOMENOLOGIC CHARACTERISTICS

Regardless of the differing interpretations of the genesis and psychodynamics of obsessional states, there are a number of phenomenologic characteristics that are generally agreed upon. All agree that, "the obsessional state is classically a state in which there is great activity of thought" (Sullivan). All agree that there is retreat from feeling to thinking. "The compulsion neurotic, being afraid of his emotions, is afraid of the things that arouse emotions. He flees from the macrocosm of things to the microcosm of words."[9] It is recognized that his intrapsychic communication shows an imbalance between thought, language, and feeling states. His relationship to the outer world, his perception communication with the outer world, is also disturbed. Reich recognized that the obsessional character is structured on resistance, that it is character armor. In other words, in the obsessive character, a barrier to interpersonal relatedness is also interposed; that is, a disturbance in interpersonal communication exists.

#### VIEW ON OBSESSIONAL STATES FROM THE STANDPOINT OF COMMUNICATION

From the point of view of communication, the obsessed person flees from direct experience of feeling states by means of manipulation of intrapsychic communication. His efforts to delete feelings from his awareness and to shun the contextual situation and interpersonal experience in which his feelings arise are an ongoing pattern of inner life. He often

New Delhi Library www.dhalilibrary.org.in

experiences this way of life as a positive value, as an ideal of the inner life, which, regrettably, he does not achieve. The various compromise formations—substitutions, displacements—are further distortions of intrapsychic communication. By attempting to alienate affects from himself, to make them foreign bodies, so to say, he succeeds only in alienating himself, in losing the sense of his emotional identity.

The alienation of the self affects interpersonal communication intricately. One by-product of the flight from having emotional experiences is very often a repudiation of awareness of emotion and mood experiences of others, indeed, a flight from empathy, a denial of the emotional reality of others. Some of the symbolic private rituals of the obsessional state are an expression of the tremendous effort to control and redirect intrapsychic communication, to correct an unacceptable self-image. In the classic example of mysophobia, the washing is as though to achieve, by physical cleanliness, the subjective lost moral cleanliness, or rather, to undo the moral or sexual "uncleanliness."

The tendency of the obsessive person to construct systems of thought by which he thinks he lives, and which he often tries to enforce on others, is not infrequently associated with distortion of fact. This high premium on the person's own system of thinking and his imposition of it on others is reminiscent, in miniature, of paranoid thinking and system making.

In the obsessive character (Reich) the personality is organized to ward off the free emotional ideational flow with other people and within himself, an insulation which threatens his aliveness of spirit. For obsessive persons, the obsessional substitutions, says Sullivan, "are simply all-encompassing attenuations of contact which protect them from their abnormal vulnerability to anxiety."

The expressive communication of obsessional people—of verbal language, voice quality, gesture and movement, of the affect accompanying speech—is often experienced by the listener as dry and brittle, as though only the steel structure of thought remained. This communication profile is present to some degree in most obsessional people. Sometimes the affect of anxiety, irritation, anger, or impatience seeps through this steel structure; sometimes its only evidence is change in verbal pace, that is, an intensification of the defense against affect. Sometimes the principal sign is increased tensility and increased rigidity in the person and his communication.

An obsessive person has a predilection for the symbolism of logic rather than for the symbolism of sense imagery, to verbal fantasy rather than to imagery fantasy. "He intellectualizes," we say. Often the logic contains the little distortions of reasoning which are so frequent and banal that we are dulled to them and take them as common sense. They often are plausible rather than true and sound. The mesh of rationalization is often so firm and finely knit that it, surprisingly, often passes for genuine thought. The rationalization is actually comparable to a very mild delusional system, with a faulty frame of reference.

The patient does not get relief from airing his reasoning comparable to what is achieved in the ventilation of emotion. Indeed, this differentiates abreaction from emotionally toned obsessive reiteration.

He often lacks the language and the respect for affect. He does not necessarily lack affect, though his range of affect is often greatly restricted. He may say, "I felt bad" and not be able to be more descriptive.

The obsessive person tends to undercut a wave of feeling by taking brisk action. One patient who recognized this in himself, said, "I often plunge into decisions so fast I don't have a chance to experience what I feel."

Sometimes the narrowing of experience involves not only affect, affect language, but also sense perception. Several patients blanked out sight and hearing when confronted by the call for affect.

Often, the dreams lose richness of meaning, imagery, and affect; the dramatic quality diminishes. Instead, dreams are brittle, fairly prosaic statements in which the manifest content and latent content are surprisingly close. The reduction in imagery, particularly in the dream-life, is part of the denial of the autistic side of communication, with which the obsessive person often feels he dare not or cannot deal.

Downloaded from www.freelibrary.org

It is not surprising that these people characteristically have great difficulty in psychoanalysis in genuine free association, based on emotion and subjective experience, and, instead, ramble on more in word associations. Sometimes the interview is prestructured. One compulsive patient, who had extreme difficulty in speaking in analysis without directive cues from the analyst, put it, "I try to prepare before I come. I feel as though I am taking an oral exam and I am not prepared for it."

The difficulty in intrapsychic communication, the overvaluation of the symbolism of logic, the paucity of imagery and affect, and the high premium set on illusory accuracy are experienced by the person as an emptiness and as anxiety about verbal communication. One patient said, "As if, if I don't have words, I have nothing." Indeed, the anxiety about achieving verbal communication is characteristic of obsessional people. "Conversation," said one patient, "is like waving a flag; it's my way of saying 'I am at ease.'" These disturbances may be so intense that the person experiences a sense of dissocation, a sense of cutoff within the self and from others. This cutoff differs from the usual schizophrenic dissocation by not seeming irrational or illogical to others and by not having autistic content either to his or the other's awareness.

## *Schizophrenic States*

Schizophrenia is a montage of disturbed communication. Not only is communication seriously damaged in every direction—intrapsychic, perceptual, and interpersonal—and in its various modes, but its pattern varies with the different phases of schizophrenia. Indeed, the communication patterns give each of the phases its character.

The gap between the afflicted person and the professional people working with him is further increased by our tendency to understand communication predominantly in the mode of discursive logic. The patient's responsiveness to therapy depends more often on the therapist's reaching the patient than on the patient's ability to move toward us.

Dissociation, autism, symbolism of imagery and myth, discursive logic, nonverbal communication including body-language, and verbal language patterns are all of basic concern in the communication problems of and with schizophrenic patients.

### COMMUNICATION ASPECTS OF AUTISM, ESPECIALLY IN SCHIZOPHRENIA

It was on the basis of autism that Bleuler, in his classical study, *Dementia Praecox or the Group of Schizophrenias*,[4] separated schizophrenia as a syndrome from other major psychiatric disorder patterns. Autism, said Bleuler, is the term applied to the "detachment from reality, together with the relative and absolute predominance of the inner life," which characterizes schizophrenia. He also made mention of autistic processes in normal experience.

One's autistic experience includes the store of private meanings, reveries, emotions, and formulations of experience which are difficult to communicate interpersonally. When one is absorbed in autistic processes, the communication with the outside world is diminished. To help us understand the inner world of the schizophrenic person and to remind us of the gradations between the well and the sick, Sullivan, in "The Language of Schizophrenia,"[16] described subtleties of process that are in every person's range of autistic experience. He emphasized not only the reverie processes but the experiential quality that prevails in infancy and very early childhood, and also the emergence of language with its autistic and socialized verbal meanings. He pointed out that when we mute the world about us by means of preoccupation, sleep, or fatigue, we submerge into the autistic mode.

There are, however, a number of respects in which the normal experience differs from the schizophrenic. We can, with a sense of freedom of choice, resume our usual communication with the world about us, which the schizophrenic person cannot do. The message coming from the autistic experience, when it is not processed for outside comprehension, generally is not directly interpersonal, nor is it so intended; an additional inner operation is necessary to translate the autistic into a comprehensible form, which the openly schizophrenic person cannot perform. We all must

Downloaded from www.dbraulibrary.org.in

work out a balance between our autistic life and relatedness to the outside world, which, also, the openly schizophrenic person is not able to do.

The autistic life of the schizophrenic person contains characteristic experiences in communication which are experienced both intrapersonally and *as if* interpersonally. Some of these are "thoughts-out-loud" and hallucinatory experiences, affective experiences which are outside the experience in the subjective state we consider normal, difficulty in finding symbols and language for strange affective and ideational experiences, and breakdown in the competence of language and thought built up in the person's lifetime of maturation.

"Thoughts-out-loud" is the term that Jonathan Lang, a student of psychology who himself had experienced schizophrenia, suggested in his paper[17] for "hallucinoid, minimal automatic, sub-vocal speech."

These thoughts-out-loud are often experienced as coming from another authority, such as the Divine Being.[5] We may say that the authority of the self has weakened; the organizing activity of the psyche has become ineffectual. These thoughts-out-loud are reminiscent of inner language, a pattern of integrating thought and of communication with the self, which is characteristic of early childhood, but in the schizophrenic break in organization is experienced as "coming to him."[5] This overwhelming immersion in verbal communication with the self obliterates verbal communication with others.

In the calm-appearing autistic state, affective experiences nonetheless are going on, contrary to what often is the impression of the onlooker. Lang noted that he placed a high affective value on the experience of ideation as such (we might call it an erotization of thought), and that his affects were appropriate to the "hallucinary thoughts-out-loud."

In the agitated autistic state, the affective experiences—euphoria, terror, religious ecstasy, martyrdom, messianic benevolence—are outside of our ordinary experience. The universe is experienced with a sense of vast significance, of meanings not yet understood. To meet the mystery of the universe, the patient "tries to decipher the code by which one can communicate with the friendly forces without giving oneself away to the unfriendly. This code is sought in supposedly significant gestures."[5]

The hallucinatory experiences the schizophrenic person is undergoing are dissociative, fragmented communication within himself which so often he does not recognize as being his own productions. They are *as if* they were interpersonal. Characteristically, there is an unequal balance of power between the communication of the hallucinated others and himself; they shout him down, expressing their power by their insistent control of communication with him.

### The "Change-Over" to Open Schizophrenia

The major dissociation which ushers in the autistic state of open schizophrenia is an assault on basic communication within the person and in his relatedness to the outer world. We might designate this transitional phase the change-over. It has a quality which is different from that in the established autistic state.

The person who has just made the change-over into open schizophrenia is beset by communication disorder. He has great difficulty remaining in active reciprocal communication with people and with life going on about him; his perceptions of the material outer world may be disturbed, and his perceptions pertaining to his own body and affective states sometimes are disturbed but sometimes are indicative of a disturbed state which is being reported accurately. The change in relatedness to the meanings and the significance of the cosmos has already been mentioned. Time and space are experienced differently from our usual mode. The change-over is a manifestation of disrupted intrapsychic communication, a weakened central authority of the self, a failure of the organizing function of the psyche.

In the panic state the patient is often aware of and distressed by the slipping away of reasoning and the collapse of communication and relatedness. He may make desperate efforts at holding onto the self and communication, such as phoning to distant persons across the country. A patient, Martha John, in the throes of

Downloaded from www.pdfbooksfree.org.in

her change-over, phoned the writer during the night and, in a penetrating whisper, said, "I have forgotten something. You know the secret I have forgotten." Patients in this panic may clutch and cling physically to a trusted person. This alienation from the self is often projected onto others. It is they who become unreal. This changed experience of people, the fragmenting of the self, and their projection externally account for some elements of symbolization in schizophrenia. Martha John, during the change-over, ran around shrieking: "The walls are falling; the walls are made of paper."

The patient may engage in symbolic acting out. The affects and what they mean to the patient may be performed symbolically as charades, as a kind of pun in action, which Martha John did in throwing things out of her bureau drawers. "I must put my house in order," she cried out.

Symbolic expression may be in the form of ritualistic and mysterious gestures, symbolic of magical wishes and efforts at control, whether of a hostile universe, or demonic beings, or evocative of benign power. These differ from the obsessional person's rituals, actions, or gestures, which take a far more prosaic and sensible-seeming pattern. The obsessional person is not as clearly aware of what the magical meaning is, which, indeed, may be present in his subconscious if the obsessional state is an overlay on schizophrenia.

The schizophrenic person experiences the symbolic meaning of his gestures in full emotionality. He may be able to verbalize what the symbolism is (if he still communicates verbally) but not the basic emotional necessity beneath the symbolized frame of reference.

### General Statement of Communication in Schizophrenia

Though communication is intricately disrupted, disproportionate, and confused in the schizophrenic state, the afflicted person is active and involved in the universe of communication. The writer believes that, however deteriorated or regressed the schizophrenic patient may be, and however extreme his withdrawal, there emanates from him a sense of inner activity. This communication activity is, of course, not immediately interpersonal, not related to the ongoing world, but rather is self-contained in the autistic state, in which fantasied communication prevails, communication as an "as if." The exception may be when depression complicates the illness, for in depression the inner experience is that the drive to communicate has been eradicated.

The messages, verbal and nonverbal, may be incomprehensible to their receiver and to the sender; they may be intended to be incomprehensible, whether consciously or unconsciously. The messages may be intended to be understood but may fail of comprehension, either because they are garbled or because the receiver does not tune in on them. They range from utter confusion, to skillful distortion, to exquisite subtlety, perceptiveness, and accuracy.

The messages may be in verbal language, either predominantly in the form of logic or in the form of imagery. They may be in code words, by gesture in deliberately significant form, or in postures, attitudes, and movements that are unconsciously revealing. They may be assuming a role and acting the part. They may be in writing, speech having been given up, or by means of objects selected and arranged to convey significance. The nonverbal messages may be emanations of mood, apprehended empathically.

Schizophrenic persons may, particularly in the panic state, long for relatedness and a sense of being in communication with people. They also are afraid of having their psychologic privacy invaded and of being the recipients of enforced communication. This is particularly intense with the admixture of paranoid symptoms in the acute phase when patients express their fear, in delusional form, of being controlled by nonverbal, remote communication. It is a paradoxical polarity that the paranoid schizophrenic persons themselves attempt to manipulate and control communication by nonverbal "magical" means.

Before turning to the patterns of communication in the classic four phases of schizophrenia, let us consider how the individual modes of communication are affected in this most intricate disorder of communication. Since the relatedness to the world of reality is

Downloaded from www.dbraulibrary.org.in

based on percepts, we will first discuss their functioning in schizophrenia.

### Perceptual Experience in Schizophrenia

A percept, in the language of communication theory, is a "bit" of "information" entering the "receiving wires" (the sensory tracts) connecting the "central switchboard" to the outer world or the somatic inner world. In the more psychologic phraseology of communication, a percept is the first integration of sensation with "meaning" and pertains to some phase of material reality. Arieti[1] speaks of an additional element, the affective component of percepts. A percept is moment-to-moment self-reporting. Whether conscious or not, it has an influence on consciousness and is influenced by it.

Evidence of how another person perceives is not arrived at simply, for what we are granted, generally, is either a statement or behavior indicating a percept; that is, there is reporting and/or observing and interpreting. Obviously, verbal communication and symbolization pertaining to the percept introduce variables in our inferences about another's perceptual experience. These are among the factors that have made it difficult to ascertain whether what we infer as a percept in a schizophrenic person is true or false, whether it is a fault in the "receiving wire" or the "central switchboard."

The range of perceptual functioning in schizophrenia sweeps from the exquisitely accurate to an apparent absence. Perception may be sensitive and accurate even in the midst of delusional and hallucinatory activity. Twenty-three-year-old Millie was consistently clear in differentiating between her distortional experience and the evidence of her five senses. She said, "I know every sound in this house. I know the click of every door."

This accuracy of perception occasionally was resymbolized into distortion, and the steps of the distortion were clear. For instance, hearing the phone bell from another room, and judging, from the respondent, who the distant speaker might be, she would "imagine" their conversation and hear it vividly, apparently as "thoughts-out-loud," but she could distinguish between the actually heard and the vividly imagined. Sometimes her sense of the speakers as personalities enabled her to approximate the theme of the unheard conversation. Whether or not her inference was accurate, she was insistent and accusatory, imposing her frame of communication on the speakers and their conversation. This is an indication that the "feather-sensitive perceptiveness" of the paranoid schizophrenic person has something to do with focused selective attention, and there is evidence also that there is an accompanying selective inattention.

Sometimes the reporting of the percept is accurate, but the percept bears a faulty relationship to its stimulus; the person recognizes that the percept cannot be true, and the experience is delusional, that is, judgment and remembered experience are corrective. With intensification of the disruptive forces, judgment dwindles and the delusional orientation takes over.

For instance, Raymond, a young man with recurrent schizoaffective elations and paranoid trends, tested himself for improvement early in one episode by noting his percepts on looking at photographs in a pictorial magazine. Sometimes the faces wavered out of the page, coming alive and mocking him with their eyes, and he recognized that he was still sick; when they subsided into the page and became inert again, he "knew" he was better. In the height of his elation he did not challenge his erroneous percepts and delusional inferences.

Szalita[28] cites the experience of her patient who was aware that the wavering of the design on the ceiling in the therapist's office was a faulty percept and that his seeing it as an aggressive witch was his emotional response to the percept.

The percept and its report may be accurate but may pertain to a phenomenon outside our usual awareness. A communication difficulty arises when we interpret the patient's report as symbolic or metaphoric when, actually, it is a literal description. For instance, Millie would down inordinate amounts of soft drinks to assuage a "bitter feeling." We discovered that this behavior accompanied rage, which was close to her awareness and of which she

Downloaded from www.dbtaurian.org.in

experienced only an actual taste—dry, raw, and bitter—which was fluctuant during the day. On the other hand, the bizarre but accurate percept of a disturbed body state may be symbolized delusionally, as in the hypochondriacal pregnancy delusions of schizophrenia.

The perceptual experience may be a vividly remembered image percept, reactivated with hallucinatory force and significance. On some occasions of intense persecutory anxiety, Millie smelled stale blood, which, she claimed, harked back to her childhood when she came upon her mother lying on the floor with her wrists cut and bleeding. Sometimes a percept which was accurate to outer reality was integrated into Millie's prevailing mood. In terms of outer reality, she was overreacting, but not in terms of the feeling state. One day, entering an unfamiliar room, Millie stopped short and gasped; her glimpse of flimsy curtains hung on a precarious rod had given her a "shaky feeling." She then recalled her nightmare of the previous night—of walking precariously on a wooden bridge that was collapsing ahead of her. Thus the percept of the outer object was fitted into her inner life.

Similar to this experience of percept and affect is the inaccurate percept which is used not in its function as an indicator of reality but to support a projected affect or symbolization which has been pressing intrapsychically. This disparity has been studied by Beck in Rorschach tests of schizophrenic patients and interpreted by him as a misconstruction, a misapprehension, of the true forms of the stimulus.[2]

The imperfection of percepts may be a manifestation of the shrinkage of the power of the self, of the ego, so that the entire universe of things, becomes disproportionately powerful, while the reality of people fades. This disruption of percept, meaning, and experience throws the person back to childhood competence of perceiving, to the era before he had integrated his percepts with meaning and before he had learned corrective experiences for normal sensory shortcomings (such as occur in optical illusions). An example of such a defusion of percept and meaning is given by Sechehaye[24] in the following subjective experience of Renée's: "I noticed a complete loss of the sense of perspective. I sketched like a child. I got lost easily and could not orient myself spatially."

Some perceptual impairment in schizophrenic persons may be due to a shift in focal awareness, perhaps from being absorbed in hallucinatory projections. The patient may repudiate all conscious experience and cut off his perception relatedness to the point of submerging himself in catatonic sleep or stupor. In patients in the terminal phase of schizophrenia, Arieti has reported perceptual loss as the extreme outpost of defect, which he considers psychic agnosia characteristic of the regression.

From this general survey, it is clear that the perceptual states of schizophrenic persons are varied and variable. Some are not alien to "normal" experience, although infrequent or unnoted; others are bizarre but accurately communicated; still others are symbolized delusionally; and, finally, the most fundamental relatedness to outer reality may be damaged.

### THOUGHT IN SCHIZOPHRENIA

The integrated functioning of both language and thought is disrupted in schizophrenia. Typically, neither language nor thought functions in the closely knit organized form with which we are familiar in our competent, mature intellection.

Since language is one easy indicator of how reasoning is proceeding, a discussion of reasoning involves a discussion of the correlated language. (To repeat a word of caution, language patterns do not entirely or accurately reveal the progression of reasoning. The operation of finding words for a felt logic or a felt reasoning is not the same and coextensive with the reasoning itself, as is shown in experience with inarticulateness, extreme fatigue, and expressive aphasia.)

One of the disturbances in thinking is the breakdown in discursive logical thinking; that is, thinking is not governed by the laws that are intrinsic for either things or the movement of ideas, and often it is not purposive and consistent with its own premises.

Arieti accounts for the disturbance in logical

Downloaded from www.libtool.com.cn

thinking as a regression to a less advanced level of mental integration, earlier phylogenetically and ontogenetically, in which other patterns of thinking and logic are characteristic. This pattern he designates as "paleologic," in contrast to the later and more advanced pattern of thinking which is in terms of Aristotelian logic. In the latter, he states:

> . . . only identical subjects are identified. . . . In paleologic thinking, on the other hand, the predicates lead to the identification. Since the predicates of the same subject may be extremely numerous and one does not know which one will be chosen by the patient in the process of identification, this type of thought becomes bizarre, unpredictable, individualistic and often incomprehensible.
>
> The inability to abstract the common quality leads to the identification of the two subjects.[1]

Arieti's hypothesis might apply to the following: A young woman, in an agitated panic state transitional to open schizophrenia, was persuaded to eat a cupcake. The word caught her fancy, and she perseverated on it, removing the cake from its fluted paper container and putting a cup into the paper as though it were a saucer.

The principle of paleologic is an accurate and illuminating description of the pattern of reasoning. Whether it is fully explanatory of the psychologic operations involved requires further study.

Typically, thinking in schizophrenia is not in the service of reality testing but becomes subservient to emotion and motivation, and this is one reason for its false logic and distortion of purpose. A seeming exception occurs in the paranoid style of logic, which uses reality and the forms of our logic in the service of the person's irrational, emotionally determined objectives, much as Captain Ahab used his ship and crew in his monomaniacal pursuit of Moby Dick. The perversion of the goal to which the logic and reality are put is, in a long-range sense, a failure of reality testing.

### Verbal Language in Schizophrenia

Though one thinks of verbal language in its consensual, interpersonal sense, one root of language lies embedded in thought and in the competence of related skills of intellection. Its disruption in schizophrenia reflects damage to both intrapsychic communication and interpersonal relatedness.

Many schizophrenic persons, before their illness, have been particularly centered on verbal language, skilled in its use, sensitive to words and their nuances of meaning. Schizophrenic children, before the full-blown clinical illness has declared itself, often have been precocious in language, with a preoccupation and overinvestment in it. So the breakdown of language functioning in open schizophrenia is all the more striking.

In the autistic state, language may be fixated at any station from unformed phonemal utterances to well-phrased, recognizable thought and fantasy. It may be in the form of neologisms, of word-salads, or of expressions that are prophetically intoned and oracular in import. The psyche may be brought so low that the person experiences an inability to think in words, to form words. He may have an elaborate rationalization as to why he must not use words.

In the *Autobiography of a Schizophrenic Girl*,[24] Renée describes how far below the threshold of consensual language she found herself. She recalls her utterance, signifying, "Raité, Raité, was habe ich gemacht?" which, she says, was "sorrowing in my own 'language,' in the meaningless, recurring syllables, 'icthion, gao, itivare, gibastown, ovede' and the like. . . . Sunk beyond language, beyond thought, I reflected no more on the murder of Abel." It is also noteworthy that she had been absorbed in a timeless mythic theme, the murder of Abel, which symbolized an unrevealed personal theme.

The defusing of percepts and meanings often goes on to attack the innermost meanings of language. The mesh of meanings and words that has grown up around things as part of maturation and experience becomes a torn fabric. In Renée's experience: "When . . . I looked at a chair or a jug, I thought not of their use or function—a jug not as something to hold water or milk, a chair not as something to sit in—but as having lost their names, their functions and meanings; they became

Downloaded from www.pharmacyfreak.org.in

'things' and began to take on life, and exist."

This experience is strikingly the reverse of Helen Keller's in learning "water," the sound, for "water," the phenomenon.

An illuminating report of subjective experiences of the excited schizophrenic which involves language and meaning is given by Boisen:[5]

> Seeming incoherence is apt to be due to the very quickening of the mental life, to the tendency to accept as valid all the ideas that come surging in, and to the difficulty of keeping pace with the thoughts. In such states meaning outstrips symbol. Not only does the excited schizophrenic have to find new words to express the new ideas which throng in upon him, ideas for which the conventional language is inadequate, but he has no longer any language of which he is sure.

We may hypothesize that one psychodynamic for neologism and word-salad is this unstable and altered relationship between experience, meaning, and symbolization. Into the making of neologisms also enters the inability to follow a thought through; sometimes playfulness and teasing enter into the invention of new words, to bewilder the listener.

The schizophrenic person may use language in the patterns of the obsessive person, with literally meaningful verbal content and with meticulous syntax. Most strikingly, however, his language is highly metaphoric, overcharged with significance and with the private meanings which normally we submerge.

### BODY-LANGUAGE IN SCHIZOPHRENIA

Body-language in schizophrenia functions in three dimensions: the signs by which we read the schizophrenic person and which are not necessarily linked with his communicative intent; the use of nonverbal body-language as his means of purposive communication; the experience of body percepts.

The signs are strikingly and highly characteristic in the varied clinical picture of schizophrenia. Posture, stance, movement, muscle tension, and facial expression give a wide range of information of the patient's inner state of emotion and of communication, including the following: his emotional attitudes, such as rage, anxiety, beatitude; the age at which he is experiencing or fantasizing himself; often the thought-content he is symbolizing; the degree of withdrawnness from the environment in autism or in catatonic stupor; his inner communication with hallucinated figures; and the change-over to stereotyping of gesture and facial expression from spontaneous expressive movements.

