# CONTRIBUTORS

Downloaded from www.digitallibrary.org.in

D. Wilfred Abse, M.D.

*Professor of Psychiatry, Lecturer in Psychology, University of North Carolina, Chapel Hill, North Carolina.*

Kenneth E. Appel, M.D.

*Professor of Psychiatry, Chairman of the Department, School of Medicine, University of Pennsylvania, Philadelphia, Pennsylvania; Consultant, Institute of the Pennsylvania Hospital, Philadelphia, Pennsylvania.*

Silvano Arieti, M.D.

*Clinical Associate Professor of Psychiatry, State University College of Medicine at New York City; Member of the Faculty, William Alanson White Institute of Psychiatry, Psychoanalysis and Psychology, New York.*

Hyman Bakst, M.D.

*Physician-in-Charge, Psychosomatic Service, Medical Division, Montefiore Hospital, The Bronx, New York; Associate in Clinical Medicine, Instructor in Psychiatry (Psychosomatic), Albert Einstein College of Medicine, New York.*

Dominick A. Barbara, M.D.

*Certified Practicing Psychoanalyst associated with the American Institute for Psychoanalysis, New York; Psychiatrist-in-Charge, Speech Therapy Department, Karen Horney Clinic, New York.*

Norman W. Bell

*Research Assistant, Laboratory of Social Relations, Harvard University, Cambridge, Massachusetts; Assistant Sociologist, McLean Hospital, Wayerly, Massachusetts.*

Virginia Bellsmith

*Professor of Social Work, The New York School of Social Work, Columbia University, New York.*

Avrum Ben-Avi, Ph.D.

*Adjunct Associate Professor of Psychology, New York University Graduate School of Arts and Sciences, New York; practicing psychoanalyst.*

Theresc F. Benedek, M.D.

*Staff Member, Institute for Psychoanalysis, Chicago, Illinois.*

Newton Bigelow, M.D.

*Director, Marcy State Hospital, Marcy, New York; Clinical Associate Professor of Psychiatry, Upstate Medical Center, State University of New York, Syracuse, New York.*

Daniel Blain, M.D.

*Director, Department of Mental Hygiene, Sacramento, California; Project Director, American Psychiatric Association Manpower Project.*

Harry Bone, Ph.D.

*Diplomate, American Board of Examiners in Professional Psychology; Fellow, William Alanson White Institute of Psychiatry, Psychoanalysis and Psychology, New York.*

Henry Brill, M.D.

*Director, Pilgrim State Hospital, West Brentwood, New York; Associate Clinical Professor of Psychiatry, Albany School of Medicine, Albany, New York.*

Henry W. Brosin, M.D.

*Director, Western Psychiatric Institute and Clinic, Professor and Chairman, Department of Psychiatry, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania.*

Walter L. Bruetsch, M.D.

*Clinical Professor of Neurology (formerly Psychiatry and Neurology), Indiana University School of Medicine, Indianapolis, Indiana; Director of Research Laboratories, Central State Hospital, Indianapolis, Indiana.*

Norman Cameron, M.D., Ph.D.

*Professor of Psychiatry, Yale University School of Medicine, New Haven, Connecticut; Associate Psychiatrist, Grace–New Haven Community Hospital, New Haven, Connecticut.*

Gerard Chrzanowski, M.D.

*Faculty Member, William Alanson White Institute of Psychiatry, Psychoanalysis and Psychology, New York; Director, Bleuler Clinic, Jamaica, New York.*

Hervey M. Cleckley, M.D.

*Clinical Professor of Psychiatry and Neurology, Medical College of Georgia, Augusta, Georgia; Chief of Psychiatry, University Hospital, Augusta, Georgia.*

Stanley Cobb, M.D.

*Bullard Professor of Neuropathology, Emeritus, Harvard University, Cambridge, Massachusetts; Formerly Psychiatrist-in-Chief, Massachusetts General Hospital, Boston, Massachusetts.*

Joseph B. Cramer, M.D.

*Associate Professor and Director, Child Psychiatry, Albert Einstein College of Medicine, New York.*

Hester B. Crutcher

*Formerly Director of Social Work, New York State Department of Mental Hygiene; Formerly Consultant in Mental Hygiene, United States Veterans Administration of Foster Home Care for Mental Patients.*

Henry A. Davidson, M.D.

*Superintendent, Essex County Hospital, Cedar Grove, New Jersey; Lecturer in Psychiatry, Columbia University, New York.*

Franklin G. Ebaugh, M.D.

*Clinical Professor of Psychiatry, University of Colorado Medical School, Denver, Colorado.*

Armando Ferraro, M.D.

*Formerly Clinical Professor of Psychiatry, Columbia University, New York; Formerly Principal Research Scientist (Neuropathology), New York State Psychiatric Institute, New York.*

Jerome D. Frank, M.D.

*Associate Professor of Psychiatry, The Johns Hopkins School of Medicine, Baltimore, Maryland; Psychiatrist-in-Charge, Psychiatric Outpatient Department, The Johns Hopkins Hospital, Baltimore, Maryland.*

Walter Freeman, M.D., Ph.D.

*Formerly Professor of Neurology, George Washington University, Washington, D.C.; Attending Neurologist, Santa Clara County Hospital, San Jose, California.*

Paul Friedman, M.D., Ph.D.

Manuel Furer, M.D.

*Medical Director, Masters Children's Center, New York.*

George E. Gardner, Ph.D., M.D.

*Clinical Professor of Psychiatry, Harvard Medical School, Boston, Massachusetts; Director, Judge Baker Guidance Center, Boston, Massachusetts.*

R. W. Gerard, M.D., Ph.D.

*Professor of Neurophysiology, Departments of Psychiatry and Physiology, and Director of Laboratories, Mental Health Research Institute, University of Michigan, Ann Arbor, Michigan.*

Edwin F. Gildea, M.D.

*Wallace Renard Professor of Psychiatry and Head of Department of Psychiatry and Neurology, Washington University School of Medicine, St. Louis, Missouri.*

Alvin I. Goldfarb, M.D.

*Chief, Department of Psychiatry and Neurology, The Home for Aged and Infirm Hebrews, New York; Consultant, Services for the Aged, New York State Department of Mental Hygiene.*

Kurt Goldstein, M.D.

Maurice R. Green, M.D.

*Lecturer, William Alanson White Institute of Psychiatry, Psychoanalysis and Psychology, New York.*

Ralph R. Greenson, M.D.