The symptom of stereotyping of gesture, facial expression, and utterance is particularly interesting as having a communicative quality in forme fruste, as being symbolic and expressive, though what the message is may be lost to the patient and mystifying to the onlooker. It has been suggested[9] that the stereotyped gestures are indications of emotion which is no longer intended for communication, remnants of intended communication, or substitutes for emotion. The stereotyping generally does not evoke in us the responsiveness that we experience to gestures which are in the full service of communication, partly because the meaning is not clear, partly because the communicative charge has been reduced. This diminished responsiveness of ours contributes to our sense of the uncanny in the patient and to our alienation from him, which is one of our obstacles in communicating with him.

That catatonic stupor has meaning to the patient on a high symbolic level is suggested by the experience with Millie, who had made several suicidal attempts and who, on several occasions, retreated into catatonic "sleep" for eighteen hours at a stretch. On her emergence from this state, she revealed that she had been almost overwhelmed by rage at the therapist (and on previous occasions at the mother) and by the urge to destroy herself. "Isn't it better to sleep for eighteen hours than to kill myself?"

Turning from the signs by which we read and occasionally understand the schizophrenic patient and which are not of communicative intent, we find a wide range of expressive activity which the patient does intend communicatively. The schizophrenic patient may express some of his longings for closeness by means of direct body-language. One young man in his late twenties, hospitalized for

Downloaded from www.dbraulibrary.org.in

chronic schizophrenia some ten years, who was restricted to stereotyped verbal expressions, in several interviews with the writer moved his chair closer and closer until he was almost in direct physical contact. A patient in open panic may cling to someone as to a solid object in a storm. Sometimes the longing for closeness, sometimes the gamut of emotion from love to destructive rage, expresses itself in sexual behavior and intercourse.

The schizophrenic patient often uses gestures after giving up the use of words. His use of gesture, however, lacks the equivalence to word language, the clarity of meaning and the appeal to consensual experience, which, for instance, characterize the art of pantomime or the efforts of a foreigner to express meaning for which he lacks language. For the schizophrenic patient, the expressive function is impaired in both words and the wordlike use of gesture.

His gestures have true symbolic value, sometimes indicated by the annoyance, pleasure, or refutation he may express in his communication with the figures in his hallucinated world. His gestures may have specific meanings, as in an instance, reported by a colleague, of a schizophrenic girl who exposed herself to the therapist in what appeared to be a homosexual invitation.

Frieda Fromm-Reichmann communicated with schizophrenic patients by means of entering into a gesture interplay with them, expressing herself symbolically to the patient and experiencing a sense that mutual recognition and progression of exchanged meanings had occurred.

### Other Varieties of Nonverbal Communication in Schizophrenia

Another variety of nonverbal communication that schizophrenic patients sometimes engage in, and which occasionally occurs in our general experience as well, is the use of objects solely to convey meaning symbolically. Millie gave the writer several gifts of little wishing wells that she had constructed. Raymond, in the course of a schizoaffective elation, came "visiting" the therapist with a little suitcase containing, among nondescript articles such as underwear, a length of rope suggesting a noose, which he took out, laughing, and saying, "Don't worry, this is not for suicide."

Some actions are highly symbolic though not necessarily transformed into ritual and stereotyping. Martha John kept throwing things out of her bureau drawers because, "I must put my house in order," in the context of referring to her personal life.

Some of the interpersonal actions and behavior have intended symbolic significance reminiscent of the communication by hysterical characters. This mode of communication, which may or may not replace verbal language as acting out, is particularly characteristic of the patients designated by Hoch and his associates as pseudoneurotic schizophrenics.

The schizophrenic patient's withdrawal into silence and inactivity may be the necessary condition for productive intrapsychic communication. David Rioch refers to a patient who, in the course of psychotherapy, retreated into silence and took to bed for several days—but was not catatonic—and, on emergence, reported that he had worked out one of his "problems."

### Empathic Communication and Schizophrenia

Though his competence as sender and receiver of consensual communication, particularly verbal, is limited, the schizophrenic patient nonetheless is often extremely sensitive to affects, emotions, and personality qualities in those about him, as evidenced by later accurate reference to subtle events and experiences.

He experiences and reverberates to the moods of those about him—the anxiety, acceptance, rejection, resentment; he experiences vividly possessiveness, withdrawal, and manipulativeness. He senses the other person's genuine strength or his simulation of strength. He is sensitive and often surprisingly aware of the communication situation between him and others, especially with the therapist. He is particularly alert to the other person's pseudo comunication, clichés, or disproportionate reassurances.

Though we are all more subject to other people's moods than we acknowledge, the

Downloaded from www.dbraulibrary.org.in

schizophrenic patient is generally as exposed to other psyches as a baby is, in the same diffuse, vulnerable way. This kind of sensitivity characterized a mute patient who wrote in her nightly letter, "You were so sad yesterday," after the therapist had been reflective and in doubt about the course of treatment. The alert, active, paranoid schizophrenic patient not only empathizes moods but picks up discernible subtle signs of behavior that he then weaves into his distortion.

In the other direction, *from* the schizophrenic person, particularly when he is quite absorbed in the autistic state, may emanate a powerful and uncanny mood, an effluvium of such frightening affects as anxiety, despair, rage, open panic, apathy, and unfilled longings for affection and sex, which are disquieting and often anxiety-evoking to others. Though direct verbal communication with the person in the autistic state may be seemingly unrewarding to one's efforts, he may be extraordinarily available to nonverbal empathic communication from the therapist—as Frieda Fromm-Reichmann has taught us—and, indeed, to the affect accompaniment of verbal communication.

### Communication Patterns in the Four Classic Patterns of Schizophrenia

The four classic varieties of schizophrenic reaction are characterized by four basic communication patterns by which the schizophrenic person establishes a new, though sick, equilibrium. The new equilibrium serves to give him structure, to give him a mode of being, relating, and functioning. Whether these are earlier modes phylogenetically that once were normal but were discarded in our evolution, as suggested by Arieti, or whether these modes are intrinsically pathologic is a moot question.

The patterns of disturbed interpersonal communication in the classical categories of schizophrenia appear to the writer to be intensifications of faulty communication with which we all have experience in miniature. The large correlations of the classical clinical patterns and the patterns of communication transaction follow.

**Catatonic State.** In the catatonic state, not only is there absence of action but an almost total severance of communication to and from the outside world. Generally, verbal communication is given up, and the remaining communication is empathic and in body-language. There is some evidence of ongoing intrapsychic activity, as in Millie's coping with her acute destructive impulses in the "sleep."

**Paranoid State.** In paranoid schizophrenia, communication, whether in the symbolism of discursive logic or of imagery, is distorted. In some cases the person not only distorts communication but also imposes authoritarian control over communication and insists on formulating it in his own terms. Verbal communication may function competently as language but not as thought.

Verbal communication may be renounced, and dependence may be placed on autistically significant signs which are intended to be communicative but, since they are not consensually validated, are not communicative. A related phenomenon is the patient's conviction of his own power of nonverbal communication:

Carl, an artist in his early forties, in the change-over period of a paranoid schizophrenic episode, visited a friend who had been emergently hospitalized in a catatonic excitement and with whose wife Carl had been intimate. He gave the friend a special handclasp, reporting, "I wanted to show him I was mad, too. I know he got the message through my hand."

The person with paranoid schizophrenia is often afraid of having has thoughts read or influenced: Ellen, who was almost entirely mute and hallucinated and attended to "whispers" from behind closed doors, had a period of what amounted to sleep reversal. She wrote to the therapist, "I can hear people think during the day and that interferes with my thinking. I think better when they are asleep."

The paranoid schizophrenic patient may use code words portentously and mystically as references to an esoteric religion. Sechehaye's patient spoke of "The System"; Staveren's of "The Line." Both these patients gave every indication of longing to communicate with their therapists.

Downloaded from www.iran-archive.com

**Hebephrenic Reaction.** In the hebephrenic reaction of detachment and "silliness," the person has set up delicate but drastic disjunctive operations in pseudocommunication, verbal language fragments, gesture, and expressive utterance.

The hebephrenic patient introduces what may be considered psychologic and verbal "noise," which serves to keep out messages from "normal" people. Sullivan has pointed out, however, that hebephrenic patients, habituated to each other on a ward, set up a tolerance for each other's presence.

**Simple Schizophrenia.** In simple schizophrenia, communication is very much reduced and constricted. It appears to the writer as being more uniform than in the other classic patterns, and involves the verbal mode, gesture, and expression of feeling state. The writer has experienced patients with simple schizophrenia as children who are to be seen but not heard.

Though considerable attention has been devoted to verbal language disorders in schizophrenia, in this incomplete discussion of communication we may close with Frieda Fromm-Reichmann's warning against the "over-estimation of the significance of understanding the contents of schizophrenic communication. . . . With the schizophrenic, unqualified thriftiness in content interpretation is indicated even more than with other patients. . . . The schizophrenic needs help in understanding the genetics and dynamics of his communications, not their content."[13]

## *The Depressive States*

The present clinical categories of depression, with which a number of writers have expressed dissatisfaction, can be accounted for on the basis of two phenomenal elements which do provide consistency: (1) the mood experience and (2) the patterns of communication. The various personality defenses against depression modify the patterns of communication, which, while they deviate from the core experience, yet retain a central relatedness to it. The subjective experience of the depressive mood is the motif of all the depression pictures and is as central for considering depression as autism is for schizophrenia.

### General Statement of Communication in Depression

To take full-blown retardation as the paradigm of depression, communication is massively impaired, with shrinkage and diminished activity in all dimensions. Imagery stops, the flow of ideas becomes slowed, emotion flattens. There is little giving or receiving of communication. Seemingly, the impulse to communicate is lost.

Retardation depression is the polar opposite to schizophrenia in respect to the quality of communication, and is opposite to the manic state in respect to the intensity of the drive to communicate with the outside world and people.

Instead of the typically exaggerated and sick activity of the autistic side of the personality in the schizophrenic person, autistic activity in retardation depression is seemingly diminished, with the exception of the final disruption of personality.

The favored symbolic mode in schizophrenia is imagery; on the whole (with exceptions in agitated depression), the symbolic mode in which the person with depression communicates interpersonally is logic. However, he often experiences imagery characteristic for depression but which he refrains from communicating to others. Instead of the schizophrenic person's involvement with communication, faulty and disturbed though it is, the person with depression experiences a diminished impulse toward communication and despairs of attaining it, though he longs for it. The person with the extreme of retardation depression is reduced to a vegetative deteriorating state, far more shrunken in communication on every level than is the patient with terminal schizophrenia.

### The Relatedness to the Self and Subjective Experience

In the writer's clinical experience with the nineteen patients with psychotic and psychoneurotic depressions who form the basis of this study, some suggestive trends in their communication patterns emerge, despite differences in sex, age, occupation, associated symptomatology, and the specific syndromes of the

Downloaded from www.dominiclibrary.com

depressions.* None of these patients was stuporous or completely out of touch at the time of his experience with therapy. However, when retarded, their verbal and empathic communication was seriously impaired and was a trial to patient and therapist alike. The following reports of subjective states were obtained after efforts to outmaneuver oppressive silences, and may cast light on the experiences and processes which progress to maximal severity among hospital cases.

Depressed persons, when encouraged to describe what they are experiencing, voice their awareness of themselves in imagery which is characteristic of depression.

The subjective experience often is one of being insubstantial to the point of being hollowed out. Mrs. Anne H. recalled her experience as she was slipping into a psychotic postpartum depression after a period of obsessionalism and agitation: "I almost believed that if the bathroom had life, my being there would make no impression on it, except as a ghostlike mass of flesh."

Mr. John J., whose depression was complicated by alcoholism, said, "Sometimes I feel I had just skirted a circle just out of my reach. It's almost a physical sense. . . . I feel hollow, like a crust of information."

This subjective sense corresponds to what we may interpret as an attenuation of the ego. It is also experienced as a sense of being out of relatedness, of alienation from the self and from others, of loneliness. The interference with intrapsychic communication is paralleled by a sense of noncommunication with others. This is illustrated in the following description by Mrs. Paula M., a very effective businesswoman whose long-standing depression had been kept well in hand until her early forties, when she made a serious suicidal attempt with barbiturates and required hospitalization: "I feel alone. In a room with people—yet I have a feeling like hanging over a crevasse, a deep ravine, and if only someone could touch me—but having their hands all over me would not make me feel it. I could still be alone."

We are prone to take the statements of the depressed person about feeling empty, not as the self-perception, which the above examples demonstrate, but only as self-derogation (which indeed is often added to the experience) and even as valid self-appraisal.

The depressed person is particularly afraid to experience emotions: Generally, the fear is of experiencing resentment and anger, but often it concerns pleasure, liking, and happiness as well. Though this self-distrust is not limited to depressed persons, it is they who have come close to deleting the experience totally.

Mr. John J. said, "I don't like to experience resentment. It is too unpleasant, because it's like a crime. . . . I felt anger, then limpness [at his father's interfering letter]. Oh what's the use. . . . It's a kind of detachment. Maybe that is why I feel empty so often."

Miss Ruth T., with depressions on and off for twenty years, had come to psycho-

* These nineteen patients with depressions consist of nine men and ten women, ranging in age from sixteen to fifty-five years. They were in therapy with the writer from six months to seven years, except one patient with whom there was no direct contact but whose therapist was supervised for three years. The occupations ranged from unemployed to school, household, business, various professions, and creative writing. Eight patients had been in psychotherapy for the same condition previously; these attempts at cure numbered as many as six.

Fourteen patients suffered from psychoneurotic depressions, five from psychotic depressions; there were no reactive depressions.

Three patients had been hospitalized for depression of psychotic intensity with serious suicidal attempts and had received electroshock. Two of these patients were involutional, the other postpartum. They came to the writer for psychotherapy immediately on discharge from the hospital, still retarded, with suicidal thoughts or fantasies but without any active impulses.

One patient had been hospitalized for recurrent hypomanic episodes which were immediately followed by depression. He began therapy with the writer when he was in a depression. His elated states were characterized by bizarre and delusional content, and the diagnosis shifted from the original one of manic-depressive psychosis to schizoaffective disorder.

One patient, who refused hospitalization and who had strong suicidal drives, had manic-depressive swings with agitation when depressed, with homosexuality, and alcoholic tendences. His condition suggested the diagnosis of schizoaffective disorder of psychotic intensity.

Two patients with psychoneurotic retardation depression were alcoholic, one moderately and the other severely.

One patient had psychoneurotic manic-depressive swings.

The depressions occurred in various personality types. A number of the patients with psychoneurotic depression had harbored suicidal preoccupations.

Portion Protected by www.brainlibrary.org

therapy at the recommendation of her physician, because of increasingly severe headaches and muscle pains which, she feared, were due to trichinosis. In the course of therapy she was often silent and resistant. Concerning her reluctance to experience and to speak of feelings she said: "Feelings? feelings? I've been trying to unlearn feelings. If I had permitted feelings, I would have blown up with rage and frustration and I wouldn't get anything. . . . I don't want to go around crying. I have no words to describe it. . . . Never expect anything and you will never be disappointed. You might be pleasantly surprised."

The relatedness to the self in the interpersonal situation, even in psychotherapy, is revealed in the words of Mrs. Betsy P.: "How can I oppose something as frail as a feeling against what you say? My feeling has no validity against what you suggest for my good."

This dread of experiencing and communicating feeling has also been reported by O. Spurgeon English.[8] "'To live,'" said one of his patients, "'is like opening all my pores on a cold day and subjecting myself to exposure.'"

The person with retardation depression often suffers from diminution of reverie processes. He may be afraid of indulging in fantasy, or embarrassed to admit even to himself that he does. Miss Ellen C. said: "I want to get into the importance of fantasy all my life and the need to keep it hidden all my life. It's quite important to keep it hidden. . . . What occurs to me in thinking of the fantasies, the word 'ersatz' comes to me. . . . Now you see some of the curse is taken off ersatz." Her fantasies consisted of images of happier home life, of release from the illness and poverty that bedeviled the family.

Mr. John J. remembers being dreamy as a child, looking beyond horizons, and that he was shamed out of daydreaming by reproof.

Sometimes the person with retardation depression experiences the loss of imagery very regretfully, particularly people who have placed a high value on imagination and fantasy, such as creative writers. The remaining imagery tends to be restricted to patterns which are quite typical of depression. This will be considered in the next section.

At the most intense retardation the person no longer has the subjective experience that he might or might not choose to indulge in fantasy; imagery, fantasy, even dreaming, are attenuated almost to the vanishing point as conscious experience. Whether these processes are occurring in the depths of unconscious experience is still a matter of conjecture.

Mr. De L. said he had been encouraged to start psychotherapy because he was beginning to dream again and was hopeful that he had something to work with.

In contrast to the schizophrenic patient who erotizes thought and who experiences some emotions and fantasies in the never-never land of his autism, the depressed person does not achieve even fantasied fulfillment and becomes inarticulate not only to others but to himself.

### Perceptual Experience in Depression

The perceptual experience in retardation depression, though significantly different from the schizophrenic experience, is more damaged than is generally realized, and we are as prone to misinterpret the one as the other.

In retardation depression, perception, which is seemingly accurate, is restricted, the meaning component is reduced, the affective component is bleached out. Zubin[32] notes the clarity and accuracy of language and of observation in retarded depression and suggests that the retardation itself helps in the accuracy. However, the precision and accuracy are at a high cost and dependent on severe limitations.

The depressed person often experiences the world with a sense of remoteness and clarity. He has a sense of physical distance and of being cut off which is not spatial but as though there were an invisible, alienating screen. Mrs. Anne H., for instance, described the onset of the retardation after a period of agitation, "Everything became dulled, toned down, the radio voices remote, everything hushed."

In contrast to the sense of the hush following the onset of depression, Zubin reported instances of the converse—depression ensuing on the sudden loss of hearing.

Pure culture depression unaccompanied by other malignant trends has been observed in per-

Downloaded from www.dbraulibrary.org.in

sons who are suddenly deprived of their hearing by war-injuries or other accidents. The sudden removal of the background noises which give the normal hearing a continuous feeling of being alive brings about sadness and grief and a feeling of the *world being dead* [italics mine] even in individuals who were otherwise apparently not prone to depression.[32]

Such experiences suggest that there is a deep, reciprocal relationship between loss of perceptual awareness of the world and depression, perhaps depending on the cutoff in the sense of relatedness to the world.

The perception experience, that the world lacks substance, indeed that the world lacks people, is so frequent in depression as to be characteristic. Mr. Martin R., returning from a holiday in Europe to his workaday world in New York City, suffered an accentuation of his long-standing psychoneurotic depression. He described the grayness of the experience, a sense of "huge buildings, devoid of people."

Not only are sounds reduced, particularly the sounds meaningful of man's presence and functioning, but the awareness of people is reduced, both as physical objects in space and as personalities.

This is strikingly illustrated by the case of Mr. Robert S., with depression of many years' standing, sometimes with suicidal impulses, who also complained of difficulties in his highly skilled and demanding work situation as executive. Though he voiced his depressive ruminations freely, there was a paucity of description of any people in his contemporary life at home and at work. Interestingly, his Rorschach responses were completely devoid of human figures, another example of the simple subtractive defect of perception in retarded depression.

The restriction of the field of perception also involves subjective physical percepts, indicative of a changed relationship to the body. This disturbance is seldom voiced spontaneously. For instance, Mr. Martin R., sitting vis-à-vis the therapist, hand grasping ankle, was silent, depressed, and seemingly resistant. He was encouraged to describe his experience of the moment in terms of his mood and of his body. He said, "I have the sense that I am composed only of my left finger tips and the anklebone on which my fingers run. My mind is a blank."

Mr. Harry U., who was motivated for psychotherapy partly because of difficulties in establishing intimate relationships, in addition to his long-standing depression, complained of a cottony taste, and recalled his depression at about the age of eight, as "the dreary cottony feeling in which I am lost and wandering about." As this young man's condition improved, he took singing lessons (a good commentary on his efforts to regain communication) and noted, "I felt fine; enjoyed standing, enjoyed the way the soprano was hitting a high note, went 'zoom' with her. Gee, it was wonderful."

So far the examples have been those of simple subtraction of perception. Occasionally, however, the percept is faulty, perhaps a distortion of experience, perhaps a faulty interpretation. Mrs. Betsy P., prone to agitation rather than to simple retardation, would experience her arms as being so heavy and inflated they could swoon away, the same feeling as in a faint and delirium that she recalled from her preadolescent depression.

The perception defect in depression often bears a relationship to the drive to repress, to manipulate awareness, that is, to what is after all a voluntary tampering with communication.

Mrs. Anne H. said, "[I had] a lifelong tendency toward voluntarily making my muscles rigid to achieve relief, sometimes pleasure, and sometimes an avoidance of pain."

Miss Ruth T. reported on one occasion the interplay between mood, repression, body experience, and perception "I have two moods. I feel cheerful and with tension, and also sad and impatient with myself. This resistance I would like to get rid of. I can feel tension in my shoulders, arms, back of neck and my legs. My legs are twisted around the chair."

In the privacy of her home when she felt this way, she had come to accept her mood of depression and would allow herself to weep. "After a time I say to myself, 'Well, you can't spend the rest of your life weeping' and I

Downloaded from www.dbraulibrary.org.in

snap out of it; I blank out. Then I find it hard to concentrate on reading. Sometimes I get up in front of the mirror and square my shoulders and say 'Buck up!'" to which the therapist commented, "Maybe squaring your shoulders has something to do with the pain in your neck and shoulders."

Sometimes, with the restriction of perception of the outer world and of the world of emotion, what remains in awareness is the perception of inner somatic experience. Mrs. Anne H. recalled the efforts to cut herself off from outer reality in her childhood depression: "I really was more conscious of my bodily discomfort than of what went on around me. . . . Then, as often before and afterwards, it was as if standing still and trying to cut off perception of outside stimuli, I could 'hear' more clearly what was going on inside of my body . . . (like rumbling in my stomach, or the beating of my heart)."

Such perceptions of visceral experience reverse our usual experience, in which outer perceptions dominate over the inner ones. The predominantly visceral experience, when verbalized, suggests hypochondriasis to the therapist. Indeed, sometimes the depressed person resymbolizes the experience and himself interprets it hypochondriacally or delusionally. The patient who experiences "heavyheartedness" or the difficulty in breathing frequent in depression, coupled with his sense of a nihilistic universe, often becomes anxious about heart disease and seeks medical help in terms of that self-diagnosis and not for the depression.

It is quite significant that, with the lifting of the depression, the restriction of perception is also removed. Mr. Charles J., a novelist suffering from depression and a "writing block," noted with delight the return of sensory clarity and perceptivity: "Everything smells better and clearer and more interesting. I walked through the streets sniffing odors."

### Symbols and Imagery in Retarded Depression

Symbolization in retarded depression bears significant contrast to the schizophrenic pattern. The symbolization of the universe, for instance, is destructive, but openly so and impersonally. There are no mysterious forces that play baffling, promising, threatening games. There may be an austere, waiting, depriving deity. In agitated depression the hostility of the universe is a vivid and central experience. Miss Ellen C's symbolization, which she referred back to the span between age five and thirteen years, was, "I felt God must be very angry, just like my father. . . . A very powerful punishing Person and you really couldn't get away with anything."

Even in the meanings projected onto the universe, there is the tendency to reduction to the monolithic, in contrast to the heightening, multiplication, and varicgation of meanings in schizophrenia.

The images that come to mind in depression often symbolize the depression itself—the barrenness of life, emptiness, loneliness. The depression may be symbolized by a concrete image or in imagery capturing the mood. Mrs. Anne H. had a recurrent visual image: "The Great Stone Face—I see a wind howling through this dead face."

The image may be symbolized in a figure in a dream. Miss Ellen C. dreamed of being taken to a house called "the Maw." Her association was that "in the Maw" signifies the maw of depression.

Sometimes lines of poetry are cherished by the depressed person as speaking for his mood. Mr. John J. said, "My favorite image is from 'The Mauve Decade,' 'The children struggle briefly and languish in the cool tide of rectitude.'"

Imagery may be projected onto the physical world, as an altered perception of the physical world and may be a projection of the barrenness of the inner life, of the retardation itself. This has already been discussed in the section on the perceptual experience in depression.

The depression may be symbolized in terms of holidays of special significance to the group or society and to which the depressed person adds his more personal intensification; for instance Yom Kippur, the Day of Atonement, with its solemnity, its reminder of sin and reform, its recall of death of near ones, the

Downloaded from www.dbraulibrary.org.in

cessation of busyness, arouses echoes in depression. The major high holidays, such as Christmas, symbolizing warmth and family closeness, intensify the sense of loneliness for many depressed patients.

Summer vacations, with the dream of being free-roving, of finding new friendships, are often experienced with intensification of loneliness if the person has difficulty in making quick vacation relationships. Sometimes when the vacation is over, without significant change in the person's life, the depression intensifies.

The image may be a projection of the sense of dirtiness, of being refuse, of being "crapped upon." Sometimes the symbolization is in terms of the person himself, how he symbolizes himself; sometimes the symbolization is in terms of the surroundings, or even of a significant person.

Edith D., a seventeen-year-old girl with a depression of moderate intensity precipitated by a catatonic episode in her nineteen-year-old sister, said to the writer, "I feel such garbage. I'm nothing. How can a seventeen-year-old girl have anything worthwhile to say to you?"

Miss Ellen C. often dreamed of toilets overflowing with feces; she often felt she had been "crapped upon."

To the writer's observation, the period during which such imagery may be revealed is associated with a drabness in the patient's appearance as well as in spirit, the skin tone dingy beyond simple pallor, the hair and eyes lackluster, the stance dejected. With improvement, the skin tone and hue improve, and the imagery of refuse is replaced by the imagery of food, aliveness, and growth.

The symbols in depression tend to be concrete—concrete in terms of things, both in actuality and as imagery. For instance, Mrs. Grace P. dreams of a purse. In dreams, the auto has been a surprisingly frequent symbol —its power and mobility are the refutation in wish fulfillment of the lack of power and the staticness of depression. Of course, this generalization does not exclude other significances.