*Dean, Training School, Los Angeles Institute for Psychoanalysis; Clinical Professor of Psychiatry, University of California at Los Angeles Medical School.*

Emil A. Gutheil, M.D.

*Faculty Member, Postgraduate Center for Psychotherapy, New York; President, Association for the Advancement of Psychotherapy.*

Downloaded from www.ahaulibrary.org.in

John W. Higgins, M.D.

*Associate Clinical Professor of Psychiatry, Yale University School of Medicine, New Haven, Connecticut.*

Paul H. Hoch, M.D.

*Commissioner of Mental Hygiene, State of New York; Professor of Clinical Psychiatry, College of Physicians and Surgeons, Columbia University, New York.*

William A. Horwitz, M.D.

*Professor of Clinical Psychiatry, College of Physicians and Surgeons, Columbia University, New York; Principal Clinical Psychiatrist, New York State Psychiatric Institute, New York.*

George A. Jervis, M.D., Ph.D.

*Director of Research, New York State Department of Mental Hygiene, Letchworth Village, Thiells, New York; Associate Professor of Clinical Psychiatry, Columbia University, New York.*

Adelaide M. Johnson, M.D., Ph.D.

*Clinical Professor of Psychiatry, University of Minnesota, Minneapolis, Minnesota.*

Robert L. Kahn, Ph.D.

*Research Associate, Department of Experimental Psychiatry, Hillside Hospital, Glen Oaks, New York; Research Psychologist, Office of the Consultant on Services for the Aged, New York State Department of Mental Hygiene.*

Lothar B. Kalinowsky, M.D.

*Attending Psychiatrist, New York State Psychiatric Institute; Associate Professor, New York School of Psychiatry, New York.*

Franz J. Kallmann, M.D.

*Chief of Psychiatric Research (Medical Genetics), New York State Psychiatric Institute, New York; Professor of Psychiatry, Columbia University, New York.*

Abram Kardiner, M.D.

*Attending Psychiatrist, New York State Psychiatric Institute, New York; Formerly Director of Psychoanalytic Clinic and Clinical Professor of Psychiatry, Columbia University, New York.*

Mavis A. Kaufman, M.D.

*Assistant Professor of Neuropathology, College of Physicians and Surgeons, Columbia University, New York; Associate Research Scientist, Neuropathology, New York State Psychiatric Institute, New York.*

Harold Kelman, M.D.

*Dean, American Institute for Psychoanalysis, New York; Editor, American Journal of Psychoanalysis.*

Lawrence C. Kolb, M.D.

*Director, New York State Psychiatric Institute, New York; Professor of Psychiatry, College of Physicians and Surgeons, Columbia University, New York.*

Henry D. Lederer, M.D.

*Associate Professor of Psychiatry, University of Cincinnati College of Medicine, Cincinnati, Ohio; Consultant, V.A. Hospital and Mental Hygiene Clinic, Cincinnati, Ohio.*

Paul V. Lemkau, M.D.

*Professor, Public Health Administration (Mental Hygiene), School of Hygiene and Public Health, The Johns Hopkins University, Baltimore, Maryland.*

Max Levin, M.D.

*Associate Clinical Professor of Neurology, New York Medical College, Flower and Fifth Avenue Hospitals, New York; Associate Neurologist, Metropolitan Hospital, New York.*

Maurice Levine, M.D.

*Professor of Psychiatry and Director of Department, and Director, Psychiatry Service, Cincinnati General Hospital, Cincinnati, Ohio.*

Nolan D. C. Lewis, M.D.

*Consultant in Research, New Jersey Bureau of Mental Hygiene; Formerly Head of Department of Psychiatry, College of Physicians and Surgeons, Columbia University, New York.*

Theodore Lidz, M.D.

*Professor, Department of Psychiatry, Yale University School of Medicine, New Haven, Connecticut; Psychiatrist-in-Chief, Grace–New Haven Community Hospital, New Haven, Connecticut.*

Louis Linn, M.D.

*Associate Attending Psychiatrist, Mount Sinai Hospital, New York.*

Robert B. McGraw, M.D.

*Clinical Professor of Psychiatry, College of Physicians and Surgeons, Columbia University, New York; Attending Psychiatrist, Presbyterian Hospital, New York.*

Preston G. McLean, M.D.

*Supervising Psychiatrist, American Foundation of Religion and Psychiatry, New York; Junior Assistant Psychiatrist, Lenox Hill Hospital, Psychiatric OPD, New York.*

Downloaded from www.dbraulibrary.org.in

Margaret S. Mahler, M.D.

*Clinical Professor of Psychiatry, Albert Einstein College of Medicine, New York; Member of the Faculty, New York and Philadelphia Psychoanalytic Institutes.*

Benjamin Malzberg, Ph.D.

*Principal Research Scientist, Research Foundation for Mental Hygiene, Inc., Albany, New York; New York State Department of Mental Hygiene.*

Jules H. Masserman, M.D.

*Professor of Neurology and Psychiatry, Northwestern University, Chicago, Illinois; Past President, Society of Biological Psychiatry.*

Rollo May, Ph.D.

*Fellow, William Alanson White Institute of Psychiatry, Psychoanalysis and Psychology, New York; Associate, Columbia University, New York.*

Martin Mayman, Ph.D.

*Director of Psychological Training, The Menninger Foundation, Topeka, Kansas.*

Milton Mazer, M.D.

*Faculty Member, William Alanson White Institute of Psychiatry, Psychoanalysis and Psychology, New York; Adjunct Associate Professor of Psychology, New York University Graduate School of Arts and Sciences, New York.*

Johannes M. Meth, M.D.

*Practicing psychoanalyst affiliated with the American Institute of Psychoanalysis.*

Joseph J. Michaels, M.D.

*Training Analyst, Boston Psychoanalytic Institute, Boston, Massachusetts; Clinical Associate, Harvard Medical School, Boston, Massachusetts.*

George Mora, M.D.

*Director, Out-Patient Department, Bradley Hospital, Providence, Rhode Island; Research Assistant, Department of the History of Medicine, Yale University School of Medicine, New Haven, Connecticut.*

J. L. Moreno, M.D.

*Director, Institute of Psychodrama and Group Psychotherapy, Moreno Institute, New York and Beacon, New York; Lecturer, New York University Graduate School of Arts and Sciences, New York.*

Donald W. Mulder, M.D.