Those prone to retarded depression have difficulty in accepting the validity of intangible symbols. In psychotherapy, these persons have great difficulty in working with dreams. For example, Mrs. Betsy F., a writer on scientific subjects who was interested in developing her capacity for writing fiction, said, "I still have trouble in accepting that something is a symbol for something else. It seems too tenuous to apply. When I tell a dream I hear my father sneering at it, 'How can anyone say anything about anybody from dream content?' "

Or, dreams have a monotonous quality. Mr. De L. had a recurrent dream of wandering through a deserted house, one after another of empty rooms.

The dream quality may be highly imaginative and with considerable movement, indicative of destruction, particularly if any tendency to agitation is present. Mr. John J. several times dreamed of wandering among dangerous rocks on a stormy coast.

Occasionally, a dream expresses the dread that communication is impossible, and that the dreamer is helpless. Mrs. Paula M. dreamed that her mouth was sewn together and that she was struggling to talk. She awoke and found herself testing her mouth. She commented, "In the dream I could hear voices, but I couldn't make myself heard and made only sounds."

With the stirrings evoked in psychotherapy, the patient often experiences not only a sense that dreaming is activated but also more favorable imagery.

With the lifting of the depression, imagery returns. Indeed, in the writer's experience one of the heralding symbols is the symbol of rebirth in nature, of growth of trees, new leaves.

Mr. Harry U., as his mood of depression gave way to zest in living, in going about and meeting people, said, "Trees are soft, green, round. Trees when you lie under them and look up at the sky are especially nice. They always move a little and generally there are little clouds—and green, of course. The green of trees is always very soft."

### THOUGHT IN RETARDED DEPRESSION

The functioning of both language and thought is disturbed in retarded depression. Since the language style is quite prosaic and

Downloaded from www.vidyabharati.org.in

familiar to us, the alteration demands little attention. However, the alterations are serious in deep depression, and anxiety-provoking or discouraging to the afflicted person in masked depressions.

The change is more complicated than the slowing and deletion of thought which is part of the staticism of depression. Freedom and flexibility of thought diminish, though with masked depression the person may be effective as far as the world can see. He may be aware of these difficulties in thinking before they are discernible to others, and may experience a loss of spontaneity. The loss, first subjectively, then objectively, affects originality of thinking, nuances of thought, richness of association of ideas—a very unhappy loss for individuals who place a high premium on intellectual activity. Achievement in the face of this difficulty, which occasionally occurs, is at the cost of unbelievable effort and mental labor.

Mr. Tom K., talented and experienced in his field, complained in the course of a fairly intense depression with fluctuations between agitation and retardation, "I have difficulty in assembling ideas. I have a detached feeling about work. First I have an idea strike me and then I feel I couldn't possibly do anything with this without reading on this and on that. And it ends up with forgetting the idea and I can't see how I got to make the point. I can't concentrate and I can't follow an idea through." Actually, his professional accomplishment was considerable at this very time, though he got no sense of its reality.

The subjective or the overt retardation of thought contributes to the self-doubt of depressed persons, which may be part of their self-image outlasting the clinical manifestations of the depression. Such experiences are often voiced, "I am stupid," which is taken to mean simply self-disparagment, but it is more than that, or rather, it starts as a frightened self-awareness of sluggishness and restriction of thinking.

Partly by accentuation from the diminution of imagery and partly from the person's loss of sense of self, thought, in retarded depression, emerges in remarkably logical form, though the reasoning is not sound in itself. Indeed, thought and discourse may be cast in a form about as impersonal as a Euclidean proposition. The logic, however, is inappropriate to the communication situation, to warmth of interpersonal relationships, to subjective experience of emotion. This logical style is often used defensively, or out of a feeling of inadequacy, and impedes communication.

Thought and the defensively used logic in retarded depression are defective not only quantitatively but qualitatively in that they are used nihilistically, as part of the rationalization to support the status quo of depression. The patient will set out to prove with the heavy artillery of his reasoning why he is doomed to fail, why nothing is of any use, particularly psychotherapy. He will set out to prove why it is fated that he die soon, backing his thesis with, perhaps, references to heredity for conditions in which, at most, its role is conjectural.

Dr. E., on learning of his father's cerebral thrombosis, anticipated vascular damage for himself, probably coronary thrombosis. "After all," he said, "I'm forty, I breathe more heavily. My father was a robust man. I have been very robust myself."

This kind of reasoning invokes large, impersonal, and generally immeasurable forces, and suggests an equivalence to the depressed person's characteristic relatedness to the universe as implacably destructive. His tendency to build the case against himself—whether in terms of personal worth, intelligence, or hopelessness of therapy—tends to convince the therapist of the validity of his charges. Unfortunately, both therapist and patient often become victims of this negative rationalization, which increases the difficulty for the therapist to be effective in treatment.

Another reason the depressed person leans so heavily on logical form for his inner life is his need for structure as a subtle kind of supportive exoskeleton. Since feeling and emotion are not trusted and understood, formal reasoning carries the greater weight.

Miss Ellen C., in pressing the therapist for "help," recognized that she was pressing for structure, for explanation and formulation that she could add to her stock. She said, "I am puzzled at the way you work. . . . You must

Downloaded from www.dbeonline.com

have method. You must have a method, a philosophy. . . . I need structure." She recalled the importance to her of two college professors and said, "I got a sense of structuring knowledge that somehow helped in an inner kind of structure. . . . I am getting some structuring from you."

### VERBAL COMMUNICATION IN THE DEPRESSIONS

Among the important considerations in verbal communication in the depressions are: (1) the subjective experience associated with the performance of verbal communication in itself; (2) verbal communication in terms of language style and syntax, the favored mode of symbolism, and content; (3) relatedness and responsiveness in terms of the communication situation; and (4) articulation.

These aspects reflect accurately the different clinical pictures of the several depression syndromes. Except for the subjective experience, they are directly observable and provide the observer with signs of the patient's state. Articulation, strictly speaking, is a specialized form of body-language, but it lends itself to discussion with verbal communication.

In the classical retardation, the voice is heavy, inert, of narrow range in pitch, monotonous, and hesitant. The language style tends to be unremarkable and of good syntax, though perhaps in sentence fragments and limited in variety. The content is restricted and unimaginative. Responsiveness is slow, but, on the whole, appropriate to the communication situation.

In agitated depression, the voice may be rasping and low-pitched, but articulation is brisk and fairly rapid, tense, with considerable range of pitch. The ideational content reflects the kind of agitation; it may be prosaic or sweepingly nihilistic, fantastic, or accusatory. Responsiveness may be quick and pertinent, or the current of speech may carry the patient away from genuine contact with his auditor.

In the hypomanic state, typically, articulation is vigorous, sometimes with self-aware eloquence. Voice and verbal content are diversified, with the familiar flight of ideas, which seem to be quite well related to the communication situation, especially at the beginning of the response, and then depart from the other communicator. (For a worth-while study, see Ref. 21.)

In addition to the subjective experiences of retardation of thought, the depressed person is distressed by difficulties involving words, articulation, and availability for communication. For example, Mr. Harry U. said, "When I get depressed, the words become like bricks loosened from the wall and tumbling down."

Miss Ellen C. often complained of feeling inarticulate, though the only discernible difficulty was an occasional hemming and hawing.

Often, indeed, as with thought, the competence recognizable by external standards is far greater than what the person experiences subjectively. He may experience a sense of being cut off in his verbal responsiveness though, to his awareness, he is making every effort to find words and to articulate. Dr. E. talked of feeling in a "peculiar state of vacuo. . . . I had the feeling I couldn't hear if another person spoke."

Sometimes the person cuts off out of a refusal to receive messages which he experiences fairly close to awareness. His concern is that they enter his mind and push his thoughts around. Miss Ruth T. observed that when someone speaks to her she hears him but holds the idea in abeyance to see if she wants to receive the idea, and meanwhile she keeps on thinking her own thoughts. She noted that she slows up verbalizing, first her own and then the other person's, as a way of controlling the situation.

Although the depressed person often speaks in finalistic formulations, he distrusts any one else who does. Mr. Harry U. would cease hearing the therapist as soon as abstracting statements were made, or statements that to him suggested the "shoulds" and "oughts" of proper behavior. Mr. John J. referred to his wife's "literalness."

Sometimes, out of his past difficult communication situations, the depressed person evolves his language style to serve his need for guardedness—though at a cost. Mr. Harry U. felt that if he made laconic, impersonal, noncommittal statements he could not be shouted down, but that people could only differ with him.

Downloaded from www.dbraulibrary.org

Often the feeling of being cut off in communication is extremely disturbing, and were it not associated with making syntactical sense, the quality of intense anxiety would suggest schizophrenia. Mrs. Betsy F. described her experience in arguing, which she was prone to when agitated: "I had a feeling it began in my head first with the words while I was talking, and the words were spinning around and then words came in from the outside, upside down and swirling. . . . I felt the tears and I couldn't get my breath. . . ."

The depressed person often anticipates a lack of understanding when he speaks in terms of emotion or imagination. Dr. E. would say, "I don't expect that you know what I mean."

The depressed person may lack the vocabulary to express emotion, which contributes to the discontinuity between his emotion experience and his verbal expression. Dorothy, a young woman with depression and moderate alcoholism, said, "What I feel on the inside and what I say on the outside have nothing to do with each other."

This discontinuity between subjective experience, particularly of emotion, and verbalization makes verbal communication between the depressed patient and the therapist difficult and discouraging.[3]

Many of the statements the depressed person makes have the form of a logical tautology, formulation sentences. "Well, that's how it was," Mrs. Paula M. would say with finality, immediately after making a flat statement about herself.

Miss Ruth T. often cast her statements in the following pattern: "I want to talk about what we talked about last time. I think that's a good thing to talk about."

This particular style of language lends itself to being used defensively. It is not intended for the thought to move forward or for emotion to be entered in any depth. Often, these formulatory sentences are intended to silence the other person, particularly if he is asking questions.

The depressed patient tends to rely on stereotyped, fairly conventional expressions, clichés, and formulas, more heavily than is usual and in interesting contrast to the neologisms of the schizophrenic patient. The expressions may be steretoypes of his own oft-repeated statements, an epigram gone stale, masking the fact that freshness of feeling and of thinking is missing. For instance, Mr. John J. regularly referred to his wife, with the same mannerism of seeking words and in the same words, as "a baby-face with the soul of a barracuda," without fuller description. These stereotypes may serve as props in verbal communication, as cover for the retardation of thought and language and for the reluctance to experience affects and emotions.

Sometimes patterns of social forms are relied on not only to conceal the person's lack of fresh thinking but as a safe style of discourse. Dorothy, for instance, was given to verbal social formulas which obscured all her communications, both interpersonally and in the analytic situation. She had long ago discovered that they formed a safe way of relating to her younger sister.

### Body-language in Retarded Depression

The signs of retardation depression are the familiar ones of restricted movement, dejection, and the quality of physical slump. Many depressed patients attempt to mask the depression, to convey a sense of competence or good spirits, by means of "bucking up" in an exaggeration of "good posture," with increase of the inspiratory chest position.

Gesticulation is generally reduced, but, though it is restricted, it may be used with emphasis. The facial expression may be rigid—perhaps noncommittal, perhaps amiable. With a profundity of depression, the facial tone may be slack. The look of alertness and the sense of relatedness to the milieu are attenuated. Actual alertness and awareness of the changing physical surroundings may be quite keen in a moderate retardation depression. By and large, symbolic communication through gesture and other body-language is diminished. The longing for closeness is expressed by physical moves.

Occasionally the patient does intend someone significant, such as the therapist, to become aware of his depression, of how sick he is, how helpless he is, how impoverished for affection he is, by permitting his dejection and depression to become obvious, perhaps with underscoring. Several of the depressed patients

Downloaded from www.dbraunfray.org.ar

in the writer's experience, for some little while, would communicate with sad glances to convey what they feared words would not.

The patient often is afraid of accepting the warmth he longs for; often he is afraid to give physical affection. To a marked degree, several young mothers who were depressed—and even after the clinical depression had lifted—were threatened by the need of their young children for cuddling and tenderness.

Mrs. Betsy F. experienced her robust and longed-for baby as a drain on her, not only for nursing, but for his clinging to her in the first months of his life. She felt threatened by any appeals for tenderness.

O. Spurgeon English noted that his patient with depression "did not want to nurse her child because she did not want to be touched."

There often is a discontinuity between body closeness and the emotional experience in sex. Mr. Harry U. said, "When I have intercourse there is a male in this having intercourse. But it is a personless person. It is practically not I. It is somebody who isn't paid attention to."

The depressed person sometimes feels lost if he does not have the expressive movements of the other person to fixate on, to orient toward. Mr. Martin R. said to the therapist, "That I can't look at you means I can't get inspiration from you—watching your reactions. That is why I always try to pace myself to the person I am addressing and it is like I would be entirely in a void, completely on my own—there is no road map—large open fields without any direction. It's sort of lonely."

### Empathic Communication in Retarded Depression

Seemingly, the depressed person is deficient in empathic communication. In contrast to the schizophrenic person, he is not perceptive of nuances in the nonverbal communication of others. There is some indication that this reduction is complex, depending on the retardation of perception, a lack of relatedness as receiver, and a lack of drive as sender. This deficiency of empathy makes psychotherapy difficult in its own right and is burdensome to many therapists.[3] Though the sense of an empathic exchange is diminished in therapy with depressed patients, they are distressed by noncommunication, by involved syntactical constructs, and by dejection or depression. This suggests that some empathic experience is nonetheless going on.

### A Note on the Manic State and on Agitated Depression

The manic patient, state Lewis and Piotrowski, "absorbs the world around him passionately," whereas the hyperactive schizophrenic "more or less ignores the world." The manic patient, however, despite his verbal flow, does not relate to others as receiver of their communication, and he tends to impose his verbal communication on others. In these respects his interpersonal communication is faulty. Nor does he subject his thinking or language to the scrutiny of judgment—a defect in relatedness to himself.

In agitated depression the person is absorbed in a nihilistic preoccupation which cuts him off from free relatedness to the world, other people, and himself. Whether or not his verbal production is accelerated, it is hardly a free exchange with others; the symbolism, whether expressed in subjective or projected terms, is nihilistic.

In both the manic phase and agitation, empathic exchange is diminished, perhaps even more than in simple retardation.

Acknowledgment to the depressed patient with moderate retardation that some of his difficulty involves communication often makes him more available for communication. Exploring his communication difficulties often also mobilizes relevant experiences from his past. Coping explicitly with his communication difficulties reduces both the patient's and the therapist's sense of helplessness and unproductivity.

CHAPTER 47

# STUTTERING

Dominick A. Barbara

Downloaded from www.dbraulibrary.org.in

STUTTERING, AS A SYMPTOM, may be defined as a disturbance in the smooth flow of speech owing to tonic and clonic spasms involving the functions of respiration, phonation, and articulation. Tics and spasms near to or remote from the speech mechanism are frequently associated.

The term "stuttering" is commonly used to describe repetitious speech, and "stammering" to describe hesitant speech. The two are often used interchangeably, but, according to the derivation, stuttering stands for labored, difficult, hesitant speech with resultant defective conversation; stammering refers to defects of articulation and should never be confused with stuttering. Stammering depends on performance; stuttering depends on emotional disturbances.

Stuttering is a highly complex syndrome. It has a multiple etiology, combining morphogenic, chemogenic, neurogenic, psychogenic, and socioenvironmental factors, and has often, and properly, been called the disorder of many theories. Specialists in practically every field of medical research and treatment, seeking to cope with this problem according to their individual findings, have but added to the complexity and confusion. Only by approaching the problem from a dynamic and holistic point of view, with emphasis on the total organism involved, can we hope to understand its nature. To be effective, this approach must concern itself with the affliction less as a speech disturbance and more as a manifestation of the feelings, attitudes, and responses implicit in the crucial speaking situation.

## ¶ Theories Concerning Genesis of Stuttering

As a speech defect, stuttering has been recognized as a problem from time immemorial. That it has a history dating back at least to ancient Egypt, we know from certain symbols said to have been found in the hieroglyphics. It is mentioned in the Bible and by ancient philosophers. Moses is reputed to have been a stutterer. Aristotle, Aesop, Demosthenes, Virgil, Erasmus, Charles Lamb, and in our time, Sir Winston Churchill, King George VI, Somerset Maugham, Gary Moore—all have been so afflicted.

The genesis of stuttering was originally as-

sumed to be physical. Hippocrates held that it was due to a "dryness of the tongue"; Aristotle laid it to too thick and hard a tongue; Francis Lord Bacon attributed its cause to coldness and moisture of the tongue. Physicians used to reason that, since a stutter is a disorder of speech, it must, of necessity, be caused by some abnormality in the speech tract. Santorini, the Italian anatomist, believed that two holes of abnormal size located in the middle region of the palate was the causative factor. Morgagni, regarded as the founder of pathological anatomy, rejected this theory and inclined toward the belief that the hyoid bone was the most likely cause. The idea that the tongue was the basis for defective speech was so firmly fixed that, by the middle of the nineteenth century, European surgeons were rivaling each other in being the first to improve on operative techniques. In 1841, nearly two hundred cases in France alone submitted to the operation. At the end of the year, a cry of warning went up, and those who had tried the experiment had the courage to admit themselves in error. Present-day organicists differ from those of earlier times as to what *is* the causative factor; today, the organicity is related to the complicated neurophysical aspects of the entire speech tract.

Some researchers attribute psychological factors to the *modus operandi*. The modern theories of stuttering are too numerous to cite in any one particular chapter, and the following are just a few of the more predominant psychological evaluations.

1. Blanton[11] believes that psychological factors are the primary causes of stuttering, and the fear states of the stutterer prevent the cortex from exerting control over the organs used in speech. The cause lies in the emotional conscious and unconscious mind of the stutterer. Stuttering is the symptom of the emotional difficulty, and the physical symptoms can be explained neurologically.

2. Coriat[12] applies Freudian principles to the psychoanalytic theory of stuttering:

> Stammering is a psychoneurosis caused by the persistence into later life of early pregenital oral nursing, oral sadistic and anal sadistic components. The term "pregenital" refers to the organization of the sexual life of the child during the early infantile period before the genital zone has assumed a dominating role. In cases of stammering, these various pregenital tendencies can be definitely observed when attempts are made to speak, and they also appear in characteristic oral nursing and oral cannibalistic dreams, showing that the stammerer has not overcome these pregenital impulses in the course of adult development.

3. Greene[16] places the individual who demonstrates stuttering speech in what he terms the "stutter-type group." The individuals in this group are characterized by a basic tendency toward excitability and disorganization, an exaggerated capacity for response to stimuli, and a relatively high potentiality for the spread of emotional tension. Their mental and physical activities are continually being disturbed or inhibited because of uncontrolled reactions. This disturbance is manifested by arrhythmia or hesitancy, not only in speech but in many other forms of psychomotor activity.

4. Froeschels[13] calls stuttering "dissociative aphasia." He believes that there is a disturbance of the thought processes, a deficiency in word finding and sentence formation and, later on, an interference between the ideas which the patient wants to utter and ideas of existing difficulties. At the onset the causes are largely physiological in nature (because about 80 per cent of children pass through a short period of syllable-repeating), but, as time passes, psychological reactions develop which may be considered a form of psychoneurosis. Froeschels finds considerable evidence that the affliction is linked up with subconscious volition, the will to stutter.

5. Karlin[21] believes that stuttering is basically due to a delay or a slower progress of myelinization of the cortical association areas concerned with speed.

6. Solomon[24] uses a sociopsychobiological approach: "Stuttering, as a clinical syndrome, is a specifically conditioned personality, emotive behavior, and speech disorder in the struggle for integration and equilibrium during social speaking."

Attempts to arrive at the genesis of stuttering through physical examinations, laboratory and

Downloaded from www.jbaudiology.org.in

biochemical studies, and psychological testing have not proved specific. Neurological examination in the average stutterer reveals no evidence of peripheral neuromuscular involvement or of any pathological disturbances of the speech organism. Electroencephalography has also been proved to be nonspecific for any stutterlike pattern. It has merely shown that the stutterer is characteristically an awkward, tense individual, suggesting deficiencies in motor integration. More than often this incoordination appears to be related to emotional disturbances rather than the resultant of any correlated cortical disturbances.

The question of organ or symptom choice in stuttering is a most difficult one to answer. It is my feeling that it arises primarily from a combination of organic and psychological factors occurring at approximately the same time. These factors or disturbances are: (1) the suggestion of the presence of constitutional factors which predispose the stutterer to emotional imbalance in general and to motor and speech disorganization, and (2) the added stress placed upon this organic instability by parental and cultural restrictions, prohibitions, and taboos specifically related to the areas of speaking and self-expression.

## ¶ Facts and Characteristics Concerning Stuttering

Some of the common facts and characteristics that have been determined in regard to stuttering are as follows:

1. The incidence of stuttering amounts to about 1,300,000 in this country alone, 15,000,000 in the world. It has been placed at about 1 per cent of the general population, roughly half of whom are children. Stuttering has no respect for social or economic status, religion, race, or intelligence.

2. The question of sex distribution in stutterers remains as yet in a controversial state; males are from four to eight times as frequently affected as females.

3. Though there are no hereditary facts found in stuttering, we do know that there is a familial tendency. Stuttering does appear in families with some history of stuttering more often than in those of nonstutterers.

Despite the lack of any strong evidence pertaining to the inherent causative factors in stuttering, there is some suggestion of the presence of constitutional factors which predispose an individual to emotional imbalance in general and to stuttering speech in particular. There also appears to be some predisposition in people who stutter to an original motor disorganization, since stuttering children are observed to be more awkward and less adept at acquiring motor skills than is the so-called normal child. This observation has been corroborated in a study made by Berry[10] of the developmental history of 500 stuttering children as compared with 500 normal children. She found that the children who stuttered were definitely retarded in acquiring motor skills. They were retarded in learning to walk, when compared with the nonstuttering children, and "also showed a serious retardation both in the initiation of speech and in the development of intelligible speech."

4. The question of handedness in stuttering has also been one of considerable controversy. Its premise was originated by Orton.[23] Briefly, it postulates the presence of a speech center in each cerebral hemisphere, one of which centers is the dominant one. Either owing to a lack of development or as a result of the reversal of the handedness (the center of which is closely linked with that of speech), the dominance in the one speech center is lost. Then the two centers have the same influence, resulting in hesitating speech.

5. Other characteristics noted include relatively high incidence in twins and in family history of twins, relatively high incidence of sinistrality and ambidexterity, and slowness in speech development.

6. Relating to the actual content of the stuttering itself, we find that 10 per cent of words are stuttered, that stuttering lasts usually less than two seconds, and that repetition of initial sounds, prolongation of initial sounds, or exaggerated hesitancy to speak are common. Also, in this same context, there are associated parakinetic reactions such as eye closure, nostril dilation, and slight breathing abnormalities.

Downloaded from www.dtic.mil

7. Finally, stuttering is found to be reduced in repetitive reading, reading in chorus, and in singing.

Though so much has been concluded in regard to stuttering, it still remains a perplexing problem. One of the chief reasons for this confusion is the revealing fact that no two stutterers are alike in make-up or development. Where research is sorely needed, and may aid to clarify and shed more light onto this clouded issue of stuttering, is in the study of personality development.

## ¶ Psychodynamic Patterns in Stuttering

Any workable hypothesis concerning the understanding of the nature of stuttering must take into account the organism as a whole. So-called symptoms of neurosis are not essential constituents, but they develop as an outgrowth of the neurotic character structure and can be understood only on that basis. Stuttering is to be considered as an expression of anxiety, which results when the protective structure of the organism in a neurotic process becomes threatened and disorganized. Goldstein[14] refers to this as the organismic approach. He states that not all deviations of behavior are directly related to the underlying defect, but some are the expressions of protective mechanisms which the organism utilizes against the disastrous consequence of the defect.

To better understand the nature of stuttering, one should make an attempt to understand the neurotic trends in the individual stutterer's character structure, with its particular functions and consequences to his personality and way of life. Emphasis should be directed less on the symptom of stuttering, much more on the underlying forces which drive the patient to stutter, and, finally, on the feelings, attitudes, and responses in the crucial "speaking situation."

### *Early Childhood and Parental Influences in Stuttering*

The soil from which the individual who stutters grows and develops is similar in nature to that in other forms of neurosis. It differs mainly in regard to the quality and degree of the individual responses and experiences to the particular environmental background.

Individuals inherently tend toward self-realization and constructive individual growth. Given the chance and a more or less healthy soil, a child can grow to become apparently normal and can fulfill his growth possibilities. Basically, the soil must contain a feeling of genuine warmth, love, and respect. A child needs to feel that he is wanted, loved, and needed; he needs a sense of belonging. If these conditions are lacking, then a state of emotional stirring is generated in the child, which is felt as difficult to understand or accept. He may thus be rendered weak and insecure. This can easily be the focal point around which his difficulties, with increasing further frustrations and disappointments, originate.

The reasons why a child does not receive adequate love and warmth at this stage of development may lie in the parents' incapacity to convey them, because of their own problems. This may be expressed openly, in the form of hostility toward an unwanted child; in a detached, disinterested, and aloof manner; or camouflaged in the form of an oversolicitude or the self-sacrificing attitude of an "ideal" mother.

In the stuttering child, disturbed parental and environmental factors which begin at an early age—usually between three and four years—result in the weakening of the child's ego and generate basic anxiety, with accompanying feelings of helplessness and hostility.

As a result of the early age at which such a child feels himself threatened, he will, because of an already weakened emotional state, be unable to organize his inner forces in sufficient strength to restore order to his disorganized personality.

Finally, as a form of safety and protection to this altered ego, neurotic trends and defenses are developed which, because of their contradictory nature, create further conflicts. This is usually the origin of the primary manifestations in stuttering.

The following are two brief illustrations of various combinations of parental settings in stutter-type environments:[6]

Do not duplicate without permission. www.brainlibrary.org

Johnny's family on both sides were of German-Polish descent, middle class. He is an only child born through a forced marriage due to an illegitimate pregnancy. His mother is a large, heavy-set, domineering, and perfectionistic individual. In her own family constellation she played a minor role, being constantly oppressed and pushed into the background by her own mother and older sister, who was the family favorite. Johnny's father played instead a detached, aloof, and indifferent role, succumbing many times to his wife's demands in order to avoid too many arguments or friction. As a boy, Johnny was in constant fear of being punished in not being able to live up to his mother's absolute and perfectionistic demands. She exposed him to a domineering form of overprotection, as she dictated and charted every possible move he took. Onset of stuttering began at the age of 9.

Tony was born in a poorer Italian section of Brooklyn in 1927. Both parents were Italian, born in Sicily; they had migrated to this country because of social and economic goals. Tony was the only boy in a family of five older sisters. There were eight pregnancies in all, two of them ending in miscarriages. Tony's father felt angered and hostile each time his wife gave birth to a female child. He would rage at her for her incapacity to bear worth-while children, and felt insignificant as a male in the eyes of his relatives and neighbors. He is further described as being aggressive, domineering, controlling and as an arrogant, vindictive tyrant. Because of his own cultural background he strongly held to the dogma of male superiority. When Tony was born, his father shut his barber shop for a week and the home became a temple of worship and festivity. His "Christlike" son had been born, and no longer had he to hang his head in shame and humiliation. Tony's mother, on the other hand, is described as being self-sacrificing, oversolicitous, and martyrlike in her suffering role. Tony's life had been charted and dictated ever since his birth: he was to become a successful doctor, lawyer, or dentist. The intense pressure of the unattainable goals forced upon Tony from an early age resulted in his beginning to stutter at the age of 8.

In the foregoing illustrations, though there may be some basic similarities between the cases, there appears to be no definite difference from those factors found in backgrounds of other neurotic developments.

## *The Onset of Stuttering*

The onset of about 90 per cent of stuttering occurs under the age of ten, and the majority of these cases start in the first five years, when the first major social adjustments begin. Orton[23] divides the onset of stuttering into two periods, one beginning at the period of speech learning (two to three years of age) and the other at the time of writing (six to eight years of age).

It is at about the age of three that the average child begins to show enough meaning in his speech to have his parents pay attention to what he is saying and how he is saying it.

The onset of stuttering in childhood may be precipitated by any experience which, in an emotionally inadequate child, generates anxiety and fear. Such traumatic experiences are fright, accident, illness, operations, forcible conversion from left- to right-handedness or a tense and worrisome home environment. The element of fright as a situational traumatic experience plays the most prevalent role. The most common experiences of this type are being frightened by the dark or by lightning; receiving severe punishment at the hands of a domineering and stern parent; being frightened by a dog or some other animal; being chased or mobbed by a gang of "tough boys"; being yelled at by an angered person; being thrown into water for the first time; and being caught in the act of masturbation by a parent.

The following examples are illustrations of adult stuttering—individuals whom I've studied—with known precipitating factors beginning in early childhood:

N.H., a 35-year-old male, was the product of a domineering, stern, and rigid mother and an alcoholic father who had little time to spend with his children. The family environment was one of constant friction and quarrels. At an early age he was subject to nail-biting, temper tantrums, and nightmares of "being beaten up." His eldest brother was his constant and only companion, the one in whom he confided and whom he respected. At the age of 8, while chasing his brother

Downloaded from www.bracu.ac.in

through the streets while playing, he saw his brother struck by a truck and instantly killed. Involuntarily, following this tremendous psychic shock, he began to stutter.

A.D., a 33-year-old male, was left-handed since birth. Both parents were described as being vigorous, intolerant, and demanding. There is a history of a brother and a maternal cousin who stuttered. There was a constant fear of not meeting his parents' demands and of receiving some forms of punishment in consequence. As a child he wet the bed and had frequent nightmares of "falling off tall buildings or of floating off into space, without being able to come back to earth." At the age of 5, he was forcibly threatened to be converted from left- to right-handedness, and subsequently he stuttered.

The above cases are not meant to be examples of cause-effect relationships in stuttering. They have been cited to illustrate conditions in which emotionally disturbed children can be prone to feel threatened in the face of overwhelming anxiety-provoking situations, and, as a result, give expression to their fear in the speaking situation.

## *Disturbed Communication in Stuttering*

In our particular culture, language is considered the chief medium of communication. Through it we express our opinions, feelings, attitudes, and actions. The earliest conflicts of a child are expressed in his communications, both socially and verbally, to his parents and to the outside world about him. Where other children can pass through the primary stages of communication and early development fairly comfortably, the stutterer, because of his emotionally crippled position, is much more prone to anxiety.

Speech is the human's most complex and finely balanced muscular activity. Because of its complicated nature and its numerous nerve areas and muscle groups which require almost perfect coordination and harmony, speech is extremely susceptible to disorganization and nonperformability during periods of emotional tension. At such times, the lines of communication are thrown out of gear, the nerve messages go astray, and we find distortions and definite emotional disturbances in the area of verbalization. It is, therefore, in his speaking that the stutterer experiences the most destructive threats to his basic security and identity.

Free-flowing and spontaneous speech obtains mostly in an environment of parental warmth in which the child feels himself accepted. Hesitancies in speech will first appear in response to parental prohibitions and restitutions. Although nonfluent speech or hesitancy in younger children may be fairly normal,* tense parents who are perfectionists will often find this hesitancy alarming and will tag it as a stutter. Once the child has been so labeled, his position becomes unique in that there is set in motion a chain reaction of worries, anxieties, and preoccupations which will be a source of grave concern to both child and parents. Since language is the chief medium of communication for a child at this time, it is also the area first affected when the protective structures of the organism are threatened and anxieties result.

The speaking situation normally used to convey an idea, express a feeling, or ask a question now becomes a self-assertive, self-conscious act fostered by emotions of hostility and fear. Simple social situations in which speech is required now unconsciously become a testing ground for possible social combat, and the hesitation that results from the conflict between the rational impulse to speak and the irrational fear of speaking becomes crystallized into a stutter. (Psychologically, this is the same process which characterizes occasional stuttering in both child and adult.)

At first, the child, except for the expression of some subjective feeling of tension, awkwardness, or slight muscular incoordination, is unaware of the seriousness of his affliction. However, the threats and apprehensions of his anxious parents will soon make him conscious that, when he speaks, he is doing so differently from others and thus is something of an oddity. He soon begins to feel inferior to other children—peculiar and self-conscious. When, in due course, he enters school, the

* Most children normally repeat 40 to 50 times per 1,000 words spoken.

Downloaded from www.libtibrary.com

added stress and competitive atmosphere in which he finds himself involved will only further cripple his personality. As additional emphasis is placed in terms of presupposed dangers and threats in speaking, speech, which is ordinarily not a conscious effort, will be identified, for him, with his fear of making those funny hesitant sounds and of finding himself rejected by his playmates.

Once the child becomes conscious of his speech and passses from the phase of simple, loose, repetitious speech (primary stuttering) to forcing and compulsively straining his verbalizations, he enters into what is known as "secondary blocking." He now becomes terrified at the mere thought of speaking, and this is intensified as the situations increase in number. In addition, a change in his outward expression and a marked difference in his attitudes toward speech take place.

As his fears increase and he becomes more conscious of his blocking, the child now discovers that, to compensate for his speech difficulty, he is in need of further defenses and means to conceal it. He attempts to find actions and rituals to avoid difficult words and thus begins the hopeless task of substituting. At first, as Gottlober[15] states:

> . . . this works, but soon he fears the word he is using for substitution and it is not long before he runs out of synonyms. Then the "starters" begin, sounds or acts which he thinks will help him to begin talking. He snaps his fingers, stamps his feet, clenches his fists, screws up his face or whistles. Each trick has its few moments of effectiveness and then helps no more. But he continues using them just the same and the ritual that precedes even a single word soon may take from a few moments to more than a minute to complete. He has never seen himself talking or trying to speak, but he is painfully aware of many of the devices he is using. He has felt them in twisted and overcontracted muscles and they have been pointed out and laughed at or mimicked by jeering, teasing friends and sometimes even by his own loved ones. In time he stops trying to talk almost completely and withdraws from the playground and other human contacts.

Stuttering, which is but an outward expression of anxiety in conflict, is secondary to an unhealthy personality development and is manifested specifically and implicitly in speaking where lines of normal verbalization and communication are disturbed.

In the confirmed or adult stutterer, on the other hand, we find a much more pronounced development of the neurotic structure and additional complex attempts at neurotic solutions in which the stuttering habit has become a means of externalizing conflict. A fundamental aspect of the whole personality, the function of speech is both verbal communication and the expression of an individual's interpersonal relations. The syndrome of stuttering must then be considered as a problem involving both interpersonal and interpsychic aspects of inner conflict. In this, the symptom in itself is due primarily to the struggle of the stutterer to keep together as a whole the warring aspects of his personality. In this way, stuttering manifests such attempts at solution as the afflicted one utilizes to maintain his psychic unity in the process of achieving self-realization and holistic integration.

## *Secondary Manifestations of Stuttering*

Many stutterers feel that they are set apart —different; that although others too have their problems, they are at least better able to cope with and live with them, while they themselves are more obviously crippled because their speech defect is something they cannot hide. They will further rationalize this line of thinking by admitting that, while those who are victims of migraines, asthma, stomach ulcers, and so on *do* suffer, they are able to conceal their troubles generally, whereas stutterers must put up with an added burden in the way of social criticism and judgment. As a result, those so afflicted feel themselves entitled to special conditions and privileges from a society which should be obligated to make allowances for the stuttering difficulty.

Some stutterers, embittered, will blame a way of life where such gadgets as telephones, dictaphones, and other means of verbal communication make speaking a "must." According to them, others more fortunate should take over for them in speaking situations which may give them bad moments—the others

Downloaded from www.cbsalibrary.com.in

should answer the phone, make the necessary verbal requests, supply all necessary data and information, and give their complete and undivided attention to the stutterer when he speaks. The reasoning here is that "since you know I stutter, you should help me by making an all-out effort to understand me when I speak and so protect me from embarrassment and ridicule."

The stutterer may know realistically that he has stuttered for years. He knows too that in certain situations he has always found it difficult to speak. Nevertheless he blindly refuses to accept his shortcomings and feels compulsively driven toward speaking flawlessly rather than just settling for speaking with some degree of improvement.

The stutterer has a strong sense of dependence upon words as the sole means for communicating his thoughts and reactions; he feels at a disadvantage in the speaking situation, and so his whole concept of the act of speaking becomes confused and defective. And while within himself he may feel compelled to use the right word at the right time, yet he will rebel against any form of outside coercion, be it explicit or implicit. In any reference to a thing or an object as he speaks, he will give himself little freedom or choice in his use of words, so driven is he to be perfect, exacting, and absolutely correct in all of his communication. Since he invariably thinks of the speaking situation as controlling him and not of his being in control of it, he will resort to many forms of neurotic solutions to help him cope with his difficult and precarious position.

The stutterer plays with words, changes them about, makes substitutions, and may even, if he finds the going difficult, create his own vocabulary. Emotionally under pressure, he feels he must be master of his own language and that, by one device or another, he should be able to make it suit his own particular needs. He may become annoyed, however, if his listeners do not understand the meaning of his cryptic verbal communications, his coined words, his gesticulations, his unfamiliar pronunciations. At still other moments when speech is difficult, he will attempt to save himself by filling in gaps with falsities, absurd rationalizations, or even obvious distortions. If questioned as to the validity of his remarks, he is seemingly offended at his listeners. Actually, what he experiences under these circumstances is rage at himself for not having reinforced and foolproofed his magic solutions. Had he not failed to bluff his way through to a convincing performance, his defenses could not have been penetrated. So here again, this neurotic stutterer reveals his blind faith in himself and his compelling dependence on his maneuvers and duplicities.

The various bodily movements and contortions used also carry with them a sense of implied ritual. The pressing of both hands against the body, the blinking of the eyelids, the placing of the palm of the hand over the mouth—these are but a few of the many bodily "magic" gestures used in stuttering. Each has its specific and all-powerful meaning for a neurotic need at the moment of conflict.

As a whole, these are unconscious attempts to hold together whatever is disruptive and chaotic at the time. Most stutterers, oddly enough, feel that they should and must hold together their disorganized personalities, and so they will even go so far as actually to pinch themselves into a semblance of spontaneity, and will struggle to cover up their deficiencies by changing words to suit their fancied needs and to blot out of their awareness—and that of their audience—any apparent weakness or discrepancy in their idealized image of themselves. Rarely do such devices succeed, yet, in trying to understand the stutterer, it is most important that we constantly keep in mind the tremendous neurotic pride invested in these solutions. The stutterer neither can nor dares to give them up; he cannot lose faith in them. Without them, he will experience himself as being lost, a nothing, prey to the onslaught of his waiting self-hate. Only through a slow unveiling and resolution of his conflicts as a whole will his reliance on these neurotic props be abandoned.

Most stutterers are in constant dread of being defeated as they speak. Even before they begin, they are overwhelmed by the fear of not being able to initiate the utterance of a

Downloaded from www.pbookshop.com

single word or sound. Threatened, they will anxiously whip up and distort the facts or the actualities until they regard the situation in the light of a calamity and doomed to failure. They say to themselves "I won't even be able to open my mouth," "I can't do it—I know I shall stutter," or "I shall be paralyzed with fear." They fear ridicule, criticism, and embarrassment not as self-recrimination but as coming from the outside and from others. Since they are driven compulsively toward the achievement of perfection in speaking, their main emphasis is directed not in terms of what they want to express but on how they will appear before others when they speak, on how they will finish up in terms of the audience's reaction. Owing to their profound sense of inadequacy, each new attempt at speaking becomes a testing ground for their actual existence.

Speaking, as a result, becomes a conscious process. Constantly at odds with himself and tortured by almost every attempt to express himself verbally, speaking, so habitual a function with normal persons, is for the stutterer an ordeal which fills him with panic and a sense of disaster.

In social or job situations, the stutterer is compelled to protect himself from exposing his speech difficulty by constantly avoiding the necessity for speech. He will go out of his way to avoid lengthy conversations, have others answer the phone for him, will seldom ask for directions, will restrict his spoken desires—anything rather than to encounter verbal friction.

What the stutterer fails to recognize in himself is his need to comply, his fear of aggressively disturbing and intruding upon the privacy of others. Should he ever dare to interrupt another who is talking, he will immediately become involved in anxiety over his boldness and will begin to stutter. What might perhaps be a healthy and perfectly normal act on his part will suddenly have become one that is aggressive and presumptuous. And, as with any unconscious attempt toward expansiveness, this will threaten his protective structure to the point that what he actually experiences is now an overwhelming sense of going to pieces, of crumbling.

Still other stutterers use expansive attitudes to cover up their shortcomings in their life situations. They will brag about the advantages they, as stutterers, have over average speakers. They take a peculiar destructive delight in showing how cunningly they avoid difficult situations by using their stuttering not as a crutch but as a powerful excuse device. Some will take great pride in identifying themselves with stutterers such as Churchill or Somerset Maugham who have accomplished so many great things.

In his interpersonal relationships, the resigned type of stutterer sees to it that he maintains his emotional distance from others. Although he may appear to have many friends and acquaintances, he rarely becomes emotionally involved with anyone. Many have even withdrawn physically into an isolated, inconspicuous existence. They never marry and, by avoiding most social contacts, manage to live very much like hermits. Some go to the extremes of avoiding buses, restaurants, or other public places where they run the risk of having to speak in order to communicate their wants to others.

It is also true that the man or woman who stutters is a chronic hesitator in other areas of his life. Stuttering, with all its blocks and hesitations, almost always represents the localized and externalized expression of a general state of indecisiveness and wavering. Before attempting to speak, the stutterer procrastinates and anxiously thinks about what he will say, how he will say it, and when. Since he cannot be spontaneous in his choice of words and speech must therefore be a conscious act, he is extremely cautious and perfectionistic in what he communicates. Even when he is quite certain that he knows what he wants to say, his self-doubts grow, and he will be forced back into a position of indecisiveness and further hesitations. In the end he finds himself in the dilemma of either offering passive resistance and refusing to say anything at all or of involving himself by pushing himself into the speaking act. Or he may externalize this and persuade himself that others are coercing him into doing so.

As a result of these many conflicting tendencies, he will grow more entangled and

Downloaded from www.dbraulibrary.org.in

rebellious, more anxious and hostile and trapped, and this will lead him inevitably to a state of constant confusion and a chronic stuttered speech.

The stutterer is therefore unable to find relaxation, enjoyment, or an inner contentment. The tremendous expenditure of energy implicit in a conflicting ordeal of this sort is bound to leave a person frustrated, hopelessly resigned, inert, and exhausted. Spontaneous initiative is either paralyzed within him or is short-lived, as all his attempts at constructive effort are thwarted or diverted. The energies which might have been utilized to achieve positive direction toward his goals must be consumed in his efforts—negative ones—to release himself from the opposing forces of his neurotic conflicts. But by a progressive resolution of his inner struggles and by carefully worked-out changes, the stutterer may in time —and often does—overcome his conflicted self and so arrives at a rewarding and healthy state of self-realization.

## ¶ Treatment

### *Psychotherapy*

In a problem as complex as stuttering, any attempt toward treatment should be composite in nature. Adequate therapy should include investigations of a medical, social, psychiatric, and re-educational nature. Stuttering is to be considered not as an isolated disorder of the speech mechanism but as an outward expression of a more basic character disorganization. Any effective treatment must also be directed toward helping the individual to understand his particular neurotic difficulties with their neurotic solutions and to arrive at some resolution of the underlying conflicts. It must also include a rehabilitation of his entire speech mechanism.

The goals in treatment have changed considerably from those of our forerunners. Today, the emphasis is away from symptoms as the prime expressions of underlying disturbances and toward the treatment of the total personality, the whole man. This holistic approach involves not only the individual's disturbances in relation to others but the nature and importance of intrapsychic processes. Our responsibility is to help the stutterer not only to overcome or alleviate his stuttering but to find himself as an individual—to release those energies now bottled up in his neurosis toward self-realization, capacities for creative work, better human relationships, and assumption of responsibility for himself.

A detailed presentation of treatment in stuttering cannot be given in one chapter, so only the basic principles and methods of effective treatment are mentioned here. Aside from the preventive and educational procedures which are of value in all disease entities, treatment in this particular context will be undertaken from a combined psychotherapeutic and speech technique.

Since stuttering usually begins at an early age, treatment, too, should begin as early as possible. For therapeutic purposes we can distinguish two phases of stuttering—primary and secondary.

#### Primary Stage

In treatment during the primary stage (five to ten years of age), when the child is less cognizant of and anxious about his speech problem, the approach is mainly one of treating the parents and, through them, removing unfavorable environmental influences. The prime objective is to be able to give support and yet aid the child to lessen the degree of his inner turmoil and conflicts, to attempt to arrest the disorder, and, if possible, to prevent perpetuation of the problem into the secondary stage or into confirmed stuttering. The parents or parent surrogates of the stuttering child are made as aware as possible of the many workable means available to ease the demands made upon their children, and how these same pressures can lead to stuttering. An ideal situation, it goes without saying, would be one where either or both of the parents could be encouraged to enter into treatment themselves, to help them work through some of their own most disturbing emotional problems, which, in turn, would better the child-parent relationship. Where this is not feasible or is met with resistance, treatment of parents must assume the form of specific instructions. These instructions are directed toward (1) avoiding making the child feel unique or different from others,

Downloaded from www.dbraulibrary.org.in

avoiding making him "speech conscious," and especially allowing him to develop a sense of freedom of expression through speech and a feeling for an independent choice of words; (2) improving the general health of the child; (3) balancing his environmental tempo, with the removal of some of the more exciting and disturbing tension factors; (4) encouraging in the child a sense of confidence, responsibility, mutual love, and respect; (5) working toward a sense of coordination and rhythm in the child's personality as a whole; (6) encouraging the child to mix freely with other children and especially with members of his own family; (7) encouraging more constructive methods of discipline; (8) enabling the child to grow at his particular pace and helping him find his own potentialities and creative capacities; and (9) establishing a feeling of real love, warmth, and mutual belonging in the family unit. Though these goals may seem to be so comprehensive as to be difficult of attainment, even partial achievement of them can aid the stuttering child in his later struggles toward self-realization.

### SECONDARY STAGE

In the secondary stage of stuttering (eleven to nineteen years of age), the stutterer is now consciously aware that he has a speech difficulty and is particularly affected by what others think of him. This adolescent or adult stutterer develops a keen sensitivity concerning his affliction and is easily affected by criticism and his own particular shortcomings. Treatment in this stage, in contrast to that of the primary stage, consists primarily of a direct approach. The individual's problems are tackled directly, and the aim is toward personality and speech reorganization.

Once the primary objectives are established and a plan of approach is decided upon by the therapist, more feasible and productive therapeutic work can begin. In accordance with the original premises of this chapter, especially that of promoting self-realization, it is important to recognize early in the therapeutic process the various resistances and blockages which are keeping neurotic processes going and simultaneously are interfering with healthy growth. Since we are primarily interested in helping the patient find himself, we must remove those obstacles which obstruct his growth, interfere with his real self, and cause him to feel alien to himself and to others. The following precepts are, I believe, most worthy of attention.

1. Encourage the stutterer to begin and continue treatment.

Doubts and feelings of doom have become fixed in the minds of those many stutterers who have gone from clinic to clinic, from specialist to specialist, or have been subjected to so-called "miraculous cures." When these unfortunates are initially interviewed for what they may feel is another new and futile attempt, among the many others, they are often skeptical and cautious. They have little real incentive for receiving help in the solution of their problems, and a difficult area of resistance is set up. The therapist must therefore give a great deal of himself by way of encouragement.

It might be well for the therapist to give his patient some pertinent information concerning his own professional background and his experiences with psychological problems, particularly the problem of stuttering. Then he should try to ease the patient's doubts and anxiety about himself by relating to the patient in a firm but sincere, warm, open, and consistent manner. He can reassure the patient further by saying something like: "Yes, I have no doubts about being able to help you with your problems, provided you are ready to cooperate with me. If you help pitch in, I'm sure we can do the job together."

2. Remove those resistances which are perpetuated by the individual's disturbed productivity and intellectualizations.

Besides the stutterer's hesitations when speaking, he presents similar inhibitions and blocks in the quality of his productions. The stutterer blocks with his whole organism—his feelings, attitudes, beliefs, and actions.

The stutterer thinks highly of "wisdom" and "intellect." His thinking is usually in terms of absolutes. His responses are purely on an intellectual level. His own inner fear of feelings forces him to seek logical and clean-cut answers to his problems. Seeking his conflicts at a distance, he tries to compartmentalize and ration-

Downloaded from www.dbmedicinary.com

alize many of his shortcomings and opposing tendencies.

Progress in treating a stutterer is often slowed by the fact that his associations are usually not free and spontaneous in quality. The patient must be made aware of this blocking agent early in his treatment, so that a more real, down-to-earth atmosphere may be promoted in the therapeutic situation.

Of course, the actual stuttering symptom is one of the blockages in productivity. The therapist struggling to remove the symptom itself and not working with the total character structure is easily caught in a tangle of intellectual discussions on the presupposed cause-and-effect correlations of stuttering. What the stutterer is trying to express when he speaks, especially when he stutters, must be kept in mind. The therapist must intercept and decode the messages the patient sends by the way he presents himself in speaking, his hidden meanings, feeling tones, anxieties, inhibitions, hesitations, and especially his own word jargon.

3. Alleviate disturbances in the therapist-patient relationship.

The stutterer's use of magical claims creates a formidable obstructing force in the therapeutic relationship. The patient externalizes his own feelings of magic onto the therapist and endows him with superhuman powers impossible to attain. The therapist is a magician, he feels, who can easily and effortlessly rid him of his dilemma. In order to place himself in a position less threatening to his neurotic solutions, the stutterer may use his affliction, with its distractions and its rituals, to keep his therapist off guard. The therapist must therefore and nevertheless maintain a balanced, firm, and consistent position as well as his superior status. The patient secretly and truly desires this, despite his seeming to fight the therapist's firmness and consistency. In this way only will the therapist ultimately receive the stutterer's real respect and regard and be able to give his patient a sense of security.

4. Relieve the stutterer of his fears regarding any disturbance to his neurotic status quo.

The stutterer lives in constant dread of having his protective structures invaded or removed, with its accompanying terror of crumbling and psychically going to pieces. His need for mastery, particularly in the speaking situation, causes feelings of self-hate to develop when his pride values in this direction are undermined. The stutterer cannot face his conflicts squarely or bear their related anxiety. He therefore quickly retreats by pleading helplessness and having abused feelings. As he feels the situation becoming more desperate, he will adopt more strategies with his last area of refuge—that of avoiding conflict entirely. By resigning himself to a state of pseudo-unity, he is able to save face in at least part of the struggle.

It is very important that the stutterer begin to see himself less as "just a stutterer" and more as a human being despite his stuttering. He can be helped to feel more hopeful and on firmer ground and, conversely, less resigned and frustrated. His anxiety and the threat to his "lofty position" being lessened, he will then be able to take a stand in relation to his conflicts and have the courage not only to face himself as he really is but also to change.

## *Specialized Speech Techniques Used in the Treatment of Stuttering*

Recently, among those directly associated with the speech field, there has been a reaffirmation of the point of view that, essentially, stuttering is a learned form of behavior not necessarily associated with basic neurotic personality or atypical neurology. The objective of this particular group of speech therapists has been one of working directly with the speech difficulty. Among the objectives of the techniques used here are the following: (1) to weaken the forces which tend to maintain and strengthen stuttering; (2) to modify and decrease the severity of the stuttering blocks by eliminating the secondary symptoms of stuttering; (3) to help the stutterer to speak, even though he stutters, in a relatively easy and effortless fashion rather than to avoid fears and blocks; and (4) to help the stutterer in an over-all adjustment to his environment.

At this point only a few of the better-known speech techniques used in speech clinics today will be mentioned.

Downloaded from www.dbeuhler.org.ru

### VOLUNTARY STUTTERING

Voluntary, or intentional, stuttering is based upon the psychological principle of negative practice. The stutterer is trained first to do intentionally what he has been doing involuntarily and unintentionally, so that he may gain control over a habit which has been controlling him. The stutterer (Berry and Eisenson,[10] p. 288) must learn to stutter intentionally, at first repeating his complete spasm with all the associated mannerisms. He is also encouraged to try to feel as he does in his involuntary stuttering. Aids in this procedure are the use of a mirror, which he can use to observe himself as he stutters; imitating another stutterer who, by prior arrangement, has agreed to imitate him; or attempting to imitate how he himself sounds by listening to a tape recording of his own speech.