*Consultant, Section of Neurology, Mayo Clinic, Rochester, Minnesota; Assistant Professor of Neurology, University of Minnesota Graduate School, Mayo Foundation, Rochester, Minnesota.*

Wendell Muncie, M.D.

Ruth L. Munroe, Ph.D.

*Clinical Psychologist; Visiting Professor, Graduate Division, College of the City of New York.*

Gardner Murphy, Ph.D.

*Director of Research, The Menninger Foundation, Topeka, Kansas.*

Marie Nyswander, M.D.

*Senior Supervising Psychiatrist, Postgraduate Center for Psychotherapy, New York; Consultant, New York City Department of Health.*

John F. Oliven, M.D.

*Associate Attending Psychiatrist, Columbia-Presbyterian Medical Center, New York.*

Mortimer Ostow, M.D., Med. Sc.D.

*Riverdale, New York.*

Winfred Overholser, M.D.

*Superintendent, Saint Elizabeths Hospital, Washington, D.C.; Professor of Psychiatry, George Washington University School of Medicine, Washington, D.C.*

James Papez, M.D.

*Late Director, Laboratory for Biological Research, Department of Mental Hygiene and Corrections, Columbus, Ohio; Late Professor of Anatomy, Emeritus, Cornell University, Ithaca, New York.*

Hildegard E. Peplau, R.N., Ed.D.

*Chairman, Department of Psychiatric Nursing, College of Nursing, Rutgers, The State University of New Jersey, Newark, New Jersey.*

Isidore Portnoy, M.D.

*Associate Dean, American Institute for Psychoanalysis, New York; Attending Psychoanalyst, Karen Horney Clinic, New York.*

Florence Powdermaker, Ph.D., M.D.

*Director of Research, William Alanson White Institute of Psychiatry, Psychoanalysis and Psychology, New York.*

Ralph D. Rabinovitch, M.D.

*Director, Hawthorn Center, Northville, Michigan; Consultant, In-patient Services for Children, Department of Mental Health, State of Michigan.*

Sandor Rado, M.D., D. Pol. Sc.

*President and Professor of Psychiatry, The New York School of Psychiatry; Formerly Clinical Professor of Psychiatry and Director, Columbia University Psychoanalytic Clinic (1944–1955), New York.*

Downloaded from www.dbraulibrary.org.in

Anatol Rapoport, Ph.D.

*Associate Professor of Mathematical Biology, Mental Health Research Institute, University of Michigan, Ann Arbor, Michigan.*

Morton F. Reiser, M.D.

*Professor and Director of Research, Department of Psychiatry, Albert Einstein College of Medicine, New York.*

Janet MacKenzie Rioch, M.D.

*Fellow and Trustee, William Alanson White Institute of Psychiatry, Psychoanalysis and Psychology, New York; Associate in Psychiatry, Columbia University, New York.*

David B. Robinson, M.D.

*Assistant Professor of Psychiatry, Upstate Medical Center, State University of New York, Syracuse, New York.*

Leon Roizin, M.D.

*Chief of Psychiatric Research (Neuropathology), New York State Psychiatric Institute and Hospital, New York; Associate Professor of Neuropathology, College of Physicians and Surgeons, Columbia University, New York.*

Howard P. Rome, M.D.

*Head of Section of Psychiatry, Mayo Clinic, Rochester, Minnesota; Professor of Psychiatry, University of Minnesota Graduate School, Mayo Foundation, Rochester, Minnesota.*

Milton Rosenbaum, M.D.

*Professor and Chairman, Department of Psychiatry, Albert Einstein College of Medicine, New York; Director, Psychiatric Service, Bronx Municipal Hospital Center, New York.*

Robert Rubenstein, M.D.

*Assistant Professor, Department of Psychiatry, Yale University School of Medicine, New Haven, Connecticut; Assistant Medical Director, Yale Psychiatric Institute, New Haven, Connecticut.*

Jurgen Ruesch, M.D.

*Professor, Department of Psychiatry, University of California School of Medicine, and the Langley Porter Neuropsychiatric Institute, San Francisco, California.*

Helen D. Sargent, Ph.D.

*Senior Psychologist, Research Department, The Menninger Foundation, Topeka, Kansas.*

Melitta Schmideberg, M.D.

*Chairman, Executive Committee, Association for Psychiatric Treatment of Offenders, New York; Member, International Psychoanalytic Society.*

Calvin F. Settlage, M.D.

*Associate Professor of Psychiatry, Temple University School of Medicine, Philadelphia, Pennsylvania; Director of Training, Child Psychiatry Clinic, St. Christopher's Hospital for Children, Philadelphia, Pennsylvania.*

William M. Sheppe, Jr., M.D.

*Assistant Professor of Psychiatry, University of Virginia School of Medicine, Charlottesville, Virginia.*

John P. Spiegel, M.D.

*Associate Clinical Professor of Psychiatry, Harvard Medical School, Boston, Massachusetts; Lecturer, Department of Social Relations, Harvard University, Cambridge, Massachusetts.*

Rose Spiegel, M.D.

*Fellow and Instructor, William Alanson White Institute of Psychiatry, Psychoanalysis and Psychology, New York.*

Edward Stainbrook, Ph.D., M.D.

*Professor and Chairman, Department of Psychiatry, University of Southern California School of Medicine, Los Angeles, California; Director, Clinical Services in Psychiatry, Los Angeles County General Hospital.*

Ian Stevenson, M.D.

*Professor and Chairman, Department of Neurology and Psychiatry, University of Virginia School of Medicine, Charlottesville, Virginia.*

Hans Strauss, M.D.

*Attending Neurologist, Mount Sinai Hospital, New York; Lecturer in Neurology, Columbia University, New York.*

Thomas S. Szasz, M.D.

*Professor of Psychiatry, Upstate Medical Center, State University of New York, Syracuse, New York.*

Edward S. Tauber, M.D.

*Chairman of Faculty, William Alanson White Institute of Psychiatry, Psychoanalysis and Psychology, New York; Clinical Professor of Psychology, New York University Graduate School of Arts and Sciences, New York.*

Clara Thompson, M.D.

*Late Executive Director and Chairman, Board of Trustees, William Alanson White Institute of Psychiatry, Psychoanalysis and Psychology, New York.*

Downloaded from www.bhatiapan.org.in

George N. Thompson, M.D., F.A.C.P.