When the stutterer has reached this stage and becomes efficient at self-imitation, he is ready for his next step in voluntary stuttering. He can now learn to repeat his evocation and be able to modify it in one or more respects decided on in advance. Normally fluent speech is not the immediate goal in this technique; rather, it is the control of stuttering through modified stuttering. Even if he feels beforehand that he can speak without stuttering, the stutterer is encouraged to pretend or fake stuttering—but to do so in a way different from his usual manner of stuttering. Finally, he is further directed to stutter easily, without struggle behavior, without blocks, and without tension, if at all possible. The objective in this form of therapy is to aid and influence the stutterer to modify and weaken his own stuttering pattern and to substitute for it a more fluent form of stuttering.

### DIFFERENTIAL RELAXATION

Differential relaxation requires that the stutterer be able to relax one set of muscles which are to be used in a voluntary act, regardless of how tense other muscles may be. In stuttering, for instance, the major group of muscles employed are those which involve the articulatory mechanism. In the beginning, the stutterer is taught differential relaxation by encouraging an unconsciously produced tense articulatory position. He is directed to press hard, even harder than he does involuntarily, in the articulatory contact for a *t*, and to then relax the contact while he exhales so that a *t* may be produced. Following this, and soon after, the stutterer is asked to make the slightest possible contact necessary to produce a *t*. Once he can do this for one type of sound, he is given exercises to practice on other plosives, continuants, nasals, and affricates—until they are all learned. The stutterer, in this practice, has achieved his goal when he can imitate "bogey" words and feared articulatory acts with relative ease.

### ADAPTATION

The last speech technique to be mentioned here is that known as "adaptation." Johnson[20] and some of his associates employ the technique of repeated readings of the same material to demonstrate that the incidence of stuttering is reduced with successive readings. The underlying theoretical premise for this approach is that the occurrence of stuttering in the first reading dissipates sufficient anxiety so that there is less stuttering in successive readings. Since this has been found to be true in practice, Johnson and his colleagues feel that the use of this technique can demonstrate to the stutterer that, in some situations, his severe nonfluencies can be quickly reduced and relative fluency of utterance attained. In so doing, the speech situation is changed from one conducive to stuttering to one usually conducive to relatively fluent speech.

## *Conclusion*

Since stuttering, in this particular context, is being considered as a problem involving the whole person, it would seem to follow that the most suitable form of treatment should consist not only of vocal exercises and suggestions but of treatment of the whole personality as well.

In the final analysis, as the stutterer slowly finds himself progressing toward self-realization, he will tend to discard his neurosis and all that it implies—including stuttering. The length of time in treatment varies from individual to in-

Digitized by www.library.org.in

dividual, depending upon such factors as age, severity of the stuttering symptom, degree of neurotic involvement, familial and environmental conditions, etc. It can vary from one year in a young child to several years in the adult. Finally, the main criterion for evaluation depends not so much on the complete elimination of the stuttering symptom in itself as on the total growth of the individual himself, in terms of what Karen Horney[18] advocates when she says,

. . . it concerns all that is involved in self-realization. . . . it means striving toward a clearer and deeper experiencing of his feelings, wishes and beliefs; toward a greater ability to tap his resources and to use them for constructive ends; toward a clearer perception of his direction in life, with the assumption of responsibility for himself and his decisions. . . .

CHAPTER 48

# SYMBOLIC REORGANIZATION IN BRAIN INJURIES

Edwin A. Weinstein
Robert L. Kahn

Downloaded from www.dbraulibrary.org.in

THE CONCEPT OF CHANGES in symbolic organization as modes of adaptation to stress is based on formulations of the relationship of language and behavior found particularly in the works of Edward Sapir,[65] G. H. Mead,[34] Benjamin Whorf,[81] and Karl Lashley.[28] It becomes increasingly clear that language is not simply the label placed on already formed perceptions, thoughts, and feelings, but that the symbols we use are a product of a pattern of interaction in the environment. What we see or hear is the result of a process of selective perception and generalization which, to a great extent, goes on outside awareness. Sapir has pointed out that the physical aspects of a stimulus are only points in a pattern, and take on form and meaning by reason of their place in a total pattern of relatedness. We hear the melody rather than the individual notes, and a different set of notes may sound the same, provided they bear the same temporal and spatial relationship to one another. The color blue would have no meaning in a world where everything was blue; the quality of blueness takes on meaning only against the background of other colors.

Furthermore, the manner in which we structure the environment is determined in considerable degree by cultural orientation. The reality we perceive is not a universal one, for participants in different cultures classify the environment differently. For example, among the Navaho Indians there are color terms equivalent to our white, red, and yellow, but none corresponding to black, gray, brown, blue, and green. To the Navaho, blue and green are the same color and, most important, are *felt* as the same color. If they are seen as different, it is in the sense of varieties or shades of the same color. Whorf has suggested that even our space, time, and matter organization of the universe is influenced by the grammatical structure of our language.

In language we not only classify the environ-

ment but express a relatedness in it from which we derive a sense of reality and a feeling that things are what they are. The fashion designer, with his puce, mauve, beige, etc., is not only designating colors as he sees them but identifying himself with a particular cultural group. On a broader scale, let us take an expression such as "the exotic East." This is a term for which meaning and feeling derive largely in the context of Western social values. The people of India or China do not feel that their country is exotic, nor do they regard themselves as being of the East, except by reason of their orientation to Western culture. Yet the person who uses the expression, in so far as he does think about it, believes that he does so because East is East and it *is* exotic. The reality that we experience has been called by Sapir a "social reality" and the feeling of the reality of one's experience is related to the degree to which the symbolic representation identifies one with the values of his culture.

Sapir has offered a classification of symbolism into referential and experiential, or condensation, types. Referential symbols are those designations and classifications of the environment on which there tends to be arbitrary and universal agreement and which primarily serve purposes of communication and reference. This type is exemplified by numbers, letters, the Morse code, and systems of flag signaling. Experiential symbols are those which seem to express a particular emotion or feeling, such as a prayer, a vow, the password of a fraternal order, and most gestures. Actually, it is difficult to find symbols that are purely referential or purely experiential, as both features are usually present in some degree. In a referential sense, the American flag denotes territorial sovereignty, while experientially it may be associated with feelings of patriotism and security. These feelings are not determined arbitrarily by the symbol but depend on the particular situation and the degree to which the person is related in his society. One is apt to be more aware of the referential aspect rather than the social aspects of language. The religious worshiper, for example, regards the feelings of faith, love, fear, or reverence derived from prayer in terms of communication with a deity rather than in the way the symbol identifies him with his cultural values. He is quite unaware of the interaction in the environment and *feels* the symbol not as language but as the very essence of reality.

Changes to more experiential types of symbolic organization may occur in situations of stress. Examples are metaphors, prayers, vows, proverbs, humor, slang and profanity, and superstitions, to name several in the verbal sphere. All of these involve a shift in the level of interaction in the environment. Thus, in a certain situation, the breaking of a twig may be a sign that someone will be hurt. One may seek the solution of a problem or accept the truth of a statement by restructuring it in a proverb such as "where there is smoke there is fire." Now this is manifestly untrue. Yet the speaker gets the *feeling* of truth and a resolution of his doubts by reason of the altered pattern of interaction (as compared to the referential aspects). In humor there is a similar relationship between the referential and experiential aspects of language. In this chapter we shall present certain delusions as adaptive processes. When a patient claims that his food is poisoned, he may be saying, in effect, that people don't like him. But he says it in this language because using the symbol gives him a *feeling* of well-being, anger, martyrdom, righteousness, or what not, derived from a relatedness in the environment in terms of the cultural value, food. Here the delusion is quite analogous to the use of food in religious rituals, to various customs and manners concerning eating, and, in the verbal sphere, to metaphors, homilies, and vows about food.

## ¶ Classification of the Material

The type of stress that will be considered is that which occurs with brain injury and physical incapacity. Here the stress is very great; the patterns are striking and enduring and, as compared to neurologically normal persons, less susceptible to change in the course of study. Rather than sharply divide organic from functional, it should be recognized that changes in brain function occur with any type of stress, although our methods of study are still inadequate. The principles to be outlined apply not only to states of physical incapacity associated

Downloaded from www.dbraulibrary.org.in

with brain damage but to psychological stress as well.

The material will be presented in its neuroanatomical, neurophysiological, psychodynamic, and social and cultural aspects. It will be classified in terms of the motivational concept, denial. This forms a unifying category for many seemingly diverse forms of behavior, and the data can be brought into line with clinical syndromes already familiar, in some degree, to the reader. The approach also lends itself to a classification of the environment in spatial, temporal, personal, and somatic aspects. The various denial syndromes may be grouped into verbal and nonverbal forms and explicit and implicit types. Verbal patterns will be described under the headings of explicit denial, confabulation, paraphasia, reduplication, and amnesia. Nonverbal patterns are designated as inattention and withdrawal, mood changes, and altered sexual behavior and behavior related to other physical activities.

## ¶ Verbal Patterns of Denial

### *Explicit Verbal Denial (Anosognosia)*

Explicit verbal denial has been described in the literature mainly in the form of denial of blindness and hemiplegia, referred to as Anton's syndrome and anosognosia of Babinski, respectively. Actually, patients may deny any type of physical incapacity, when studied under the conditions to be specified, and cases have been reported of enduring denial of aphasia, deafness, involuntary movements, diplopia, ptosis, urinary and fecal incontinence, paraplegia, and loss of a limb or an eye. Phantom limb may be regarded as a transitory form of anosognosia, which may become enduring under the conditions of brain function to be specified. An interesting form of anosognosia occurs in the toxic encephalopathy following severe burns, where the patient denies he has been burned and disfigured. In Paget's disease the patient may disclaim any knowledge of his osseous deformities. Where several disabilities exist, such as hemiplegia and blindness, any or all may be denied. Patients may disclaim ownership of an affected member of the body, attribute it to someone else, or displace it into space. Thus patients with a paralyzed limb may say that it belongs to the nurse. A woman brought to the office by her daughters told the doctor to examine them as *they* were ill. Another claimed that her paralyzed limb was lying on her bedside table "like a set of false teeth." In states of partial denial, patients may admit the existence of some of the manifestations of illness but attribute them to some trivial cause or blame them on the actions of someone else. Thus patients will say that they cannot move an arm because it is sore from a hypodermic injection.

Along with physical incapacities there is denial of events or situations of traumatic import. Patients with self-inflicted wounds of the head deny not only the shooting but the existence of the problems that led to the act. Following craniotomy and prefrontal lobotomy there is frequently denial of the operation.

Patients with complete denial are bland and affable in interviews, and there are no signs of clinical anxiety. There is a general lack of spontaneity, and, as a rule, patients talk only when spoken to. Apart from interviews they appear dull and inactive, but in the expression of the denial they become animated. There is a conspicuous absence of the "catastrophic reaction" described by Kurt Goldstein in many patients with brain disease. Patients with incomplete forms of explicit verbal denial often appear paranoid, as they may admit some of the manifestations of illness but attribute them to the actions of others or claim that the injured part of the body belongs to someone else. However, markedly euphoric, manic, and highly paranoid reactions are much more apt to occur in patients without explicit denial, as will be described in a later section (see p. 975).

Often, a patient will deny his incapacity in one form of language and admit it in another. It was this observation that initially turned our attention to the matter of symbolic organization rather than consideration of the phenomena as manifestations of specific neural defects or as equated with psychological or physiological drives such as the "wish" to be well. Thus a patient complains about the "hammer-

Downloaded from www.freudinstitute.org.in

ing and sawing" done on his head but denies having had an operation. Patients may admit not moving their limbs but deny that they are paralyzed. They may deny or "forget" having sustained an injury but describe the identical accident as having occurred to someone else. Even though patients deny being ill in any way, they accept medication, submit to operations, and carry on the ward routine in a manner not different from other ill persons.

Patients with explicit verbal denial of illness had previously shown certain characteristic patterns of behavior. These, in particular, concerned health and work. They were reported by relatives as always having denied illness, seeming to regard it as a form of weakness or failure. The maintenance of health was regarded as a personal responsibility tied up with self-esteem. They were apt to put off going to doctors and excuse or rationalize the manifestations of sickness. They were described as conscientious, compulsive, responsible people, and these attitudes were especially exemplified in attitudes toward work. For such people, health and work were ethical values. Through social relationships involving health and work, they gained a sense of "being." When ill or unable to work they were isolated and, through lack of a relatedness, did not derive such a feeling of self. Thus the manifestations of illness are not felt as "real" or as a part of one's own experience when they are not elements of a pattern of social relatedness.

Patients with paranoid forms of explicit denial, in which the manifestations of illness are recognized as existing in some degree but are blamed on others, show some of these personality characteristics. There is the same compulsive drive and need to deny illness. The paranoid group, however, had previously expressed their needs and feelings in a more "physical" fashion. They did not use words as magically, and their attitudes toward illness had been those of open fearfulness and resentment rather than having been verbally expressed in negation, rationalizations, justifications, clichés, and homilies. Thus, patients in the paranoid group might say that they did not go to doctors because they couldn't stand the sight of blood, or smells, or injections. Whereas the patient with complete verbal denial was apt to be concerned with ethical principles, the paranoid person sought perfection more through physical attributes, particularly those relating to physical appearance, masculinity and femininity, cleanliness, and particular food and bowel habits. He was much more apt to react in situations with physical displays of force and violence.

## *Confabulation*

The negation of illness is commonly accompanied by confabulations and delusions (see footnote, p. 968). Many of these are seemingly designed to amplify the denial, minimize the traumatic implication of the illness, and explain away the manifestations. Thus the fact of being in the hospital is ascribed to "visiting a sick friend," "a run-down condition," or "a check-up." A man who had shot himself through the brain, leaving a spherical skull defect, said that he had "tripped over the cat and hit my head on a golf ball." Other patients, both men and women, said they had come to the hospital to have a baby. Some patients, while admitting the existence of incapacities, told stories of activities transcending their limitations. One of these was a young soldier who, following a head injury, was left with a paraparesis, dysarthric speech, and some intellectual deficit. He admitted this defect but confabulated that he had graduated from automotive engineering school and had been a vocalist in a seventeen-piece band. A number of these stories of the past were in themselves true but were used in a context where they served the purpose of a confabulation.

Other confabulations do not seem to deny illness but, taken in a referential sense, even magnify the disability. Thus one man said he had been blown up in an atomic explosion. Here the confabulation is a metaphorical or allegorical representation of current problems and disabilities. For example, one patient became blind after a craniotomy for a brain tumor. When asked what his main trouble was, he replied "I was slugged and rolled in a blind alley." Another officer had sustained a head injury in Korea when the jeep in which

Downloaded from www.dbraulibrary.org.in

he was riding overturned. He was left with a weakness of his right upper extremity, a mild dysphasia, difficulty in reading, and an inability to write. For many months in the hospital he persisted in a confabulation that he had been an intelligence officer bringing in suspected Communist security risks and had been hit by an enemy shell. He would continue with a long rambling account of having written everything down so that any jury in its right senses would be sure to convict, and how "red" the suspects were. In the story the terms "intelligence," "writing," "security," and the homonyms "read" and "red" came up repeatedly. When it was appreciated that the patient was talking about his own problems of intelligence, security, reading, and writing, the importance of including these seemingly irrelevant details became apparent.

Another aspect of confabulation is that it identifies the patient with significant cultural values of his experience. Like explicit denial of illness, it is a means of establishing a relatedness in the environment whereby the patient derives a feeling of reality and being, and avoids isolation and nothingness. For example, in a military hospital, paratroopers who have sustained head injuries in automobile accidents frequently admit the injury but confabulate that they have been hurt while jumping. Personality study of these subjects indicated that their feelings of esteem and belonging had derived mainly from membership in the paratrooper group. A confabulation such as "the parachute got fouled up" not only symbolizes the patient's predicament but gives him a sense of identity.

Some confabulations, such as the ones about the Communist spies and the atomic explosion, may seem bizarre, yet, from the standpoint of language, this content is highly conventional and popular. This aspect is borne out by the generally banal and colloquial character of the language. Thus, a patient with a subarachnoid hemorrhage said he had gotten a headache while "waiting for a streetcar." After a craniotomy another woman claimed that she had been "hit by a Mack truck." Such clichés are important forms of socially organized language. One of the most amazing features of language is that an element which in one context is catastrophic may be a form of adaptation to stress in another.

### CONFABULATION ABOUT CHILDREN

A particularly interesting illustration of the correlation of the content of confabulations and delusions* and patterns of social relatedness is found in stories concerning children. The patient may talk about nonexistent, or "phantom" children, or actual children. Frequently they are said to engage in the same activities or have the same disease or injury that the patient himself has. Or patients talk of their own fears and feelings of helplessness in terms of a "child" being mistreated, neglected, raped, kidnaped, or killed. A twenty-one-year-old soldier had suffered a head injury which had left him with a moderate weakness of both legs. Throughout a long hospitalization he had a great deal of difficulty with the doctors and nurses, who, he felt, rejected him. Following a period of marked aggrievement, he was a week AWOL from a week-end pass. On his return he gave as the reason for his tardiness a story about his daughter (the patient was childless) having contracted poliomyelitis. He described with a great show of feeling how his "daughter," aged three, had developed paralysis of her legs. He said he had taken her from hospital to hospital, and all of them had turned the child away, thus expressing his own aggrieved feelings.

It should be pointed out here that in ascribing an injury to a child or, for that matter, to anyone else, the patient is not releasing "hostility" or gratifying a previously unfulfilled wish. Nor is he now expressing long-repressed feelings toward some sibling. Rather, he is talking about himself and his problems in language which has particular meaning for him. People who confabulate about children are those who have formed their most significant social relationships either by taking the role of a child or placing others in it. Some are characterized by informants as "childish," "immature," and "dependent," while others are described as

* Confabulations are differentiated from delusions in that the confabulation is limited in respect to time, place, and person, whereas a delusion, in this sense, is timeless and limitless.

Downloaded from www.brainbehavior.com

having been dominating, controlling, worrisome parents, wrapped up in their children's lives. They seemed to have achieved comparatively little sense of personal identity in any transaction other than that constituting a stereotyped, highly conventionalized parent-child relationship. Many of these patients seemed to have lived for the symbolic forms themselves, to perform through themselves or others the ritual of the "good" or "bad" child.

### Disorientation for Place and Time

The forms of denial and confabulation that have been described are regularly accompanied by patterns of disorientation for place and time. The work of Paterson and Zangwill has shown that disorientation is not simply a manifestation of confusion but occurs in orderly patterns. In the acute stage of brain injury, verbal identification may occur. Here the patient says that he is in X hospital *and* some other place, such as an apartment. In the stage of misnaming, the patient uses euphemisms as "a prison" or "repair shop" or "convalescent home" or "restaurant" or calls the hospital by the name of some existing or nonexistent hospital. When an existing hospital is used, it is generally a hospital close to the patient's home or one where he has previously been for some comparatively trivial illness. Sometimes the name given to the hospital symbolizes the patient's feelings about his illness and the hospital. A woman with a tracheotomy and a paraparesis said she was in the "Fresh Air Roller Skating Academy," while a woman studied at Mount Sinai referred to the hospital as "Mount Cyanide." Almost invariably, the name given bears some similarity to the actual place as "Mount Sinai Restaurant," "Mount Morris Hospital," or "Mount Sinus Hospital."

In the pattern of displacement, the patient names the hospital correctly but places it elsewhere. The erroneous location is usually close to his home or place of business. One man put the hospital in a town where he had lived ten years earlier. Some patients name and locate the hospital properly but greatly reduce the distance between the hospital and home. A young soldier insisted that the hospital in Washington was only ten miles from his home in Detroit. Some patients could point out the location of hospital and home on a map but still condensed the distance. It is not infrequent for the patient to be oriented in one context but not in another. For example, a young soldier from Detroit, on the day that he was expecting a visit from his family, was able to give the air-line mileage and their expected time of arrival while maintaining that he was only ten miles from home.

The confabulated journey commonly appears after the patient, in the course of recovery from a brain injury, has apparently attained full orientation. This is a statement by the patient that he has taken a trip from the hospital, as having gone home the night before or having gone shopping. One man, a patient at Mount Sinai, told of how he had spent the morning "skiing with fifty beautiful girls at *Mount* Holyoke College."

Disorientation for time of day and/or date appears at some stage of illness in patients who show disorientation for place. In disorientation for time, the patient uses his own experiences as the index of time of day; the patient "confuses" night and day and morning, afternoon, and evening. In a control series of patients hospitalized for diseases not involving the central nervous system, tested in a similar fashion, patients might make mistakes of several hours, but the errors never extended across a mealtime. Disorientation for time of day was commonly observed after a patient had been sleeping. A boy, after awakening from an afternoon nap, was indignant at getting spaghetti for breakfast. Another patient tested in the morning insisted it was afternoon because "I was up all morning." Whereas another invariably gave the time as 7:00 P.M. "because that's when my daughter comes to see me." When patients were first tested, they were not permitted to look at a large wall clock in the ward. However, it was found that when temporal disorientation was present, it made little or no difference whether or not the patient could see the clock. Even though he could read it correctly, he would persist in his error. One patient when approached in the morning would be well oriented for time. In the after-

Downloaded from www.pbookshop.com

noon he would name the hour accurately but claim it was morning because "I was sleeping" (during rest hour) "and I never nap in the afternoon." It is evident that the patient has an altered pattern of interaction in the temporally defined aspects of the environment. He uses his own experiences as the index of time.

In disorientation for date the patient usually gives as the date a time in the past antedating the time of his illness. If he gives the month correctly, he is apt to name the wrong year. There, he is particularly apt to make a mistake in one digit as 1948 for 1958, or 1957 for 1958. There seems to be just enough of a mistake to make the answer wrong.

It is important to regard these types of verbal disorientation as symbolic patterns rather than as absolute defects in memory or perception. Disorientation for place should be distinguished from visual-spatial agnosia and from topographical disorientation where the patient has difficulty in finding his way about and cannot make a geographical plan. Similarly, disorientation for time should be separated from the ability to tell time. Perceptual and memory deficits may be present in the absence of disorientation, or disorientation may persist after disturbances in retention are no longer present. The persistence of disorientation, even though the data for correct orientation are readily available, is striking. One officer, for example, regularly crossed out the Walter Reed inscription on his stationery and substituted Fort Sill, a post where he had served for several years. The disoriented patient usually gives his faulty answer promptly when asked, while the patient who proves to be oriented asks questions to define the situation, such as did the examiner mean the room, the building, or the hospital. Actually, we feel a patient can be disoriented only if he *knows*, at some level of his thinking, where he is. As in confabulation and humor, the experiential symbol takes on meaning only against the background of the referential aspects.

In cases of brain injury where there is progressive clinical improvement, the way in which the same symbolic element is integrated into various patterns may be observed. A patient, on admission to Walter Reed, said he was in "Coolidge Memorial Hospital" which he located in Georgia. ("Coolidge Memorial" was a condensation of Cooley-Dickinson Hospital and Coolidge Memorial Bridge, places near his home while he had been stationed in Georgia.) In the stages of reorientation he successively located "Coolidge Memorial" in North Carolina, Virginia, and Washington, D.C. He then located the hospital accurately but called it "Walter Reed Memorial." He introduced the correct name by remarking "They say it's Walter Reed." He then stated that he had been told that a friend who had been injured in the accident had been in "Coolidge Memorial." This was given up but, through the remainder of his hospital stay, he maintained that he had a "feeling that there must be a Coolidge Memorial Hospital somewhere."

### *Paraphasia or Metonymy*

This symbolic pattern involves an altered mode of interaction in the environment in terms of misnaming objects. The patient selects single aspects of the structure or function on which he bases his designation for the entire object. Thus a hypodermic needle is called a "tiepin," a head bandage a "turban," and a wheel chair a "spinning wheel." The misnamed objects are those which related to the patient's particular problems, mainly those of illness and hospitalization. Thus errors are made when he is shown a syringe, straw, tongue blade, or thermometer. Objects of comparable complexity and familiarity which do not concern illness are much less frequently misdesignated. Sometimes the name assigned to an object expresses the patient's feelings about himself, as in the case of an electronics engineer who had sustained a severe head injury and called an electric light bulb, an object in the non-illness-connected category, a "used-up radio tube." Paraphasic misnaming may be elicited during formal testing and in conversation. Ordinarily, the patient does not seem aware of any error and repeats it despite correction.

Closely related to paraphasia is the phenomenon in which the patient talks about himself in the description of some object.

Downloaded from www.dbraulibrary.org.in

People injured, say, in an automobile accident, when asked what happened to them, tell how the car "only got a scratch" or how the car "got its top stove in." One man, apparently minimizing his accident, said he had fallen out of a "small aeroplane." The principles exemplified in disorientation and paraphasia may be applied to certain neologisms and condensations. One man referred to the hospital as a "curable place"; a woman, following a craniotomy, mentioned her "aching watch." A patient who later became aware of his subdural hematoma and memory loss would talk of his "embree" (hemorrhage plus memory).

## *Reduplication*

### Reduplication for Place

In confabulation, disorientation, and paraphasia, the designation of the event, place, time, or object has both referential and experiential aspects, whereas in reduplication these aspects are separated. In reduplication for place, the patient names and locates the hospital correctly but states that there is another place of the same or similar name to the one that actually exists. The patient says that there are two Walter Reed Hospitals. Although the "two" hospitals may have the same name and even the same personnel, there is usually some difference that is significant in terms of the patient's problems. For example, the patient may say that the "extra" hospital is close to his home, is a "convalescent place," or differs from the "original" only in that no surgical operations are performed.

### Temporal Reduplication

In reduplication for time or event, the patient states that an event or experience of the present has also occurred in the past. He may state that he has met the doctor previously in his home town or that he has gone to school with the nurse. A patient awaiting a craniotomy for an intracranial aneurysm insisted that he had been in the hospital a year before and had had the identical operation performed. It is generally impossible to separate temporal reduplication from reduplication for person, nor is it important to do so aside from purposes of definition. Patients with reduplication are apt to show it for place as well as time and person.