*Associate Clinical Professor of Psychiatry, University of Southern California School of Medicine, Los Angeles, California; Senior Consultant in Psychiatry and Neurology, Veterans Administration, Los Angeles, California.*

William J. Tiffany, Jr., M.D. (Lt. Col., MC)

*Chief, Psychiatry and Neurology Division, U.S. Army Disciplinary Barracks, Fort Leavenworth, Kansas.*

Eilhard von Domarus, M.D.

*Late Fellow and Member of the Board of Directors, Association for the Advancement of Psychotherapy; Late Supervisor, Postgraduate Center for Psychotherapy, New York.*

Edwin A. Weinstein, M.D.

*Neuropsychiatry Division, Walter Reed Army Medical Center, Washington, D.C.; Associate Attending Neurologist, Mount Sinai Hospital, New York.*

Kerr L. White, M.D.

*Associate Professor of Medicine and Preventive Medicine, University of North Carolina School of Medicine, Chapel Hill, North Carolina.*

Earl G. Witenberg, M.D.

*Associate, and Assistant Director of Clinical Services, William Alanson White Institute of Psychiatry, Psychoanalysis and Psychology, New York.*

Eric D. Wittkower, M.D.

*Associate Professor of Psychiatry, McGill University, Montreal, Canada; Associate Psychiatrist, Royal Victoria and Montreal General Hospitals.*

Lewis R. Wolberg, M.D.

*Medical Director, Postgraduate Center for Psychotherapy, New York; Clinical Professor of Psychiatry, New York Medical College, New York.*

Israel Zwerling, M.D.

*Associate Professor of Psychiatry, Albert Einstein College of Medicine, New York; Clinical Director of Psychiatry, Bronx Municipal Hospital Center, New York.*

# PREFACE

## Silvano Arieti

Downloaded from www.dbraulibrary.org.in

PERHAPS NO OTHER FIELD of human endeavor is so encompassing and difficult to define as that of psychiatry.

Like his fellow scientists, the psychiatrist must be aware of the developments in at least a score of related fields and must subject his studies to the rigor of scientific procedure. Unlike his fellow scientists, however, he extends his investigations to the subjective world of the individual and must include, in all of its aspects, the drama of man. Thus, the psychiatrist searches areas which were, until recently, reserved to the intuition of the poet and the artist and to the speculation of the philosopher. With this increased responsibility psychiatry's horizons are larger and richer, but psychiatry's consistency is threatened. The expanding horizons and the threat to consistency, however, reflect the drama of man; they are in their turn appropriately reflected in this book.

This work represents a serious effort on the part of 111 authors to present the developments, concepts, trends, techniques, problems, and prospects of psychiatry today, in a form useful for both the expert and the beginner, in which every leading school of thought and every major approach is included. Some of these approaches converge and integrate; others diverge; but until the above-mentioned threat to consistency is eliminated by the effect of an as yet unforeseen synthesis, we must follow this multiple, diversified approach. Any other path would lead not to unity or synthesis but to that pseudo-unity and pseudo-synthesis which is reductionism in its various forms.

The orientation of the editor and the editorial board was toward completeness, representation of all points of view, and reliability, rather than uniformity or consistency. Each author was requested to cover his special field; he was free to express his personal point of view, but he was asked also to present alterna-

tive conceptions and to reduce his private terminology to a minimum, or to define it immediately.

The authors who were invited to participate in this project are in most instances recognized authorities in their respective fields. In several instances, the task of selecting the author was difficult because many people had made important contributions in the same field. Some authors could not participate because of heavy involvement in other work.

A guiding principle in the organization of the *Handbook* was that of presenting a check and balance between different approaches whenever it was feasible. For example, Chapter 3 (Ostow), illustrating the basic role of instinct in human behavior, is balanced by Chapter 4 (Bone), which emphasizes the nonbiological aspects of behavior. Chapter 28, by Cleckley, which discusses psychopathic states, is predominantly nosologic; counterbalancing this is Johnson's Chapter 42 on juvenile delinquency, which is psychodynamically oriented. Communication is treated by both Ruesch and Rose Spiegel in chapters which supplement and counterbalance each other. Goldstein in "Functional Disturbances in Brain Damage," Weinstein and Kahn in "Symbolic Reorganizations in Brain Injuries," and Brosin in "Psychiatric Conditions Following Head Injury" present three major approaches to similar topics. All major psychotherapeutic and psychoanalytic schools and physical methods of therapy are included. Chapter 89, concerning the contributions from the field of religion, was assigned to four authors. Appel, Higgins, and Ostow represent the three major religious denominations in the United States—Protestant, Catholic, and Jewish—and Von Domarus speaks from a non-Western point of view.

The *Handbook* is divided into fifteen parts, and the headings and divisions are self-explanatory. A few comments, however, are perhaps necessary. Not only does the book cover all the subjects reported in a usual textbook of psychiatry, but several topics are presented here for the first time. In spite of this broad scope, some limitations had to be imposed. For instance, chapters 1 and 2 deal with the history of psychiatry in America rather than of psychiatry in general, since the space limitations would not permit an adequate account of the broader subject. Part Five covers many important, but not all of, the possible aspects of psychosomatic medicine. Such topics as psychosomatic aspects of ear, eye, and skin disorders as well as of allergic, dental, and arthritic conditions have been omitted. Part Thirteen, reporting on contributions from related fields, could have been expanded many times. Here arbitrary selection was necessary.

In spite of these limitations, the book is offered as representative of American psychiatry today. The name American used in this context refers specifically to the receptivity to all possible approaches which is characteristic of psychiatry in the United States. Although most of the great psychiatric contributions originated in Europe, in no country other than the United States is there such willingness to listen to, try out, and evaluate all theories, methodologies, and techniques and to absorb and find a place for all or many of them.

This work could not have been accomplished without the generous cooperation of many people. Some contributors made suggestions which could not be accepted because they would have altered the purposes and aims of the book. Two or three of our contributors disagreed with editorial policies but participated nevertheless. It is obvious, of course, from the organization of the *Handbook* that the views expressed in the various chapters are the responsibility of the respective authors and do not necessarily represent those of the editor, the editorial board, or the publisher.

Downloaded from www.pdfbooksfree.pk

Sadly, the period that this work was in preparation has seen the death of four of our original contributors. On January 19, 1958, Dr. Abraham Fabian, an important writer in the field of child psychiatry, died at a young age. Dr. Fabian had not yet completed his manuscript for the *Handbook*. On February 25, 1958, Dr. Eilhard Von Domarus died after a distinguished career. Dr. Von Domarus was known particularly for his interdisciplinary approach in the fields of anthropology, philosophy, psychiatry, and religion. His major contributions, which were in the field of schizophrenic thinking, stimulated others to pursue this important subject. Dr. James Papez, one of our greatest neuroanatomists, died suddenly on April 13, 1958. Dr. Papez's contributions are too many to be enumerated here, but the one which received the most consideration is his neurophysiologic theory of emotion. And on December 20, 1958, death took Dr. Clara Thompson, a distinguished clinician-teacher whose writings have done so much to integrate the cultural approach into the framework of psychoanalysis. Dr. Thompson was Director of the William Alanson White Institute, and those of us who had the good fortune to know and work closely with her have lost a source of inspiration and stimulation. The contributions of Dr. Von Domarus, Dr. Papez, and Dr. Thompson appear posthumously in these volumes.

Some of our 111 authors also served as members of the editorial board; they have been generous with their time in the original planning as well as in the revisions of some of the papers. Miss Martha Crossen, who was in charge of the editorial staff assigned to the *Handbook*, was an invaluable help with her many suggestions concerning the presentation of the various subjects, style, and similar matters. Not only the extent of this enterprise but also the spirit of cooperation by which it was animated are indicated by the number of people I have mentioned and the many more I could add. As editor, I express to all of them my deep gratitude.

# CONTENTS

## Volume One

Contributors v
Preface xi

### PART ONE: *General*

1. American Psychiatry from Its Beginnings to World War II. NOLAN D. C. LEWIS 3
2. Recent American Psychiatric Developments (since 1939). GEORGE MORA 18
3. The Biological Basis of Human Behavior. MORTIMER OSTOW 58
4. Personality Theory. HARRY BONE 88
5. The Family of the Psychiatric Patient. JOHN P. SPIEGEL and NORMAN W. BELL 114
6. The Community of the Psychiatric Patient. EDWARD STAINBROOK 150
7. Important Statistical Data about Mental Illness. BENJAMIN MALZBERG 161
8. The Genetics of Mental Illness. FRANZ J. KALLMANN 175
9. The Psychiatric Interview. IAN STEVENSON 197
10. The Psychiatric Examination. IAN STEVENSON and WILLIAM M. SHEPPE, JR. 215

### PART TWO: *The Psychoneuroses and Allied Conditions*

11. An Introduction to Minor Maladjustments. CLARA THOMPSON 237
12. Traumatic Neuroses of War. ABRAM KARDINER 245
13. Neurasthenia and Hypochondriasis. GERARD CHRZANOWSKI 258
14. Hysteria. D. WILFRED ABSE 272
15. The Phobias. PAUL FRIEDMAN 292

Downloaded from www.dbraulibrary.org.in

16. The Anxiety States. ISIDORE PORTNOY 307
17. Obsessive Behavior. SANDOR RADO 324
18. Reactive Depressions. EMIL A. GUTHEIL 345
19. Character Structure and Character Disorders. JOSEPH J. MICHAELS 353
20. Minor Maladjustments in the Aged. ALVIN I. GOLDFARB 378
21. The Borderline Patient. MELITTA SCHMIDEBERG 398

## PART THREE: *The Functional Psychoses*

22. Manic-Depressive Psychosis. SILVANO ARIETI 419
23. Schizophrenia: The Manifest Symptomatology, The Psychodynamic and Formal Mechanisms. SILVANO ARIETI 455
24. Schizophrenia: Other Aspects; Psychotherapy. SILVANO ARIETI 485
25. Paranoid Conditions and Paranoia. NORMAN CAMERON 508
26. The Involutional Psychoses. NEWTON BIGELOW 540
27. Rare, Unclassifiable, Collective, and Exotic Psychotic Syndromes. SILVANO ARIETI and JOHANNES M. METH 546

## PART FOUR: *Psychopathic Conditions, Deviations, Addictions*

28. Psychopathic States. HERVEY M. CLECKLEY 567
29. Sexual Deviations. PAUL FRIEDMAN 589
30. Drug Addictions. MARIE NYSWANDER 614
31. Alcoholic Addiction and Personality (Nonpsychotic Conditions). ISRAEL ZWERLING and MILTON ROSENBAUM 623

## PART FIVE: *Psychosomatic Medicine*

32. General Concepts of Psychosomatic Medicine. THEODORE LIDZ 647
33. Psychology of Cardiovascular Disorders. MORTON F. REISER and HYMAN BAKST 659
34. Psychology of Gastrointestinal Disorders. THEODORE LIDZ and ROBERT RUBENSTEIN 678
35. Psychophysiologic Aspects of Respiratory Disorders. ERIC D. WITTKOWER and KERR L. WHITE 690
36. Sexual Dysfunctions in Men. EMIL A. GUTHEIL 708
37. Sexual Functions in Women and Their Disturbance. THERESE F. BENEDEK 727
38. Disturbances of the Body-Image. LAWRENCE C. KOLB 749
39. Functional Disturbances in Brain Damage. KURT GOLDSTEIN 770

Downloaded from www.dbraulibrary.org.in

## PART SIX: *Childhood and Adolescence*

40. Common Neuroses of Childhood. JOSEPH B. CRAMER 797
41. Severe Emotional Disturbances in Childhood: Psychosis. MARGARET S. MAHLER, MANUEL FURER, and CALVIN F. SETTLAGE 816
42. Juvenile Delinquency. ADELAIDE M. JOHNSON 840
43. Reading and Learning Disabilities. RALPH D. RABINOVITCH 857
44. Psychiatric Problems of Adolescence. GEORGE E. GARDNER 870

## PART SEVEN: *Language, Speech, Communications*

45. General Theory of Communication in Psychiatry. JURGEN RUESCH 895
46. Specific Problems of Communication in Psychiatric Conditions. ROSE SPIEGEL 909
47. Stuttering. DOMINICK A. BARBARA 950
48. Symbolic Reorganization in Brain Injuries. EDWIN A. WEINSTEIN and ROBERT L. KAHN 964
49. Language and Pain. THOMAS S. SZASZ 982