### Reduplication for Person

In reduplication for person there is, in addition to an existing person, another of the same or similar identity, or an actual person is assigned another role.

A patient claimed that on alternate days his nurse's mother took care of him. A patient, recovering from encephalitis and concerned with her intellectual ability, claimed that the doctor had been her instructor in college. Another example of reduplication is that of a mediocre former pugilist who misidentified a decrepit elderly patient as a champion fighter. The person who is chosen as the subject for misidentification may be one who has an identity or disability comparable to that of the patient himself and/or one whose identity must be denied, as a doctor. Another factor, of course, is that the misidentified person looks somewhat like the person he is purported to be. It is of interest that the patient usually picks out only one or two people to serve as vehicles for the reduplicative misidentification or delusion.

The introduction of a fictitious person is another form of reduplication. In describing the "extra" person the patient is, in effect, talking about himself, as has been illustrated already in discussing confabulations about children. In telling of an automobile accident, the patient adds an extra person to those actually involved. He may say that this person was uninjured or that he was killed. Often the same delusion or misidentification in which a patient alludes to himself at the stage of greatest impairment of brain function is applied to someone else in the course of recovery. One man, who was markedly withdrawn and depressed, first said that he had been killed in an accident and later claimed that his brother was dead. Patients also talk of things happening to someone else which, even though true, are used in a context which expresses feelings about themselves. Thus a woman with a hemianopsia, when asked about her condition, told of how her son had lost his eye in a hunting accident. The "extra" event, person, or place is a condensed symbol of a type of relationship in the

Downloaded from www.brainlibrary.org

environment whereby the patient gains a sense of identity and talks about his problems.

The content of the reduplicative delusion can be correlated with past experience. For example, a woman, the mother of twins, a boy and a girl, claimed that she had two sons, Bill (the name of her son) and "Willie," in addition to the daughter. She had been a woman with a good deal of drive and ambition for a career, which was unrealized because of her household and family responsibilities. She had hoped to see them realized in her son and had been greatly disappointed when he rebelled at her rather controlling attitude. She had been particularly hurt when he had changed his name. In the reduplicative delusion she stated that she hadn't seen "Willie" since Christmas (the onset of her illness) but that she had heard that he was convalescing from some illness. She mentioned that "Willie's" clothes were home in the closet and that "Willie" had not changed his name, in contrast to Bill. When the course of her illness (cerebral metastases) took an obvious downward trend, she expressed great concern about "Willie," saying that he must be very sick. The patient who expressed the idea that his nurse's mother took care of him on alternate days had previously achieved identity through a mother-daughter relationship. He was described as very doting toward, partial to, and suspicious of his daughter, dependent and demanding with his wife, and promiscuous with other women. As his illness progressed, he became increasingly physically dependent on his wife to bathe and feed him and developed the delusion that his daughter had been raped by a homosexual.

### Reduplication of Body Parts

In this form of reduplication the patient says that there are one or more additional members of the body, such as two heads, three arms, or four legs. The portion of the body that is reduplicated is invariably one that is disabled in some fashion. A patient who says he has an extra left arm usually has a left hemiplegia, the one who says he has four legs will have weakness or some other incapacity of the lower limbs, and patients with two or more heads have had a head injury or craniotomy. Also, reduplication for parts of the body is associated with some other form of reduplication, as for time, place, or person. The patient may say that the "extra" limb has nothing the matter with it or that the "extra" head has not had an operation. As in the other forms of reduplication, the phantom member may symbolize an interpersonal relationship. A nurse with a hemiplegia said that the "extra" arm belonged to her friend, also a nurse. She described the arm as "heavier, thicker, and darker" than her own and "hard-working and well-used." The friend was a large, physically powerful woman who had literally taken care of the patient for many years.

### Déjà Vu Phenomenon

This may be regarded as a transient form of temporal reduplication, and the principles of reduplication may be applied to some understanding of both *déjà vu* and the closely associated panoramic memory. Repeated *déjà vu* experiences may replace reduplication when there is improvement in brain function and the new neural milieu will not sustain the enduring form. In the *déjà vu* phenomenon, which may occur as a component of a convulsive seizure and in neurologically normal people, there is a feeling that the present experience has occurred before. In the panoramic memory the person pictures a scene of his past life, usually in vivid detail. They have in common the heightened sense of reality and the exquisite feeling of familiarity. One patient had, as an aura of her seizure, the feeling of lying in her room as a child, listening to the flies buzz. Another, prior to becoming unconscious, would be "reminded" that he had seen the same object long ago. Another patient would state that the scene that he was observing was one that he had also experienced back home, but with certain differences. These differences appeared to symbolize many of his present problems. He had had two unsuccessful operations to relieve his seizures and was awaiting a third with anxiety. He would look at a two-story house on the hospital grounds and state that he had seen the exact house at home, but with three stories. Shortly after the second operation he had a seizure in which he recalled

Downloaded from www.dbraulibrary.org.in

a scene in his childhood, but, instead of the road being its usual color, it was purple and red.

### *Amnesia*

Amnesia is not ordinarily considered in terms of symbolic organization but is regarded either as an "organic" memory defect or as a manifestation of repression. Yet a study of a large number of cases of amnesia following head injury shows that it is a form of language in which the patient denies or otherwise represents his problems and expresses a relationship in his environment.

When a patient says that he does not remember his accident or his operation, he is talking about his accident or operation. While no patient who has had a severe head injury remembers the actual impact and generally has some retrograde memory loss, if he is socially related he soon learns what has occurred. When asked what happened to him, he answers appropriately. The amnesic patient, on the other hand, even after he admits the fact of an accident, will preface his answer with "I don't remember but they say . . .," indicating a feeling of noninvolvement.

The amnesia is usually highly selective, patients stating that they could not recall outstanding events of their lives. One young man had been in a car accident in which he had sustained a severe head injury and a radial nerve paralysis. He was a high-school football star and could not remember ever having played football or attending high school. In the amnesia, he expressed concern over his intellectual ability and the ending of his football career. When the amnesia cleared after several weeks these problems were stated in more referential fashion.

In the amnesia the patient not only talks of his problems but talks about them in the symbols that have been his main sources of social relatedness and personal identity. Thus, soldiers may not remember having been in the Army. One officer had a selective amnesia for having gone to West Point. In reviewing the background of such patients, one finds that they are usually career soldiers whose main bases of prestige and sense of belonging are tied up with military service. Frequently a patient will volunteer an amnesia which, from a referential standpoint, may be quite trivial. A sergeant complained that although he knew his grade of sergeant he could not remember actually receiving it. One patient volunteered that he was unable to recall who had won last year's batting championship. The amnesic content, however, becomes significant when it is learned that, prior to his injury, the patient had hoped to become a professional ball player.

The last thing that amnesic patients say that they remember is just as significant as the amnesia itself. This "last memory" may be fictitious or true, but in either case it serves to represent the patient's problems and expresses a relatedness. Thus one man who had broken both legs in a parachute jump had as his last memory "standing up in the plane." Others recall "being home." Another, who was confined to a wheel chair because of disabling fracture-dislocation of his hip, recalled "sitting at the foot of a mountain in an old broken-down car." It is of interest that, as the clinical condition improves, the "last memory" changes. Shortly after obtaining crutches this patient had as his last recollection prior to his accident "pulling into a garage and having a clutch repaired."

## ¶ Nonverbal Patterns of Denial

### *Inattention and Withdrawal*

These may be regarded as forms of implicit nonverbal denial which occur under the same conditions of altered brain function as the other symbolic patterns described. Thus, instead of verbally denying paralysis, a patient with a hemiplegia ignores his paralyzed limbs. If ambulatory, he may neglect to place the affected arm in a sleeve or habitually not wear a slipper. Some patients do not look toward the affected side; others disregard the whole side of space, paying no attention to objects or people in one half of a room, and fail to respond to questions when approached from that side of the bed. In eating, patients may

Downloaded from www.brainlibrary.co.in

take food from only one side of a tray. In looking at a picture some patients neglect figures on one side even when, in the case of a hemianopsia, the picture is placed in the functioning visual field. The selective, motivated character of the phenomenon is indicated by the fact that patients never ignore a part of the body that does not have something the matter with it. In some cases the patient does not respond to stimuli over the affected half of the body, giving a picture of hysterical hemianesthesia.

Withdrawal may be regarded as bilateral inattention. It ranges from states of lethargy and sleepiness to the clinical syndrome described by Cairns, Oldfield, Pennybacker, and Whitteridge as akinetic mutism. This is best described by saying that the patient acts dead. He lies mute, often with closed eyes, does not respond to questions or stimuli, rarely moves, and does not eat. In most patients, however, there is a selectivity of response in which they do not answer questions about hospitalization and illness or reply in a dysarthric fashion, while speaking clearly in other contexts. Others "answer" stressful questions with yawning, coughing, or grimacing. Some patients speak to a relative but not to a doctor. The akinetic state may be interrupted by outbursts of restlessness and violence.

Because of the marked restriction of verbal communication, it is difficult to evaluate other aspects of behavior. The predominant mood, however, is one of depression with some paranoid features. One patient asked her husband if she were dead and if she would be buried.

A review of the premorbid behavior of withdrawn patients indicates that symbols of sleep, death, and violence had been habitual modes of adaptation to stress and important channels of social relatedness. One patient, during the course of a right fronto-temporoparietal glioblastoma, showed akinesis, inattention to a left hemiplegia, pain asymbolia, selective muteness and dysarthric speech, and episodes of violence. He was described as having reacted to difficulties in the past both by becoming depressed and withdrawn and by going into rages in which he would strike people, throw things, and threaten suicide. In answer to the interview question as to how patients acted when they were upset, such answers as "She'd give you the silent treatment" and "He'd never argue, just clam up" were obtained.

Many of these patients had shown an attitude of silent suffering toward illness. One woman had been treated for back trouble and swollen ovaries and, although seemingly in pain, never complained and refused to wear a brace, which had been prescribed. The family felt that she did not complain because she did not want to worry them. When not well, she shut herself in her room. A son had died of poliomyelitis ten years previously, and since then she had not mentioned his name. As a girl, her way of showing resentment had been to lock herself in her room, and when she did this, the family worried that she would commit suicide. Another pattern of adaptation shown by patients in this group was the exhibiting of tragic, ludic,* behavior concerning illness and death. A girl who developed a marked akinetic syndrome had been told as a child that she had heart disease. She was fond of clutching at her chest in a mock attack and, as a nursing student, she terrified her friends by seeming attempts to jump out of windows. Another woman with a severe withdrawal reaction had developed dramatic fears of cancer and tuberculosis and germs.

There is an unusually high incidence of chronic illness in the families of these patients. This is a source of added stress and seems to predispose to the use of the symbolic content described. A soldier who said he had been killed attributed his accident to having been blown up in an atomic explosion. In an interview with his mother, she described him as a very quiet boy with rare episodes of violent temper; then she dwelt at length on how devoted he had been to her through her many illnesses. She detailed how he was almost stillborn and subsequently listed a blood clot on her heart, numerous operations for female

* This term has been used by Jean Piaget to describe the play, imitative, and pretending aspects of behavior in children.

Downloaded from www.dbraylibrary.org.in

trouble, a lung abscess, coughing up blood, etc. She went on to tell how a doctor had said, following a previous injury, that if her son ever got another blow on his head it would kill him. Her conversation was sprinkled with expressions like "worry myself to death" and "fit to kill me." Here the patterns of social interaction whereby the patient derived his concept of self seems to have been composed predominantly of symbolic representations of death and violence.

These symbols are used in a way comparable to those of funerals and mourning customs where the black dress, slow step, and hushed voice serve as imitations of death. Symbols of violent death and suffering in religious ritual furnish the content of a pattern of interaction in the environment in which the individual derives his feelings of truth, faith, and belief. The greater the stress, the more intense may be the feeling. That symbols of death and destruction may serve as modes of adaptation to stress has long been recognized. Aristotle in his account of tragedy said that one may be purged of feelings of fear by the imitation of some deed of horror.

## *Mood Changes*

The behavior of patients with euphoric and paranoid attitudes will be described from the standpoint of symbolic adaptation. Changes in mood also involve other patterns of interaction such as those relating to food, sex, money, and behavior best described as puerile.

### Euphoric and Paranoid States

A euphoric response appears to be an implicit form of denial of illness when the patient responds to a question about his condition with a laugh or a joke. Some patients show hypomanic behavior, with much clowning and horseplay. At times it is difficult to separate euphoric from paranoid behavior (or, for that matter, from depression), and it is, in part, a matter of the observer's own involvement in the situation as to whether the content is euphoric or paranoid and a laugh is a gay or sarcastic one. Thus, one patient on entering the hospital claimed that he had been beaten up by his wife. Behavior is often melodramatic in a comic or tragic fashion, and the adjective "ludic" quite aptly describes these aspects. Following a craniotomy, for example, a patient expressed no concern as to its outcome but went into an amusing (?) denunciation of the financial rapacity of his neurosurgeon. Dramatic expressions of resentment and affection were common and often intermingled. In one sense this behavior is contradictory or a manifestation of ambivalent feelings. From the standpoint of adaptation to stress, it is a form of implicit denial and a means of gaining a sense of identity through the selectively organized interaction. Thus, the patient who denounced the surgeon had himself been a highly successful businessman for whom money had been the main source of prestige and focus of social relationships.

There is also a great deal of physical identification with people, particularly doctors and nurses. Patients poll-parrot words and imitate gestures. They may answer the greeting "How do you feel?" with "How do *you* feel?" While being examined a patient may take up the reflex hammer or the pin and make an imitative gesture.

There seems to be a great need for physical contact. Patients insisted on being handled, fondled, and touched in some way. There was much noisy, puerile behavior and exposure and conspicuous incontinence of urine and feces. Patients might call for a urinal, then wet the bed before it arrived, or use it and spill the contents, followed by the patient being changed, handled, powdered, etc. In the verbal sphere many of these patients express confabulations and delusions about children. One man maintained that he could get well if he could get a certain laxative not in the hospital formulary. When, after much entreaty, it was obtained, he refused to take it. Others interact in terms of food, developing tremendous appetites or becoming finicky and demanding in their eating habits. Complaints of pain are common, in contrast to the behavior of patients with explicit denial or inattention and withdrawal. This group of patients are a trial

Downloaded from www.dbraulibrary.org.in

to the nursing staff and are much more apt to be considered disturbed and psychotic than are those with other forms of adaptation.

### SEXUAL BEHAVIOR

The alterations in sexual behavior prominent in this group have many ludic aspects. Patients charge that they are being kept in the hospital because someone has immoral sexual designs on them. When questioned about disabilities, patients respond with sexual banter. Illness is attributed to too much, too little, or a certain type of sexual activity. The manner in which altered sexual behavior serves as a mode of adaptation may be illustrated in the case of a woman who received a course of electric convulsive therapy for pain in her neck associated with the neck-torsion deformity of dystonia musculorum deformans. On admission to the hospital, she seemed anxious and secluded herself because she was ashamed of her bizarre posture and gait. After the seventh treatment she walked about openly stating that people were looking at her because they were sexually interested. She charged that some sailors had come into her room, drugged her, then knocked her on the head to take advantage of her sexually (shock treatments were preceded by an intravenous injection of Amytal Sodium). She also developed a reduplicative delusion about another patient who had a plaster cervical collar and expressed the idea that this woman "needed a boy friend to straighten her out."

Patients in this group had previously shown certain habitual patterns of social relatedness which differed from those of people who, under comparable conditions of brain function, expressed verbal denial or were withdrawn and depressed. The outstanding characteristic appeared to be the great degree of emotional identification with other people. Such adjectives as "affectionate," "excitable," "sympathetic," "sensitive," "jealous," "worrisome," "shy," and "dependent" were commonly used by relatives. This, of course, does not mean that the patient was "dependent" in any absolute sense; rather, this was a term in which the relative structured the relationship. Also, the patient's behavior seemed to conform to the cultural stereotype we have of dependence. As a group, they seem to have been very responsive to the attitudes of other people, with a need for tangible evidence that they were liked or esteemed.

Great importance was attached to the physical aspects of expression and appearance. Laughter and tears and other conventional representations of happiness and sorrow were common. One young man had grown up feeling liked by people only if he appeared happy, cheerful, and unworried. There was much preoccupation with looks. One man, for example, was fond of saying that if he were taller and had good teeth he would own the world. Many of the patients seem to have been very conscious of smells and tastes.

The use of particular symbolic content, such as sex, food, and money, under conditions of altered brain function can be correlated with the way these symbols had been integrated into patterns of social relatedness in the past. For example, patients who showed clinical aberrations in sexual behavior had habitually placed great emphasis on sex. They were described as concerned with sexual attractiveness, flirtatious or prudish, and sensitive to sexual implications in personal relationships. One woman was particularly exhibitionistic and coquettish during her hospitalization. She was a former actress, with many admirers and affairs, and was described as having been vivacious and temperamental. Other patients with similar behavior in the hospital were considered as having been extraordinarily prudish. In all cases the patients conceived their interpersonal relationships in sexual terms.

Another aspect of the social background was the tendency to classify the environment in sexual stereotypes, particularly popular ones of masculinity and femininity. Thus many male patients had felt that to be a man, sexual conquests, or reports of them, were necessary. The fact of belonging to one sex or the other had been regarded as a basis for certain character traits as, 'You can't trust a man." Some women seem to have attributed their problems to the accident of sex or to have blamed some man for them, and it was of interest that they frequently developed delusions about men changing into women.

## ¶ Conditions of Brain Function

The symbolic patterns that have been described were present in enduring fashion in patients with structural brain damage studied clinically, electroencephalographically, and anatomically. In these cases the lesions are those which, by reason of rapid development, central position, diffuseness or multiplicity, or association with increased intracranial pressure or subarachnoid bleeding, produce generalized, usually bilateral, slow-wave electroencephalographic activity. The pathology involves the centrencephalic system rather than any specific cortical area or discrete projection system. Pathological conditions include infiltrating gliogenous and multiple metastatic tumors; acute vascular accidents, particularly with subarachnoid bleeding; cerebral lacerations; and toxic-inflammatory and disturbed metabolic processes. While any lesion which displaces the ventricular system may be associated with enduring denial of the types described, the optimum milieu is furnished by lesions of the diencephalon and midbrain and aneurysms of the circle of Willis. Such patients manifest the various denial syndromes most clearly because they do not have the gross defects in perception and symbol formation, such as aphasia, found in cases with cortical damage. The requisite neural milieu is also provided by bilateral prefrontal lobotomy and the effects of usually four or five electroshock convulsions.

Despite the presence of this pathology, lesions of the centrencephalic system do not cause denial per se. Other patients with comparable lesions showed little change in symbolic expression, according to the methods of study used. Nor can one predict the clinical syndrome on the basis of a knowledge of the pathology and the electroencephalographic record alone. In individual cases, however, the correlation of changes in behavior with the development of diffuse slow-wave electroencephalographic rhythms is often striking. In the progression of a brain tumor, for example, during the stage where the electroencephalographic record is normal or focally abnormal, a patient may be anxious and worried about his illness. With the appearance of a diffusely slow-wave rhythm, he becomes euphoric or offers a bland denial of his problems.

When recovery from the brain injury is rapid, as in instances of encephalitis, trauma, subarachnoid hemorrhage, or the successful removal of a benign tumor, a clinical picture comparable to the abstinence syndrome in drug withdrawal may appear. Here the patient becomes extremely agitated, may hallucinate, and becomes depressed. There is, thus, the paradox of an improvement of brain function and an apparent worsening of the clinical state.

In most cases, the abstinence reaction does not appear, but instead confabulations and delusions are superseded by other symbolic patterns. These include accounts of the illness of other people and references to their own condition in terms of what doctors, nurses, or their relatives did or said. Patients may become obsessively preoccupied with trivial ailments, past or present. Vows and resolutions about the future are common in this stage. Some patients use humor at the points in the interview where disorientation or confabulation was formerly elicited. When these patterns of language supervene, clinical anxiety does not appear.

It is evident that there are many types of explicit denial, disorientation, confabulation, paraphasia, amnesia, withdrawal, ludic manifestations, and altered sexual behavior that occur as responses to stress at various levels of brain function. In barbiturate intoxication the patients deny staggering gait and dysarthric speech. In anoxia there is denial of failing capacities, while states of euphoric denial are seen following cortisone administration. People with normal brain function deny the existence of cancer, venereal infection, or pregnancy, while the Christian Scientist denies the very existence of disease. Whatever the level of brain function, there is a relationship among the degree of stress, the situation in which the behavior is being studied, and the personality or social background.

## ¶ Applications

The formulations that have been made may be applied in many areas of neurology and

download from www.freeclinicallibrary.com

psychiatry. They are most relevant to the relationship of behavior to changes in brain function, where they indicate the need for study not only along anatomic-physiological lines but in psychodynamic and social and cultural contexts. A great deal of current thinking equates certain aspects of behavior with functions of the brain more or less localized in particular areas, either anatomically defined or distinguished by physiologically measurable properties. For example, patients with explicit denial or euphoric responses are commonly regarded as showing "loss of insight," and the lesion is usually localized in the frontal lobes. The implication is that there is a function, "insight," residual in the frontal lobes. Such a "function" is what Lashley has termed a pedagogical abstraction and is simply a version of the patient's behavior. It completely ignores the highly selective and motivated character of the behavior and the fact that the patient may show excellent judgment and insight in areas that do not concern his problems. Similarly, explanations for altered sexual behavior have been that the brain lesion has caused a "release of repression" or a "loss of moral sense." Here, one confuses socially inherited concepts with physiological functions. A review of some of the theories of anosognosia points up the need for a multifactorial approach.

## *Theories of Anosognosia*

In the literature, anosognosia has been generally regarded as a disturbance of body scheme. This is conceived as a three-dimensional image of the body represented in one parietal lobe or its connections. When this localized region is destroyed, the patient becomes unaware of the existence of his limbs or those parts of the body which are represented, apparently in a manner comparable to cortical motor and sensory representation. We have found the body-scheme hypotheses inadequate in many respects. First, anosognosia, as with hemiplegia or blindness, does not occur as a unitary phenomenon but in association with other changes in symbolic organization such as disorientation or reduplication. Patients deny not only physical disabilities but *anything* that they feel is a problem, and one would have to construct an incredible mosaic of functions in which parts of the body, their diseases, and various traumatic situations would be represented. No matter where the lesion is placed, many patients with such brain damage, and even with hemispherectomy, do not show either explicit denial or inattention. The hypothesis quite ignores the role of premorbid personality factors.

A more psychodynamic approach involving motivational factors has been taken by others. Goldstein pointed out that denial in itself is a psychological mechanism present in normal persons. He felt that the greater the defect, the greater the defense. Sandifer stressed the motivation of the patient to be well and interpreted denial as a means of avoiding a "catastrophic reaction." This view equates denial with a psychophysiological process or drive rather than considering it as a form of symbolic organization and does not take up the cultural, social aspects of motivation.

## *Prefrontal Lobotomy*

The observations are also applicable to a hypothesis of the action of somatic therapies, particularly prefrontal lobotomy, and the shock therapies. These have in common the factors of added stress and altered brain function. Following bilateral prefrontal lobotomy the matter of success or failure seems to be one of the type and duration of the symbolic reorganization that occurs. If the patient explicitly denies his operation and the problems that led to it, or if he speaks of them in a euphoric fashion, then the operation is regarded as "successful." If his adaptation is in the form of lethargy and withdrawal, then it is "unsuccessful."

## *Electric Shock Treatment*

In electric shock treatment, therapeutic improvement likewise depends on the creation of an altered milieu of brain function, in which new patterns of symbolic organization occur. It should be remembered that "therapeutic improvement" is only one category of behavior that can be correlated with other aspects. In

Downloaded from www.dbraulibrary.org.in

one series of patients treated with electric shock treatment for intractable pain, symptomatic relief, that is, denial of, cessation of complaints of, and apparent indifference to pain, occurred only in those subjects who showed patterns of disorientation, paraphasia, and reduplication.

In a group given electric shock treatment for psychiatric illness, it was found that, after four to six treatments, the intravenous injection of Amytal Sodium elicited patterns of denial and disorientation in the improved patients, while in the unimproved group such a response rarely occurred even after many more treatments. In ordinary clinical interviews the patients rated as improved showed such language patterns as denial, reduplication, changes in tense and person, clichés, and stereotyped expressions and used evasion and withdrawal to a much greater extent than an unimproved group. Studies of the relationship of personality and social factors to therapeutic improvement are in progress.

The scope of this chapter does not permit a discussion of the symbolic patterns associated with the most common type of altered brain function—sleep. Nor is there space to consider how children use confabulation, paraphasia, reduplication, and other types of symbolic organization as modes of adaptation to stress, or to discuss the role of these symbolic patterns in forced social isolation such as "brain washing." It is hoped, however, that the data will call attention to the need for new viewpoints in psychiatry in the study of symbolic processes as a whole.

CHAPTER 49

# LANGUAGE AND PAIN

Thomas S. Szasz

Downloaded from www.dbraulibrary.org.in

NOWADAYS, WHEN PSYCHIATRISTS address themselves to problems which relate to the body, they speak of the "psysomatic aspects" of the particular phenomenon. Thus, it has become conventional to speak and write about the psychosomatic aspects of cardiovascular dysfunctions, of peptic ulcer, or of pain. The terminology of "psychosomatics" is used—and I wish to underscore this since it has, apparently, not been appreciated—in psychiatric considerations of bodily (or so-called "somatic") symptoms. Contrariwise, psychiatric considerations of nonbodily ("mental") symptoms, such as phobias or character disorders, are never referred to with the adjective "psychosomatic." In order to maintain symmetry, the medical study of mental symptoms should also be labeled "psychosomatic." An examination of the present state of affairs in medicine and psychiatry will show, however, that this is not the case. In the first place, there is no such thing as a medical study of a phobia or a character disorder, and for good reasons, as will be discussed later. Secondly, while a medical inquiry into other (overtly) mental symptoms—such as hallucination, depression, elation, etc.—is possible and extant, the approach is not usually referred to as "psychosomatic."