# Volume Two

## PART EIGHT: *Organic Conditions*

50. Neurosyphilitic Conditions. WALTER L. BRUETSCH 1,003
51. Senile Psychoses. ARMANDO FERRARO 1,021
52. Presenile Psychoses. ARMANDO FERRARO 1,046
53. Psychoses with Cerebral Arteriosclerosis. ARMANDO FERRARO 1,078
54. Epileptic Disorders. HANS STRAUSS 1,109
55. Psychoses with Brain Tumors and Other Chronic Neurologic Disorders. DONALD W. MULDER 1,144
56. Postencephalitic Psychiatric Conditions. HENRY BRILL 1,163
57. Psychiatric Conditions Following Head Injury. HENRY W. BROSIN 1,175
58. Acute and Chronic Alcoholic Conditions. GEORGE N. THOMPSON 1,203
59. Toxic Psychoses. MAX LEVIN 1,222
60. Infective-Exhaustive Psychoses. FRANKLIN G. EBAUGH and WILLIAM J. TIFFANY, JR. 1,231
61. Psychoses with Huntington's Chorea. NEWTON BIGELOW, LEON ROIZIN, and MAVIS A. KAUFMAN 1,248

Downloaded from www.dbraulibrary.org.in

62. Psychiatric Conditions Associated with Metabolic, Endocrine, and Nutritional Disorders. HOWARD P. ROME and DAVID B. ROBINSON 1,260
63. The Mental Deficiencies. GEORGE A. JERVIS 1,289

## PART NINE: *The Psychotherapies*

64. The Psychobiological Approach. WENDELL MUNCIE 1,317
65. The Organismic Approach. KURT GOLDSTEIN 1,333
66. The Existential Approach. ROLLO MAY 1,348
67. Group Psychotherapy. JEROME D. FRANK and FLORENCE B. POWDERMAKER 1,362
68. Psychodrama. J. L. MORENO 1,375

## PART TEN: *Psychoanalytic Therapies*

69. The Classic Psychoanalytic Approach. RALPH R. GREENSON 1,399

CHAPTER 1

# AMERICAN PSYCHIATRY FROM ITS BEGINNINGS TO WORLD WAR II

Nolan D. C. Lewis

Downloaded from www.dbraulibrary.org.in

PSYCHIATRY HAS DEVELOPED in combination and association with the other branches of medicine to the extent that its borders, as a specialty, in certain areas are not sharply outlined, and, moreover, most of its particular concepts and aims are exceedingly difficult to trace accurately in terms of their chronological appearance.

Medicine is seen with a matrix of economic, political, social, and cultural elements. It is but one aspect of the state of general civilization of a period, and its particular philosophy and practice are determined to a considerable extent by the current cultural conditions of its locality and time.

To attempt to trace the complex growth of psychiatric thought is an interesting experience. The most satisfactory way to understand a complicated phenomenon is to follow its pathway of genesis, but, to cover the span of time indicated by the title of this chapter, one must resort to a condensed style of communication. The topic includes more than a hundred years, during the early parts of which are revealed only a few records of basic importance in our particular field; however, there are some outstanding persons and events which appear as bright promises of progress to come in later years.

Since the aim in this chapter is to indicate some of the most important trends of thought which constitute the background of present-day psychiatry in this country, no attempt has been made to present a complete history of psychiatry in America, and thus many workers and their accomplishments have been omitted. In psychiatry as well as in other branches of medicine, one can find pioneers, men whose energy and curiosity were so great as to lead them to devote their lives to the promotion

and extension of knowledge beyond the existing outposts of what was accepted and practiced. Benjamin Rush (1745–1813), "America's first psychiatrist," was one of these men.

At the termination of the American Revolution in 1783, Dr. Benjamin Rush joined the staff of physicians at the Pennsylvania Hospital in Philadelphia, which event is often referred to as being the actual beginning of American psychiatry. Although at this time Rush was only thirty-eight years old, he was already a very famous physician. He had been a precocious student, having graduated from the New Jersey College (now Princeton) at the age of fifteen. He received his doctor's degree from the University of Edinburgh at the age of twenty-two. While at Edinburgh he studied under William Cullen (1710–1790) who was one of the most famous professors of medicine of his time, with an interest in the nervous system and in behavior phenomena. Cullen was a follower of Locke, but he originated a new doctrine of physiological significance. In his system irritability of the nervous system was of special importance, and the causes of mental disorders were within the individual, that is, endogenous. Insanity was a pathological condition of the mind and not some force entering from without, and therefore its expressions should be interpreted in the light of normal psychological functions. His *First Lines of the Practice of Physik* (London, 1777) described paranoid forms of mental disorder which he called "vesaniae." Rush was introduced to Cullen by a letter from Benjamin Franklin, a fortunate occurrence since Cullen exerted a strong influence on Rush's subsequent career which was thus oriented in the theory and therapy then prevalent in Scotland and England.

Dr. Rush, equipped with a keen mind and the best training available at the time, attacked the problems of mental disorder, a subject which was infiltrated with superstition and ignorance as well as characterized by neglect and actual brutality. He was apparently the first American physician to approach the investigation and treatment of mental disorders from a scientific viewpoint, the first American teacher to propose an original systematization of psychiatry, and the first to write a general treatise on psychiatry in America. This book, published in 1812 under the title *Medical Inquiries and Observations Upon Diseases of the Mind*, remained the only American book of its kind for seventy years.

Rush's principal remedies were purgatives, emetics, and bloodletting, of which he was a particularly strong advocate. The condition of the blood circulation in the brain was a prominent focus for his theories and therapy. He devised two curious instruments, the gyrator, based on the principle of centrifugal action to increase cerebral circulation, and the tranquilizer (1810) "to obviate these evils of the 'strait waistcoat' and at the same time to obtain all the benefit of coercion." These instruments, which were certainly rough on the patient, were decidedly "shock" measures—a form of shock therapy, and, like all shock therapies including the modern ones, were interpreted as effecting cures.

Benjamin Rush was one of the earliest, if not the first, to recommend labor and prison sentences instead of capital punishment for criminal offenses, and he consistently advocated a modification of the harsh and cruel elements in the system of criminal jurisprudence. In the minds of many medical historians, he did for America what Pinel and Esquirol did for France. His biographers are in accord that he, like many originators and creators, was a strongly opinionated man, difficult to get along with, frankly intolerant of anyone who did not agree with his theories and practices, and at times actively quarrelsome. He was a very learned man who not only served the poor of his community but was foremost in patriotism and a signer of the Declaration of Independence. His was an overwhelming personality, fully justifying the title by which he is known today, "The Father of American Psychiatry."

Dr. Adolf Meyer (1866–1950) in 1945 made the following pertinent comment:

> Had Benjamin Rush had a successor akin to his own spirit American psychiatry may have had the lead over the European and its actually colonial development. It took a hundred years before the step towards a culture for responsible life began to assert itself. . . . I do not know what the

Downloaded from www.dbraylibrary.org.in

names and teachings of the immediate successors were. . . . Psychiatry may see the influence of the 1840's in J. P. Gray.[28]

Psychiatry has always been more hospital-centered in England and other countries than it has here in America, but there were some important early, as well as later, developments of this nature that are of historical significance. For example, the old San Hipolito, established in Mexico in 1566 by the philanthropist Bernardo Alvares, was the first hospital in the Americas for the study and care of mental disorders and, of course, one of the earliest for this purpose in the whole world. At first this institution was not devoted exclusively to the treatment of mentally disordered patients, but before long the increase in the number of these cases made it necessary to restrict the admissions to nervous and mental patients.

It was nearly two hundred years before the first institution to care for the mentally disordered in the American states was organized. In 1752 the Pennsylvania Hospital in Philadelphia received insane patients, and this was followed by a few other public and private institutions. In 1773 the first public hospital exclusively for mental patients was established at Williamsburg, Virginia, then the capital of the colony. For half a century mental patients were kept at the Pennsylvania Hospital, in cells in different parts of the building, but in 1796 a new wing was provided for these patients, and at the end of another fifty years a separate building was constructed for them. The Bloomingdale Asylum was another of the early institutions for the mentally disordered. It was opened in the New York City area in 1821 as a separately managed hospital, although it had its beginnings in the earlier founding of the New York Hospital. It continues today in White Plains, New York, as the Westchester Division of the New York Hospital.

Out of a meeting held in 1844 by a group called the "original thirteen" came the organization known as the Association of Medical Superintendents of American Institutions, which was the first national society of physicians in the country. From 1893 to 1921, it was known as the American Medico-psychological Association, and is now the American Psychiatric Association, with a large and ever-growing membership. In the year of its origin (1844) the *American Journal of Insanity*, later to become *The American Journal of Psychiatry*, the official organ of the Association, was established under the editorship of Amariah Brigham (1798–1849), one of the original thirteen superintendents. The *Journal* has continued to be a leader in the field by virtue of the management of a line of distinguished editors.

In their day the "original thirteen" made a lot of psychiatric history, both as a group and as individuals. It is well to note some of their particular contributions as pioneer workers.

Samuel B. Woodward (1787–1850) was the first president of the Association of Medical Superintendents of America and a strong force in its organization. He aided in establishing the Retreat for the Insane at Hartford, Connecticut. In 1832 Massachusetts was the first state in New England to build a state hospital. Woodward supervised the construction of this hospital and became its first superintendent. He believed in specialized medical care for alcoholics, and in 1838 his volume entitled *Essays on Asylums for Inebriates* was published. He was elected to the Connecticut state legislature in 1830.

Isaac Ray (1807–1881) was an avid student of scientific matters, both in America and in Europe, and a prolific writer. He was one of the most eminent and versatile of the group. In 1841 he became medical superintendent of the State Hospital for the Insane at Augusta, Maine, and later of the famous Butler Hospital in Providence, Rhode Island. He wrote a book on mental hygiene in 1863 and was interested particularly in the relationship between legislation and mental disease. As a matter of fact, the first book in the English language concerning forensic psychiatry was published by Ray in 1838, which made a profound impression and established him as a pioneer and leader in medicolegal matters. The title of this book was *Treatise on the Medical Jurisprudence of Insanity*. It was used as an authoritative text for court work for nearly fifty years.

Amariah Brigham (1798–1849), founder of the *American Journal of Insanity*, was a dis-

Downloaded from www.ebrary.com

tinguished author, teacher, and hospital administrator whose influence for the better understanding and care of the mentally sick was widespread. He wrote lucidly on such diverse subjects as cholera, religion, clinical neurology, and clinical psychiatry. At one time he taught anatomy at the College of Physicians and Surgeons in New York City. In 1842 he was appointed superintendent of the State Lunatic Asylum at Utica, New York, the first New York State public institution for the mentally disordered. This hospital, under his inspiration and effort, became an outstanding training center for medical superintendents. His book entitled *Remarks on the Influence of Mental Cultivation Upon Health* had a remarkably wide American and European distribution.

Pliny Earle (1809–1892), in 1844, was appointed superintendent of the Bloomingdale Asylum in New York. In 1863 he became professor of psychological medicine at the Berkshire Medical Institution in Pittsfield, Massachusetts. This may have been the first chair of psychiatry in a medical school in this country, and it was certainly one of the very early additions of psychiatry to a medical curriculum in the United States. From 1864 to 1885, he was superintendent of the State Lunatic Hospital at Northampton, Massachusetts.

Dr. Earle was an able hospital administrator and an outstanding contributor to the literature on mental disease. He was well versed in the European psychiatry of the day, introducing new ideas from Germany and France. He published many statistical papers, psychiatric reviews, and historical essays, and lectured widely. In 1877 he published a statistical treatise entitled *The Curability of Insanity*. He had a critical mind and a far-reaching vision, recommending small hospitals for intensive treatment and separate ones for the incurable patients. He was also an early advocate of family care and occupational therapy.

Thomas S. Kirkbride (1809–1883), after receiving his medical degree from the University of Pennsylvania in 1832, became resident physician at Friends Asylum, followed by a residency at the Pennsylvania Hospital, and later by the appointment as superintendent of the new Pennsylvania Hospital, a position which he held for forty-three years during which time he was a progressive advocate of many reforms in the care and therapy of mental patients and served as an active participant in community affairs.

Dr. Kirkbride published many important books and articles. In 1847 he published an article on hospital construction which made such an impression that for at least fifty years the "Kirkbride type" of hospital building was adopted by many institutions. A notable number, if not most, of the "Kirkbride type" buildings are still in active use today in the older mental hospitals. Dr. Earl Bond[3] has written a most informative book, *Dr. Kirkbride and His Mental Hospital*, about this remarkable personality and his achievements.

William M. Awl (1790–1876), after some years in general practice, settled in Columbus, Ohio, in 1833, where he became active in the organization of a mental hospital, the Ohio State Asylum for the Insane. He became its first superintendent in 1838 and remained at this post for twelve years, when he was removed by political factions. He then returned to private practice and also became physician at the Ohio Institute for the Blind.