## ¶ The Problem of Pain in Medicine and Psychiatry

### *"Psychosomatic Medicine": the Mixed Language*

As I have thought about the problem of pain, it has become increasingly apparent to me that the expression "psychosomatic medicine"—and the concepts so denoted—are a hindrance rather than a help to us.[8] While it is true that I myself have used this terminology in years past, I now believe that we can do better without it. The reasons for this point of view are set forth and documented in detail in my book *Pain and Pleasure*.[10] They are, in the main, neither novel nor original, and I shall state them here only briefly.

My thesis is simply that medicine and psychiatry possess separate objects of study and utilize different methods of observation. Moreover, their concepts, hypotheses, and inferences

are expressed in different languages. They thus complement one another but are otherwise unrelated and, very likely, unrelatable. Accordingly, we may regard medicine as one language, psychiatry as another, and psychosomatic medicine as a mixture of two (unrelated) languages.[12] Using this metaphor (although this is much *more* than a metaphor), it is readily apparent that a mixture of, say, English and Hungarian would result in a mixed language that would be no improvement on either, and would, indeed, be less useful for almost any conceivable purpose than either one alone.

Some workers, well aware of the methodological differences between medicine and psychiatry, still consider the "psychosomatic approach" a useful one, understanding thereby a separate use of both methods and a combination, in the mind of the observer, of what has been learned. I do not see how anyone could object to this conception of psychosomatic medicine. At the same time, I think it should prove to be extremely difficult, if not impossible, for anyone to put this conception to actual use in a clinical situation. For, when faced with a patient or professional colleague, one is usually placed in the position of being addressed in either one or the other idiom. One must therefore either respond in the same language, or else one may choose to make the language in which one has been addressed explicit (that is, make a metacommunication). Thus one may raise the question of its possible inappropriateness for the problem at hand. To illustrate: An internist, confronted by a hypochondriacal patient whose body on physical examination appears to be healthy, may respond in one of the following ways. First, adhering to the idiom in which he was addressed, he might say that he could not find any bodily disease. (The patient may, of course, persist in his habitual language and proceed to consult another physician.) Secondly, the physician may add to the previous statement by suggesting that there may be some other, nonbodily (personal) trouble in which the patient finds himself and about which he expresses himself in this (hypochondriacal) way. (We are not concerned now with the patient's possible responses to this communication, nor with certain other communications which the physician might make in this situation.) The latter example illustrates a metacommunication, that is, it is a communication *about* the patient's communication (to the physician).

Among the several alternatives from which the physician might choose in such a situation, there is one other response worthy of comment. This is the response which is made in an idiom other than that in which the physician was addressed. As an example, the physician might say something like this to a patient who is worried about hypertension: "Well, your blood pressure is a little bit high, but I do not think it is important. I think maybe what worries you is . . . (whatever it may be) your job, wife, etc. . . ." The psychosomatic approach currently in vogue seems to me to predispose to this particular type of patient-physician dialogue. Switching and mixing languages is usually (though certainly not always) undesirable for both theoretical clarity and therapeutic practice. I shall have more to say about this subject in connection with its specific bearing on the problem of pain.

## *The Language of Medicine*

Medicine, as I use this term in this essay, denotes the science and practical application of various disciplines which use the physicochemical method. The object of these disciplines is the body as a physical "thing" or "machine." This can be contrasted (not, however, for purposes of praise or condemnation!) with the psychiatric frame of reference in which the object of study is man as "person" or social being. One of the most eloquent exponents of the point of view to which I subscribe is J. H. Woodger, to whose book, *Biology and Language*,[11] I refer the interested reader for further details. Following a differentiation between the physical and psychological sciences and languages, Woodger, in fact, suggested that each of these are themselves mixed languages and may be subdivided further as follows:

Returning after these explanations to our original theme, it will, I think, be clear that we have

Downloaded from www.chiro.org

to deal not with two languages but with *four*: first, the language of the physical sciences which speaks exclusively of physical objects; second, the language of sensible objects. The statement that this yellow sensible object is more orange than that one would be an example of a statement belonging to this language. Third, we have the person language, to which such statements as "Tom loves Mary," "Tom is trying to remember his telephone number," belong. Fourth, the community language. By way of example, I may quote the opening paragraph of Tolstoy's *Anna Karenina*: "All happy families resemble one another. Each unhappy family is unhappy in its own way." That is a possible zero-level statement in the theory of families or medical psychology. To this of course belong statements in the theory of government and of law. Most of the statements in our daily newspapers belong to person language or to community language or to both. Now in a natural language like English all these languages are hopelessly muddled up. The first is the most easily sorted out, although its syntax and semantics are by no means so well known that it is impossible to talk nonsense in it without being found out. But with the others there is chaos (Woodger,[11] p. 270).

We have trouble enough in the languages of medicine and psychiatry. In "psychosomatic medicine," the chaos of natural English is augmented and glorified. But let us focus our attention on medicine. The language of medicine is comprised of the first two languages listed by Woodger. It deals (1) with physical objects, for example the consolidated lung of pneumonia, and (2) with sensible objects, for example "physical pain" (namely, "It hurts more here—in the right lower quadrant of the abdomen over an inflamed appendix, than it does there—say, in the left flank"). The therapeutic methods used in medicine are likewise physical or chemical, such as surgical procedures or chemical agents.

The word "pain" is used as a noun or an adjective in the language of medicine. We may ask how it is used and what is its meaning. A detailed exposition of its many meanings is an important part of the study of medicine, especially of anatomy, physiology, and neurology, but we shall not be concerned with that subject in this essay. We shall have to be satisfied with a few general comments which call attention to certain characteristic features of the use of the word "pain" in the language of medicine. These characteristics are the following:

1. Pain is a sensation. By this it is meant that there is a relatively constant and predictable relationship between sensory input, or stimulus, and the resultant pain sensation which it is thought to invoke. For example, a burn, a fractured ankle, or a ruptured appendix are all regarded as causing pain essentially irrespective of the sort of person who experiences these injuries.

2. The structure to which pain points as a referent is the body as a physicochemical machine. This statement is, in part, redundant, inasmuch as all sensations refer, by definition, to the body (in the sense stated). It is worth while to make this explicit in this form, however, because it underscores the fact that the word "body" here denotes a public or physical object (versus the patient's concept of his body or a fear of its injury).

3. The intensity or reality of the pain is verifiable by the observations of physicians (or other examiners). This notion is inherent in the usage as described in (1) and (2). In other words, the patient's complaint of pain is checked by the physician on the basis of his examination of the patient. If he finds no structural lesion or dysfunction—and worse, if the pain is not accompanied by its usual physiognomic signs—he may then entertain doubts about whether the patient really has pain. In other words, this matter is viewed on the model of a physical experiment. The patient's assertion of pain is the observation that is to be verified—or falsified—by repetitions of the observation by other observers. The other observers are other physicians. If a lesion is found which is considered consistent with the complaint, the patient's assertion is regarded as having been verified. If no physical disorder is found, the patient's claim to pain is contested. It is regarded as a disproved hypothesis, false and "unreal."

The value of this approach, and of this physicalistic use of the word "pain," is as

Downloaded from www.pdfbooksfree.pk

evident as is the value of the physical method in physics itself. The diagnosis of all painful illnesses of the body rests, in fact, on this method of approach which properly occupies the diagnostician, the neurologist, and the surgeon. Yet, just as the value of this method is clear whenever the physician is confronted by a problem posed by a disordered physico-chemical machine, so the uselessness of it is equally evident in those situations in which the bodily machine is functioning properly.

It may be argued that usually one does not know in advance—that is, before performing the proper physical examinations—whether the body is or is not disordered. This is true. What remains to be emphasized, therefore, is that with those patients in whom the physical studies fail to reveal bodily disease, persistence in the medical mode of inquiry becomes fruitless and cannot be justified—as it usually is—by watchful vigilance for the early signs of an as-yet-undiscovered illness which is about to manifest itself. While we may all have such undiscovered ailments, there is much reason to doubt that this type of (excessive) vigilance is of benefit to the patient. Such vigilance serves primarily the needs of the physician unless, of course, it coincides with certain psychological needs of the patient, as, for example, in cases of hypochondriasis.

## *The Language of Psychiatry*

By psychiatry I refer to what the British call, perhaps a shade more accurately, "medical psychology." These terms denote the science and practical application of those disciplines which use the psychological method and language (in a medical setting). Their object is man as a social being, his development, social identity, self-concept, and his relationships with his fellow men. The idioms appropriate to such discourse are what Woodger aptly called the "person language" and the "community language." According to Woodger[11]

> . . . medical psychology is really a branch of sociology, especially the sociology of families . . . [which] needs no dualistic language in the ordinary sense of that phrase . . . (p. 301).

And further he stated that:

> Words like "psycho-somatic" are only invented to heal a breach which need never have been made. I have maintained that medicine has no need for a dualistic language (in the usual sense) and would be better without one. If we use person language we can see that medicine is involved in the sociology of family life and that the so-called medical psychology deals with problems arising from the difficulties of living together under one roof of persons related by the parental or some derived relation (pp. 317–318).

Other scientists and philosophers (of science) have expressed the difference between physics and psychology in somewhat different terms. All emphasize, however, the need to maintain, as much as possible, homogeneity of language and to avoid jumping—particularly when such jumping is done unwittingly—from one level of abstraction to another. The confusion of languages with their respective metalanguages in the same discourse is, of course, but another form of language mixing.

Russell[8] emphasized the public character of the objects with which physics deals, as for example, the burst of a rocket, in contrast to the private character of psychological data, such as a dream. This distinction is particularly germane to the over-all problem of pain. Medicine (as defined previously) deals with pain only as public datum. I summarized this earlier when I stated that pain denotes a sensation which refers to the body (as a physical object), and which may, further, be verified or falsified by other observers.

We are now in a position to summarize the characteristic features of pain as this word is used (or should be used) in the language of psychology (psychiatry).

1. Pain is an affect. By this it is meant that the personal, including social, characteristics of the individual experiencing pain are regarded as the most important objects of observation (data). For example, even in a case of so-called physical pain, such as usually occurs with a perforated appendix, the experiencing ego's orientation to the body (as a psychological object) is the conceptual framework for the understanding of pain. This point of view adds

Downloaded from www.jstor.org

nothing, of course, to the medical view in the simple everyday occurrence of this phenomenon. In this instance the two pictures, so to speak, overlap completely, and no interesting difference between them is therefore visible. This difference shows up, however, in those much rarer instances in which the patient suffers this catastrophe without pain. A similar but even more dramatic example is that of serious self-mutilation, in which patients remove parts of their bodies without experiencing pain. The medical language fails here completely, and at the same time the value of the psychological language can be vividly demonstrated.

2. The object to which "pain" points as a referent is the body as a psychological object. Instead of "psychological object," one may say "personal object." Using Woodger's example of a statement in person language, "Tom loves Mary," Mary is a personal object for Tom. Mary is therefore a different person (different object) for Tom, who loves her, and for Jim, who does not. Even our everyday notions of psychology take cognizance of this fact. The importance of this otherwise trivial observation lies in the contrast between it and the nondifference—for several observers—of Mary's body as an object of medical study. To sum up, in psychological language, pain denotes a private affect which refers to an equally private object, namely, one's own conception (conscious and otherwise) of one's body.

3. To speak of the "verification" of the pain by other observers is meaningless in this idiom. An affect, or experience in this sense, is a primary private datum and as such can be neither verified nor falsified. William James[5] stated it this way: "Sensations are forced upon us, coming we know not whence. Over their nature, order and quantity we have as good as no control. They are neither true nor false; they simply are. It is only what we say about them, only the names we give them, our theories of their source and nature and remote relations, that may be true or not" (p. 160).

This nonverifiability of pain as an affect has the utmost practical bearing on the use of this word in the communicational pattern between patient and physician, and particularly between patient and psychiatrist.

In this chapter I shall endeavor to present a brief exposition of the psychology of pain, that is, our knowledge concerning pain as private datum, its development, organization, and communication.

## A Psychoanalytic Theory of Pain

### *The Language of Psychoanalysis*

The science of psychoanalysis began under the auspices of nineteenth-century neurology. Its objects and method, however, were consistently psychological. It is not at all surprising, therefore, that the language of psychoanalysis is a mixed one. The impurity of its idiom has persisted to this day, although it should be noted that there has been a persistent trend toward abandoning the neurological-physiological components of the language and an increasing adherence to a purely psychological idiom. This has been most noticeable, and most successful, in those areas of psychoanalysis which deal with so-called purely mental symptoms or phenomena (for example, defense mechanisms, dream interpretation, etc.). The mixing of languages has continued in its most flagrant form in connection with writings about so-called somatic symptoms (for example, psychosomatic theories). Among the latter, pain has been a prominent example, so much so that until recently this phenomenon was hardly considered to fall within the domain of psychoanalysis, unless it was first labeled "psychogenic" or "hysterical." Elsewhere, I have presented a psychoanalytic theory of pain, in a purely psychological idiom, and what follows is a condensation of this material.[10]

### *Anxiety and Pain*

The very adequate theory of anxiety in psychoanalysis makes it a logical model for our approach to the understanding of pain. Both anxiety and pain can be considered as affects. We shall thus discuss our views concerning pain by comparing them with our views of anxiety. Pain and anxiety, and other affects as well, have different meanings at different stages of ego development. The situation will first be

Downloaded from www.libtool.com.cn

considered as it exists in the case of the adult ego.

The primary meaning of anxiety for the adult ego is that of a warning of "danger ahead" (Fenichel,[2] p. 43). What is the nature of the danger that the ego signals with anxiety? Freud[3] considered this question at length in *Inhibitions, Symptoms and Anxiety* and concluded that the danger is that of losing a needed object (originally the mother). We can interpret pain analogously as a warning of the danger of the loss of a part (or the whole) of the body.

What evidence is there for this assertion? Suppose we are cut, bruised, or burned on some part of our body. In so far as the ego is aware of this event, it will experience pain. However, pain is not only a response to a danger—that is, to an injury of the body; it may also be looked upon as a signal warning of the threat of still further injury. Injury, in the examples mentioned, consists of disruption of the continuity of the skin and the loss of tissue. Pain as a signal warns against still further damage, which may be conceptualized as loss of a part of the body. The protective reactions that pain evokes—for example, withdrawal of the part involved or the emergent need to put the injured part at rest—are in harmony with this interpretation.

Schur,[7] in a recent paper, reformulated Freud's concept of anxiety as follows: "The ego evaluates the danger and experiences some shade of anxiety. Both the evaluation and experience act as a signal to induce defenses" (p. 32). According to my thesis, this reformulation would apply in so far as the ego is oriented toward personal objects. When the ego is oriented toward the body, it evaluates the danger and experiences some shade of pain. This concept thus leads us to the problem of the nature and outcome of the defenses that are induced by pain.

The meaning of pain cannot, however, be limited to the danger of body loss. Reflection about clinical observations points to another group of phenomena associated with pain. These phenomena are superficially dissimilar but are alike in that they all have to do with a relatively excessive degree of stimulation of a variety of different organs and tissues. Indeed, in so far as excessive stimulation is perceived by the ego and is experienced by it in relation to the body, it is felt as pain. Thus, we experience too-intense light or excessive sound as painful, the feeling being referred to (that is, experienced in relation to) the respective bodily parts. Similarly, certain processes in internal structures, particularly in the hollow viscera (gastrointestinal and genitourinary tracts) and in the coverings of some organs (liver capsule, dura mater) are related to the experience of pain in terms of overstimulation. In these situations the anatomical parts in question are accustomed to a certain range of change in their dimensions, as for example, the distention and motility of the intestinal tract associated with the ingestion of food and with digestion. When the upper limit of these stimuli is surpassed (which occurs with excessive distention or excessive peristalsis), the reaction is pain; whereas cutting or burning of these structures is not perceived at all. Likewise, organ capsules mediate changes in the size of the organ which they enclose. Here, distention, stretching, and vascular changes cause pain. We conclude that in each of these instances the pain experience is related to the specific (normal) function of the body part in question.

To summarize, the ego evaluates the danger in its relationship to the body and experiences some shade of pain. The meaning of the pain can be divided into two large groups. First, pain indicates the danger of the disruption of the continuity of the body and the danger of losing a part of the body. The term "body part" here denotes a picture of the surface of the body or an appendage—in other words, body parts which are cathected as objects and which accordingly can be lost (detached). This concept may include functions (such as vision, hearing, etc.) which may be lost, but which are not structures in the anatomical sense of the term. Secondly, pain is a reaction to and a warning against the danger of excessive stimulation. This meaning of pain applies to those parts of the body which are within the outer covering, at some depth from the surface. We are, of course, familiar with these two categories of danger (that is, loss and excessive stimulation) in connection with the meaning of anxiety.[1]

Downloaded from www.pepweb.org

## *The Development of Pain*

Ideas about the origin and early development of any aspect of the personality are, of necessity, speculative and hence much less readily verifiable than constructions concerning the adult. It was for this reason that I started with the adult situation and left the reconstruction of early development for later.

Once again the interlocking nature of the concept of ego and affects makes it advisable to re-examine our view of early ego development before turning to the question of the nature of the early affects of pain and anxiety. Authors differ about the way in which the primitive ego comes into being. According to Fenichel[2] (p. 36), "The sum of the mental representations of the body and its organs, the so-called body image, constitutes the idea of I and is of basic importance for the further formation of the ego." Thus, in this view, the earliest ego-states consist of bodily feelings. Here the ego is regarded as an entity. The same thought may be expressed in terms of the ego's relationship to another system: The ego's first object is the body, and this relationship is experienced in terms of (bodily) feelings.

The formulations of Hartmann, Kris, and Loewenstein[4] follow similar lines. They suggested that the mental apparatus evolves from an undifferentiated matrix. Instead of viewing the ego as developing from the id, they consider that both the id and ego evolve simultaneously from a common matrix. This was an important departure from the older view, because it was the first operational formulation of the origin of the ego (that is, ego can be said to "exist" only as it interacts with the id, and vice versa).

As I have previously suggested, we can, on the basis of object-relationships, subdivide the object world into two parts: the body on the one hand, and people as objects on the other (leaving inanimate objects out of account for the present). From this subdivision naturally arises the question of which of these objects, if either, is genetically earlier. This question is difficult to answer on the basis of reliable observational material. The *a priori* likelihood seems great that this question will be resolved in the end by an answer of simultaneity. Nevertheless, after voicing these reservations, I favor the idea that the body as an object is more important for the early ego than are people as objects.

The following argument is advanced in favor of this assumption. We surmise that it is the perception of stimuli from objects which brings the primitive ego into being. Moreover, we know that the satisfied infant is an infant asleep, and that during this early sleep he can be said to be without an ego. Awakening and awareness must first arise in connection with predominantly painful (that is, unpleasurable) perceptions, such as physical injury at birth, hunger, thirst, or cold. These unpleasant stimuli arise, of course, from the infant's body, and, in this sense, the primitive ego's first object would be the body (of the self). I must hasten to add, however, that this is not what I mean when I say that the body is an object of the ego, since, in the example cited, the knowledge of what constitutes the object (the body) is only in the mind of the adult observer. To the infant, both ego and object must be vague and undefined.

What remains to be emphasized is that, in the foregoing view, supremacy is given to those stimuli that appear to be most intense and prolonged (and these originate from the body) rather than to those that are most rewarding or necessary for survival (that is, stimuli originating from the mother). Heretofore, in psychoanalytic theory, the latter have been greatly favored over the former.

For the sake of simplicity and brevity, I will consider the ego's relationship with objects at three levels of development only and will indicate the nature of pain and anxiety pertaining to each. The many transitional stages between these three are not germane to our present inquiry. The first stage of ego development (age unspecified) is the familiar one of the differentiation between ego and nonego. There is no differentiation between objects. The affect pertaining to this stage of development is best described as undifferentiated pain-anxiety (or unpleasure, unlust). The next stage, perhaps occurring between four and nine months, is

Downloaded from www.pbpaulinaryjournal.com

that point in development at which the infant knows the difference between his own body and the person(s) who cares for him. (The ability to distinguish between mother and father probably follows shortly thereafter.) With the beginning of this differentiation, we can speak of the ego as oriented to the body or to objects (mother). Accordingly, primitive pain-anxiety becomes differentiated into pain (in relation to the body) and anxiety (in relation to objects). Finally, the third stage is that of the adult ego. The overdetermined meaning of both anxiety and pain, at this developmental level, has already been discussed. It may be noted now that pain and anxiety may also appear as defenses, each one against the other. Illustrative of this is the so-called hysterical or hypochondriacal pain which, if successfully dealt with in analysis, will be replaced by anxiety. Conversely, stoical patients with rigid defenses against illness and pain will often experience anxiety in connection with bodily ailments as a defense against feeling pain.

## *Pain Situations*

Another way in which the problem of the different meanings of pain may profitably be aproached is by scrutinizing the personal and social situation of the person experiencing pain. This mode of analysis is complementary to the developmental one. Although the two overlap, each provides us with distinct insights into the problem of pain.

### The One-Person Situation

The situation here is that of a person experiencing pain who may or may not actually be alone. In any case he does not communicate his feeling to anyone—to anyone, that is, but himself. In terms of communication, the situation is that of a message being sent from the body to the ego. The word "body" here denotes whatever is so recognized by the ego. It refers to the person's concept of his body, which may be at once sophisticated and primitive, inasmuch as numerous concepts (or images) of the body may be unconscious. Thus, a physician, for example, who may have a scientific concept of his body on a fully conscious level of functioning, may also harbor repressed, primitive ideas. This is analogous to the way in which his conscious ideas and feelings about his wife might differ from certain views of her which he might have repressed, or which he may have transferred to her from others, and which he may have therefore never actually (consciously) experienced. Moreover, the concept of "body" will usually be something rather vague in infancy and more definite in adulthood. In any event, unless there is a more or less clear-cut split of the ego into experiencing and observing parts, there can be no question, in this situation, of validating the pain. This is so because there is only one "observer," and he is the same as the "experiencer." In this situation, therefore, all pain is "real" ("organic," "bodily pain"). Most of the pain that we feel or of which our patients complain can be understood best as to its experiential meaning by assuming that it is of this type.

Validation is possible, however, even in this situation, as noted above. For this to occur, one must rise above his own experience of pain, so to speak, and become an observer of it. This is by no means impossible, and indeed, it is not even unusual. Small children cannot usually achieve such detachment from their experiences, but many adults can. A measure of educational or intellectual sophistication is conducive to achieving this type of self-observation, for the "natural" (uneducated) attitude to affects, and in particular to strong affects of a bodily nature, is to accept them at face value. The following type of occurrence is an everyday example of the validation of pain in a one-person situation. While working at a manual task, you feel a sharp pain in your eye. Instantly you conclude that a foreign body has lodged in it. There is a conviction that you *have* a foreign body in it. You proceed to the mirror, locate the speck of dirt, and remove it. The pain in the eye, sometimes quite unchanged from what it felt like before the substance was removed, may nevertheless persist. Yet if you are convinced that no foreign material has been left in the eye, your *conclusion* about the pain will be quite different from what it was a few moments earlier. In other

Downloaded from www.drabhay.com

words, the affect of pain before the removal of the foreign body and afterward is virtually the same. In the first instance, there is no validation: Body-as-object and physical body are one and the same. Examination of the eye and removal of the offending substance constitutes the validation. The pain after the removal points to the body-as-object, but is contrasted with one's knowledge that the material has been removed from the body (eye) as a physical structure. Someone may object to this analysis and claim that the afterpain is simply due to scratching of the cornea. I have deliberately neglected to mention this factor, not because I think it is irrelevant, but rather because it distracts from the phantom quality of this type of experience. In other words, the slightest injury to the eye immediately becomes heavily cathected, and this largely accounts, I think, for the type of experience which I sketched above.

### THE TWO-PERSON SITUATION

In a two-person situation we can distinguish between two different meanings of pain. The first pertains to what may be called the "basic model of pain." This refers to what is usually called "pain sensation" and denotes the phenomenon of the ego registering that something is wrong with the integrity of the body. The second meaning of pain is a product of childhood development in which the infant's expression of pain—for example, by crying—leads other persons to minister to him in ways designed to relieve the painful state. This pattern of communication establishes pain as a powerful help-seeking symbol. Accordingly, in a two-person situation the word "pain" may refer simultaneously to one or both of these meanings. This accounts for most of the ambiguities encountered in terminology and clinical practice. When a person reports a painful experience, he speaks in terms of *his* notion of his body (his own body-image), and the listener receives and interprets the message in terms of *his* own notions (of the patient's body). The distinction between physical and mental pain expresses, among other things, this difference between experiencing ego and judging observer. Physical pain denotes agreement, and mental pain denotes disagreement between sufferer and observer.

On the basis of these considerations we may also distinguish three categories, or levels of symbolization, of pain. These can be described best in terms of the object to which pain points as a referent. In the first category it points to the body; in the second *ambiguously* to both body and other people; and in the third category to a particular person.

### THE MANY-PERSON OR SOCIAL SITUATION

The principal new dimension that enters into the role of pain here lies in the social (cultural) attitudes toward this phenomenon. In other words, in certain cultures and social situations, experiencing pain and communicating about it may tend to be strongly rewarded and thus encouraged, while in others it is censured and hence inhibited. The Judaeo-Christian ethic, in general, tends to favor the aggrandizement of suffering and pain, as opposed to certain other types of distress. An obvious example of this is the "social fact" that a post-traumatic neurosis with painful bodily symptoms (incurred in an industrial accident) will usually be compensated financially. Yet if the patient responds to the "same event" with a depression, he is less apt to be awarded compensation, and in all likelihood his complaint will be regarded as a "psychiatric disorder *due* to his personality." I cite this hypothetical example (which in practice corresponds to numerous similar cases) to illustrate a prevalent social orientation to pain in our culture, and not as a plea for compensation in the latter type of disorder.

## ¶ Psychotherapeutic Applications

### *The Localization of Pain*

It is of paramount importance in medicine (in the sense of physics) that pain be localized. By using the word "localization," the physician actually has reference to two things—first, to "Where does the patient feel the pain?" and second, to "Where is the lesion?" Both questions refer to loci in physical space, and both

Downloaded from www.dbpublishing.in

must be answered as prerequisites for an accurate diagnosis. Often the two loci coincide, as, for example, in the case of a foreign body in the eye, or a fractured leg. Less often, though again quite commonly, the two loci differ; that is, the patient feels pain in one spot, whereas the lesion is in an area removed from it. This phenomenon goes by the name "referred pain," a rather misleading, though serviceable, label. This expression is misleading because it does not take account of the fact that all pains are "referred," the difference being that some are referred but a short distance from the lesion, while others are felt much farther away. For example, the precordial pain of a coronary occlusion is not considered to be "referred," because it is felt over the heart, only a short distance from the anatomical location of the disorder. Only the pain in the left arm and hand, accompanying this disorder, is labeled "referred pain."

These remarks about localization are somewhat trivial, but they are a necessary introduction to a more penetrating analysis of the problem. First it should be noted that the word "pain" is used in the foregoing paragraph in the language of medicine (and physics) and not in that of psychology.

Woodger[11,12] addressed himself to this problem in some detail, and it seems to me worth while to quote his argument. The following passages are relevant, moreover, not only to our present concern with the localization of pain, but also to what has been said earlier about the dangers of mixed languages. In a section entitled "Some Linguistic Difficulties in Neurology," Woodger[11] stated:

> Our next task is to examine some specimens of the mixed statements which occur in neurological writings and which I mentioned at the beginning of the last lecture. Among the commonest mistakes, as it seems to me, are: (i) treating sensible objects as though they were physical objects, for example, by identifying stimulus or neural impulse with sensible objects; (ii) identifying person with brain, i.e., putting a person into his own head and (iii) being too easily satisfied with metaphors, as when neurologists speak of "pictures" being "projected" on the cortex as though the brain were a kind of private cinema.

An example which illustrates most of these points is provided by the following passage from a well-known work on pathology:

> "Paradoxical as it seems, pain cannot exist in the tissues; a pain in the foot is a disturbance of those nerve cells in the brain whose function it is to receive stimuli conveyed to them by the afferent nerves from that region . . . we must recognize two orders of tissues, irritation of which may set up the sensation of pain, but in the one this process is accurately localized, while in the other the sensation is localized by the brain as originating in some other area or areas."

Thus pains are treated as though they were physical objects and identified with nerve cells in certain states. But the process of localization is not a process of saying where the pain is. A pain, being a sensible object, can only be atopically related to other objects. Localization is a process of saying where the pain appears in. And this is performed by the person, not by the brain, because it is a characteristic of persons that their parts are not persons; although certain of their parts are capable of becoming persons, otherwise surgery and reproduction would be impossible. The same point is curiously illustrated in the following passage where the writer speaks in one place of "the female cerebral cortex" and in another of "a woman." It is from a letter in *The Lancet* in reply to a previous letter:

> "First, he (the author of the previous letter) asks why in women renal pain is not referred to the ovaries whereas in men it is referred to the testes. The answer is that the female cerebral cortex (where localization of pain actually takes place) has never really had the chance to determine the position of the gonads; ovaries do not normally suffer specific traumata, whereas testes often do by reason of their somatic isolation. Mr. Brown need only ask a woman where her ovaries are, and the comparative indefiniteness of her answer will soon convince him that in this respect, even without pain, women cannot be compared to men."

This seems to me to be an extraordinary argument. Because testes protrude, in a sense, outside the body, male cerebral cortices know where they are and refer renal pain to them. Why they should do so is not stated. Ovaries, on the other hand, do not stick out, so female cerebral cortices

Downloaded from www.dbraulibrary.org.in

are not so learned in anatomy and do not refer renal pain to them. But in order to examine them in this subject you must ask, not the female cerebral cortex, but the woman who possesses it (pp. 286–288).

These statements are so lucid that they require no explanatory comments. Another way of putting the matter might run like this. In so far as we speak of the localization of pain, we must distinguish what the patient does from what the physician does. The patient reports on his affective experiences. His feelings function as pointers to his body-as-psychological-object; the latter, as has been emphasized, has a variable relationship to the body-as-physical-object. The physician, on the other hand, does not really try to localize the pain at all. What he is after is the lesion, to which the pain points in much the same way as the evidence in a crime may point toward the criminal. The physician's role is that of a detective: he is interested in apprehending the criminal, that is, in making a diagnosis.

Using the analogy between the work of the medical diagnostician and the detective, we must now ask, "What happens if the clues to the crime are misleading and confusing?" Will the detective-physician conclude that the most likely suspect is indeed the criminal, and let it go at that? Or will he assume, as is often done in totalitarian states, that some habitual criminal or some other unwanted member of society has committed the offense in question? The reasoning behind this is that he has done so before, so why not this time also? Both of these "criminal solutions" are frequently resorted to in medical practice if the problem is that of obscure pain. Illustrative of the first solution, namely that based on circumstantial evidence, is the frequent diagnosis of acute appendicitis in cases of abdominal pain. This example may apply also to the second solution, namely to that based on the theory of the habitual criminal. The appendix has been regarded in just such a way by some members of the medical profession; it is a chronically suspect, unwanted, and expendable member of the "body" (politic). Medical fashion, however, has an important role in determining what parts of the body are regarded in this suspicious light, so that the blame for undiagnosed painful ailments shifts from time to time among any of the following: the retroverted or otherwise "misplaced" uterus, the appendix, peritoneal adhesions, the tonsils, the gallbladder, the teeth (as foci of infection), and others.

Clearly, a more honest conclusion than either of the above is openly to acknowledge that the crime—the problem—remains unsolved. Perhaps it is not even a "crime," that is, there may be no "criminal" (lesion) that can be located in space (anatomy). In other words, what looked like a "crime," may have been an "accident" or a "suicide." It is, therefore, necessary for us to consider the problem of pain localization in an altogether different light. The neurological (physical) concept of pain must be abandoned and the psychological one adopted in its place. If we regard pain as an affect indicative of a particular ego-object relationship, the problem of localization—in the anatomical sense—does not arise. Pain is still felt, or experienced, in one or another body part, but this simply means "body part as psychological object." Lest it be thought that there is something unreal or mystical about a "psychological object," I would like to point out that it is no more or less mystical than are other words and concepts which designate nonphysical entities, such as, say, "patriotism" or "justice." As was noted before, the body-as-object may or may not correspond to the body-as-physical-thing (as seen by various observers). This view makes it possible to account, without doing violence to the facts of observation, for such phenomena as phantom pain and chronic pains of all sorts which are not accompanied by serious physical damage to the body. Without going into the psychological details of these phenomena, suffice it to note that the general meaning of persistent pains seems to be that of a *reassurance* that the body part in question *still hurts*, and is, therefore, still present. The pain, while apparently undesirable for the ego and for the physician, is on a more unconscious level, a denial of, and reassurance against, the danger of body loss. This antithetical meaning of pain is not as unusual as it may seem at first glance, for a similar duality of meaning also applies to most other affects. Thus, if we

Downloaded from www.pbookshop.com

are anxious, this affect not only means that we are afraid of something, but also it tells us that we are prepared and vigilant and, therefore, unafraid. Indeed, in Shakespeare's *Hamlet* Laertes says: "Be wary then; best safety lies in fear." Similarly, feelings of guilt tell us both that we have done something wrong and are "bad" and that we are conscientious and therefore "good" (Szasz,[10] pp. 147–169).

## *The Psychiatrist as Translator*

The problem of pain can also be fruitfully approached by viewing it much as one would view the task of translating a foreign language. This is true for the work of both the medical and the psychotherapeutic physician, but more so for the latter. The diagnostician's task, in these terms, is to translate from pain to diagnosis. Pain, in this context, is a foreign language for the patient, since his pains make no sense to him. It is simply a signal or message which disturbs him and to which *he must respond,* but he does not really know how. It is for this reason that he seeks a physician who is regarded as an expert in the language of pain. The physician will translate this strange and disturbingly compelling language, and will tell the sufferer (messenger) what to do about these coded commands. And, indeed, if the patient suffers from a clearly defined and recognizable disorder of the bodily machinery, the physician will be able to effect the proper translation from pain to diagnosis, and hence to medical action. Both the diagnosis and the medical action inherent in it will then be recognizable and understandable to the patient. In other words, they can usually be rendered also into ordinary English (or any other language).

If no bodily disorder is found, the problem which the language of pain presents is, as we have already seen, compounded. This is due to the fact that the language of pain, and of bodily feelings in general, is commonly used as a pattern of communication in situations other than those pertaining to disorders of the bodily machinery. I refer to the need to translate and to express certain experiences — particularly those relating to intimate personal relationships and feelings—into other than ordinary verbal language. This need arises, of course, largely as a result of cultural and social influences. And, however variable these influences may be in Western cultures, they all necessitate the avoidance of the open expression of various personal feelings. Freud was naturally struck by the avoidance of sexual and money matters in his social milieu. Viewed in terms of language and social roles, what happens in many medical situations may be briefly described as follows. The patient knows—that is, he has learned—that he is not supposed to complain about, say, sexual and marital problems. These things, and many others, are not supposed to be mentioned. Even in intimate friendly relationships, the discussion of such matters is not usually condoned. If there is trouble in these sectors of one's life, something, of course, has to give. The psychosocial pressures then become "translated," so to speak, into other idioms, and find expression in derivative forms. Some literary creations are one such idiom. Excessive drinking is another. And bodily symptoms constitute still another, very common, outlet. Thus, while the patient may feel unable to complain about personal unhappiness, he can complain about dizziness, weakness, palpitation, and pain or itching in this or that part of his body. The physician may feel similarly disinclined, and unprepared, to function as an aid to the patient in his personal troubles, but he does feel that it is his proper function to communicate with him in the language of his bodily feelings, that is, in terms of possible bodily disease.

Viewed in this light, the psychiatrist's role is like that of a translator and interpreter of a foreign language. He must translate the patient's body-language (for example, "I have pains in my chest") into the language of everyday speech ("I am unhappy with my wife, husband, job, children, religion, etc."). It is important to note, in this connection, that when patients go to physicians, they do not expect—and, as a rule, do not welcome—such efforts at translation. They wish to speak in the idiom in which they have addressed the physician, namely, in the language of bodily disorder. Moreover, it is clear that the problem is not

Downloaded from www.vibgyorpublishers.org

simply one of translation. The task at hand, as I see it, is rather to explore, in the relationship between patient and doctor, whether the patient can address himself to his problem in some other, possibly more effective, manner. Merely to tell the patient that translation is necessary (that is, "Your troubles are probably 'emotional,' therefore, you should go to a psychiatrist . . .") is of no service to him, unless two basic conditions can be fulfilled. First, both patient and physician must be able to converse in the new idiom (ordinary language, in this case) about the problem at hand; and second, there must be a likelihood that the original problem, rendered anew in translated form, will be more readily soluble than it had been before. Unless both of these conditions are met, persistent communication between patient and physician in the idiom of bodily feelings may be the best (least harmful) solution for everyone concerned.

It is always possible, however, that the patient is interested in, and capable of learning, another language. Or, better still, he may be already in possession of another language, but is afraid to reveal his knowledge lest he offend his apparently less polyglot physician. For these reasons it would seem to be good medical practice if the physician could learn to relinquish, when necessary, the language of bodily disease and would introduce, on all appropriate occasions, the topic of "translation." By this I mean, quite concretely, informing the patient that, in his physician's opinion, further inquiries along physical (medical) lines are not indicated at this time. He could then *add* that the patient, accordingly, has one of three basic choices open to him: (1) If he feels strongly that a bodily disorder is the cause of his troubles, he is free to consult another physician. (2) He may choose to do nothing further but wait to see what develops. (3) He may wish to explore the possibility of finding a solution for his troubles along psychological lines, that is, by thinking about his life and human relationships. He (the patient) may do this, moreover, either alone or with someone close to him (wife, husband, friend, or medical physician if the latter is so inclined) or, finally, with the aid of a psychiatrist. Only the patient's response to such medical advice will determine the proper course for him. If the patient does consult a psychiatrist, the possibilities of translation and "working through" in a new idiom will be explored further. Two examples illustrating these considerations, and the type of work discussed will now be cited.

### CASE I: "TRANSLATION" AND PSYCHOTHERAPY AS SOURCES OF DANGER

A middle-aged man was referred to me by a colleague in one of the medical specialties for possible help with a problem of chronic pain of the left arm. The patient was an intelligent man and welcomed psychiatric consultation. Excrutiating pain occurred several times during the day and also during the night. It had been present, on and off, for about eighteen months when I first met the patient. So much for the pain.

Let me suggest now that we think of the pain —as I did—as a thread woven into a complex tapestry. We must therefore back away, so to speak, from a close-up view of our object and look at the "ground" on which the pain is the "figure." This is what I saw.

The patient had been suffering from multiple sclerosis for nearly twenty years, and for several years had been almost completely disabled. He was barely able to move around, needing crutches as well as personal support in order to take a few steps. He spent most of his time at home in a wheel chair. He could not do useful work and had few hobbies. His wife was devoted to him, cared for him conscientiously, and was, of course, deeply involved in various pharmacological attempts to relieve his pain.

After several visits during which the symptom subsided somewhat, we began to exhaust the topic of pain as a subject of conversation. Then, as we shifted to a consideration of the patient's life situation, his serious neurological illness, and his personal relationships, a very depressing and disheartening picture came into view. While, in one sense, he knew that he had multiple sclerosis, in another he befuddled and denied what this meant to himself. Moreover, it emerged that the patient had a quite distressing relationship with his father. The crux of this was his complete submission to, and subjugation by, his father from whom

Downloaded from www.dbraulibrary.org.in

he felt escape was impossible. Indeed, he harbored a "psychosomatic theory" of his multiple sclerosis, according to which the disease was due to this conflict. The physical incapacity was regarded by him as the only "safe" means of rebellion against or noncompliance with his father. This view of the patient's, I want to make clear, had no connection with his few interviews with me. He had formed it many years before, during the development of his neurological illness.

The treatment of the pain, in a situation of this sort, as may be surmised, became an important matter for the patient, his physicians, and those about him. There developed a pattern of receiving codeine by injection every three to four hours, sometimes more often, sometimes less. He took other analgesics as well. Sometime during his painful complaints he was given an injection of sterile saline solution, and this relieved the pain as well as the codeine did. This resulted in much confusion and conflict about the "reality" of the pain.

The patient came to my office once a week, accompanied by his wife. The trip seemed to be a considerable hardship for both of them. The patient was eager to speak about his personal difficulties and hoped that improvement in his pains —as well as in his multiple sclerosis—would result from this treatment. At the same time, it became clear—both to me and perhaps somewhat less vividly to the patient—that his painful symptom, waiting for it, and treating it, had become the most important things in his life. "Translation" of the pain, and reconstruction of its onset and "meaning" offered no promise of beneficial change. It was not that the patient lacked interest in undertaking this sort of work. Indeed, discussion of the onset of his painful symptom led rapidly to his recollection of certain traumatic events with his father, and other family members, at whose hands he had been humiliated once again immediately prior to the onset of this symptom. Thus, many of the symbolic meanings of the pain were clear, as was its retaliatory implication. Yet, the fact was that the pain functioned as an important object in his life and, in addition, was a vehicle through which he was able to reach other people from whom he had receded irretrievably because of his multiple sclerosis.

The relief of the pain, in the light of these considerations, did not seem to be a desirable therapeutic goal. Whether it would have been possible to bring about relief of this pain at all, of course, is open to doubt. If it was possible, it seemed to me that the price which would have been paid for it would have been too high. Increasing contemplation of, and insight into, his personal situation could have easily led this patient into a serious depression and/or paranoid orientation. He dramatically expressed his awareness of his lifelong inability to ever "stand up" to his father, and other aggressive relatives. He felt he was doing so now by asserting himself in asking for relief of pain and, in a sense, he was. He did not feel that he could do this on a less symbolic (that is, more real-life relationship) level with them—and how could he, now, in his crippled condition?

It was a logical denouement of these explanatory interviews that we came to speak of the difficult situation in which he found himself. I stated frankly that, although some of the psychological meanings of his pain were evident, I did not believe that further inquiries along this line would be of benefit to him. I advised "bearing up," tolerating, and living with the symptom as the best course to follow. I also discussed the problem of the "reality" of the patient's pain—in the light of the effect of the placebo injection—with his wife. She was quick to grasp and to understand the patient's "need" for pain as an object of life interest. The patient expressed no wish to continue once I voiced my doubts about the advisability of doing so.

This tragic clinical example illustrates many of the previously mentioned theoretical considerations concerning pain. It shows clearly that mere "translation" of pain into the language of personal troubles is not enough. Like any method or action that can be helpful, so translation of this sort can also be damaging. This is a truism which applies equally to all forms of medical treatment and social action. Still, it is forgotten often enough to merit re-emphasis. In other words, the translation of bodily feelings (often erroneously called "somatic symptoms") into the language of personal troubles is helpful only if it leads to a successful mastery of the problem in the new idiom or, at least, to more successful mastery

Downloaded from www.abnormalbrain.org

than had been achieved before. Contrariwise, if it results, or promises to result, in an even greater and more decisive defeat of the patient, then "translation" becomes an iatrogenic trauma, roughly comparable to unnecessary surgery or ill-advised counseling.

This clinical example points to another problem which merits comment. It is the problem of what kinds of medical and surgical action are called for, and are justified, in situations of this sort. The patient's problem cited may be considered as paradigmatic of that presented by many men and women who complain of severe pain and who are often treated with measures of increasing destructiveness. These measures range all the way from increasing dosages of opiates to neurosurgical interventions at various levels of the nervous system (for example, nerve blocks, rhizotomy, lobotomy) and often culminate in combinations of these, finally ending in the commitment of the patient to a mental hospital. It is important, in considering this problem, to define clearly the aim of treatment. Is it to relieve pain? If this is the sole aim, then indeed rather drastic measures may be logically employed. Sometimes the result is a cessation of the complaint. But clearly this approach to pain does violence even to the common-sense medical practice of considering the complications and side effects of treatments, and to the time-honored adage according to which, as physicians, we should, above all, do no harm.

A more sophisticated phrasing of the problem also points to the need for extreme caution not to employ excessive medical and surgical action in such cases. We should ask again, "What is the purpose of our therapy?" It no longer is enough to answer, "To relieve pain." We must ask: "What is the matter with the patient?" "How can we help him (as a person)?" "What will be the effect of our personal therapy (whatever this may be)?" If we ask such questions, it will be evident, however terrible this may seem, that sometimes we are forced to conclude that we (as physicians) *can do nothing*. The physician's inability to comprehend and admit his own helplessness is of great significance in connection with many chronic pain problems. Yet, as is often the case, it may be possible to turn defeat into a kind of victory. For once the physician realizes that he cannot help by medical, surgical, or psychiatric treatments, it follows that he can do the most good by desisting from doing harm. Finally, these considerations may help the physician to see that, in many cases, therapy is really aimed at the relatives. In the example cited, for instance, the patient's pain was most distressing to his wife and to others about him. Silencing the pain would have been most beneficial to them, not to him. Often, the physician must include himself among those who are distressed by the patient's persistent complaint of pain. His insistence on silencing it, at any cost to the patient, can be understood best by comparing this situation with that of the parents' distress with the painful crying of their infant. Parents are driven, as we say, to "distraction" by such crying and will try to do anything to stop it. In human relationships, as in medicine, it is sometimes most humane to understand and to bear suffering. Action, no matter how benevolent (therapeutic) in intent, can add to suffering as easily as it can relieve it.

### CASE II: AN EXAMPLE OF SUCCESSFUL PSYCHOTHERAPY

The following case note* is cited to illustrate some aspects of the translation of bodily symptoms into the language of human relationships and the psychotherapeutic work which this renders possible.

A girl in her late teens came for psychiatric treatment after an incapacitating illness of about two years' duration. Her chief symptoms were attacks of severe pain referred to the abdomen, pelvis, and lower back. There were also episodes of anorexia and occasional vomiting. At first she did not accept the possible relevance of psychiatric treatment to her situation. She came only because, over a period of two years, repeated medical examinations resulted in conflicting diagnoses, and because the many treatments which were tried proved to be of no avail. Finally, she went to a large diagnostic center, where the need

* This illustration was first published in my paper, "The Nature of Pain."[9]

Downloaded from www.dbraibrary.org.in

for psychiatric treatment was impressed upon her as well as upon her family physician.

As is true of all excerpts from psychiatric observations, a few paragraphs cannot possibly do justice to all of the clinical material as it emerged in the process of psychotherapy. It must be borne in mind, therefore, that I shall cite only some highlights of the history and focus on those specific factors from the therapeutic interaction which are relevant to the problem of pain.

The patient lived in a distant community and was unable, therefore, to make frequent visits to my office. She averaged two appointments a week for a period of a year and a half. During the first six months, many appointments were broken because of attacks of pain for which she remained at home, confined to bed.

The patient was reared in a well-to-do Catholic family in a small town. She had three older sisters and one younger brother. Approximately three years before the beginning of treatment, her mother underwent an operation. There was some concern about the possibility of a malignant tumor, but at surgery it was established that the symptoms were due only to extensive fibroids. The family was relieved. Then, suddenly, the mother died of a massive postoperative hemorrhage. The patient was stunned, as was the whole family. Indeed, no one in the family seemed to recover fully from this loss. The father became depressed and withdrawn. The older sisters tried to help, but they, too, had been dependent on the mother, even though they were married and had families of their own. In this situation the patient found it impossible to "let go" and mourn the loss of her mother. Not only could she find no support for her own needs in this moment of stress, but, realizing her father's suffering and the older sisters' ineffectiveness, she began to feel increasingly that she should take an active role in managing the household and in comforting her father. Her father, however, remained depressed and about a year later drove his car into the abutment of a bridge and died immediately. Everyone in the family regarded this accident as a suicide. Shortly after the father's death, the patient became ill, with the symptoms described earlier.

When the patient first came for psychiatric treatment, she appeared to be an intelligent and introspective girl who suffered much but bore it stoically. She was neither depressed nor anxious but, on the contrary, appeared well composed. She also "looked sick" in that vague and undefinable manner in which people give the impression of being, as we say, "physically ill." Indeed, had it not been for the repeated physical examinations and the recent tragic events, I would have been strongly tempted to feel with the patient that hers was not a "psychiatric problem."

On the basis of the historical material, much of which was related during the first few hours, it could be surmised that, because of the magnitude of the traumata to which the patient was exposed, she had been unable to integrate them, and that this failure to resolve the losses which she had experienced was related to her present illness. It also became apparent that the patient, in her day-to-day life, was quite isolated from people. Although she lived in the home of an older sister, with the sister's family and with her younger brother, she was quite estranged from them. They did not understand her, and the lack of understanding grew monumentally as her undiagnosed illness dragged on and baffled, worried, and angered them. She was also alienated from her friends and her teachers at school.

About two months after the beginning of psychotherapy, the patient canceled several appointments because of severe pain. Although she had missed appointments during the preceding two months, it was not with the same implication as at this time; namely, that she was stopping the treatment. This had been anticipated and discussed with her. Now she was urged to continue the treatment. The full significance of these events did not become apparent until later. The loss of her parents and repeated disappointments in relation to her sisters and physicians had led her to feel all alone. She felt that no one cared whether she was well or ill and, further, that since no one understood what was wrong with her, no one was capable of helping her. These notions, which have well-known ubiquitous childhood sources in all of us, were reinforced by her recent life experiences. The intense attacks of pain (for which her family physician, responding to the calls of her

Downloaded from www.dbraunbooks.org.ir

panicked family, gave repeated injections of morphine) in this last episode had, at least among other meanings, the function of protecting her from the dangers of a positive transference which was developing. By urging her to continue the treatment, I gave her the realistic support and reassurance required when one's trust in human helpfulness is shaken. As she became more certain that she could rely on me, she was able to review and to come to grips with the circumstances of her parents' deaths and the reactions of the various members of the family to these events. Her distrust of physicians and the misunderstandings that ensued from her painful illness, for which no demonstrable physical cause could be found, became conscious and understandable. The persistent pathogenic effect of the confusion that resulted from her sisters' and physicians' reaction to her illness—which was added to the trauma of the original losses—was thus replaced by understanding and knowledge which became an important source of comfort to her.

The patient was greatly improved after about one year of treatment. Pain occurred very infrequently. Instead, a much broader spectrum of human emotions was experienced, and she could regard these as reflections of her relationship with the people about her. She was no longer alienated from her family. She concluded that they had little in common with her, and she now had a consciously more distant and more comfortable relationship with them. She also entered a training program for professional work from which she obtained much satisfaction.

I think it is reasonable to assume that this sort of problem is ubiquitous. The patient's story—and human distress—is paradigmatic of the problems which countless patients bring to their physicians. In these cases the possibilities for doing harm with medical and surgical treatments loom very large, and the possibilities for rendering help by providing the needed psychological assistance are equally great.

This case illustrates several communicative meanings of pain. Not only was the pain initially a request for help, addressed first to the older sisters and later to physicians, but subsequently it became an aggressive, frustrated complaint of, "You see, you still have not done anything for me . . ." Still another function of it was that of a warning signal of an impending danger. It was as if the patient, having lost both parents, had no really significant object left to lose other than her body. Then, as if to make sure that she would not be taken by *surprise* again as she was by the death of her mother, she experienced the warning signal in a chronic manner. In this way the warning itself became—as it always does in such instances—a source of security. This accounts, in part, for the patient's composure during her illness.

I may add that the foregoing interpretation of the function of pain is analogous to our ideas concerning anxiety and distrust as defenses against transference in the psychoanalytic situation. By this, we understand the patient's anxious expectation of being deserted or let down in some manner by the analyst. This fear either echoes some actual childhood (or later) event or expresses the dread of aloneness based on some other source. In other words, if we look upon the body as an object of the ego, it may be possible for us to expand the concept of transference from human objects to the body. I think that this phenomenon does occur. In this case the body functioned as a transference object, substituting for both the mother and the father. The experience of pain is the appropriate signal warning of danger in relation to the body. In this case it warned—in the last analysis—against the danger of losing the parents, thus recreating the unsolved traumatic situation in the hope of eventually solving it. The similarities between the structure of this symptom and that of melancholia are evident (Szasz,[16] pp. 150–154).