Although Dr. Awl possessed keen mental abilities, he wrote very little on mental disorders. He devoted much time and thought to the organization of the state asylum and the institute for the blind, and was concerned with the organization of the Ohio Medical Society.

Luther V. Bell (1806–1862) became superintendent of the McLean Asylum in Somerville, Massachusetts, when it had been in operation for nineteen years. He received his medical degree from Dartmouth at the early age of twenty, was in general practice for a time in New Hampshire, and also served in the state legislature, as well as participating in establishing the State Asylum at Concord before taking the post at McLean Asylum.

Dr. Bell wrote on a wide range of medical subjects, including an original description of a form of acute mania, which was named after him (Bell's disease). During his active professional lifetime he received many awards and

Downloaded from www.brainpan.com

honors and was a participant in a variety of local and national civic activities. He was the only one of the "original thirteen" to have served in the Civil War, during which he died, in 1862, in an army camp near Washington, D.C., where he was a medical inspector.

John S. Butler (1803–1890), after receiving his medical degree from the Jefferson Medical College in Philadelphia in 1828, entered private practice in Worcester, Massachusetts, until 1839 when he was appointed superintendent of the Boston Lunatic Hospital. Here, he soon instituted various reforms and striking improvements in the hospital treatment of patients. In 1843 Dr. Butler was elected superintendent of the Retreat for the Insane at Hartford, Connecticut, to succeed Dr. Amariah Brigham, who had gone to Utica, New York. Dr. Butler remained at the Retreat for nearly thirty years, during which time he demonstrated outstanding leadership and a progressive spirit. He remained active in medical matters for another ten years after retirement from hospital service.

Nehemiah Cutter (1787–1859) received his medical degree from Yale University in 1817 and entered private practice in Pepperell, Massachusetts, where he gradually built up a specialty of treating the mentally ill to the point of organizing a private hospital known as the Pepperell Private Asylum. This hospital was successful despite the prejudice extant against private mental institutions. The hospital burned down in 1853 and was not rebuilt; however, Dr. Cutter continued in a successful career as a practicing physician.

Charles H. Stedman (1805–1866) graduated from the Harvard Medical School in 1828, and in 1830 was appointed resident surgeon at the United States Marine Hospital at Chelsea, Massachusetts, where he worked for ten years. In 1834, being keenly interested in the theories of Gall and Spurzheim, he edited a translation of Spurzheim's book on brain anatomy.

Dr. Stedman started a private practice in Boston in 1840, and two years later he became superintendent of the Boston Lunatic Hospital, following the resignation of Dr. Butler. Here he proved to be an exceptionally able administrator and student of mental disorders. He was also particularly active as a staff member and consultant in medicine and surgery in various other hospitals in the city.

Samuel White (1777–1845) opened an office for private practice at Hudson, New York, in 1797 at the age of twenty years. He apparently never attended a medical school but gained his professional education by means of the apprentice system, which was possible in those early times. In 1830 he opened a private hospital, called Hudson Lunatic Asylum, where he functioned successfully until his death. From the historical fragments that have been recorded about his life and ideas, one may assume that he was progressive in thought, was accepted as an authority by his contemporaries, and that he utilized the best methods known in practice.

Francis T. Stribling (1810–1874) obtained his medical degree from the University of Pennsylvania in 1830. He was in private practice for a time in Staunton, Virginia, his native town, and at the age twenty-six years was appointed physician to the Western Lunatic Asylum of Virginia. Dr. Stribling left very little by way of published work, but he was an able clinician and was one of the early advocates of training for attendants, of prompt treatment for acute cases, and of occupational therapy.

John M. Galt (1819–1862) was a young man of twenty-two when he received his medical degree from the University of Pennsylvania in 1841, and in this year he was made the first superintendent of the Williamsburg Asylum which had been established many years before (1773). He was an unusually erudite man who read in many languages and was thus able to bring important psychiatric literature to the attention of American physicians. In 1846 he published a book entitled *The Treatment of Insanity* which contained a summary of about all of what was known of mental disorders. Other books and many articles came from his pen, and, although his life span was comparatively short, his was a powerful influence for progress since he advocated freely the proper keeping of records, the performance of autopsies, the value of research, and the need for changes in the legal

Downloaded from www.dbraulibrary.org.in

aspects of psychiatry. He utilized in his hospital several of the adjunct therapies that are in vogue today.

Of these founders of the Association of Medical Superintendents of American Institutions for the Insane, six were in charge of state institutions, five directed incorporated hospitals, and two were the proprietors of private hospitals. From the intelligence of this remarkable group of men and the examples they set in their respective areas have developed many of our modern attitudes and endeavors in the specialty. At the time they formed their national association, European psychiatry, although still relatively young as a medical discipline, had progressed to a point where the mentally sick were no longer treated as monsters or criminals but as patients suffering from very serious disorders.

Another important powerful force in the evolution of American psychiatry, for many years after 1841, was Dorothea Lynde Dix (1802–1887) of Boston. This remarkable woman, a retired schoolteacher, became "shocked" by what she saw in the care of mental patients in certain places, where they were locked up in filthy cells and not only were neglected but often treated brutally as well. Through her widespread activities not only in the United States but also in Canada, the British Isles, and on the European continent, reforms were instituted successfully through various government agencies. She is credited with having been directly responsible for creating or extending the facilities of a total of thirty-two hospitals. In this country, twenty states built or enlarged mental hospitals as a result of her personal efforts. The Government Hospital for the Insane (now St. Elizabeths Hospital) at Washington, D.C., is among those that she aided in establishing.

On the second day of the second annual meeting of the American Neurological Association held at the College of Physicians and Surgeons in New York City in 1876, with sixteen members present, Dr. George M. Beard (1839–1883) presented a paper entitled "The Influence of Mind in the Causation and Cure of Disease and the Potency of Definite Expectation." This paper was remarkable in its originality, as it dealt clearly with what is now known as psychosomatic medicine. Such a presentation was new and startling, in fact, so startling that the famous neurologist, Dr. William A. Hammond, remarked during the discussion that, if the doctrine advanced by Beard was to be accepted, he "should feel like throwing his diploma away and joining the theologians."

According to the original report in the *Transactions of the Association*, "Dr. Beard maintained that disease might appear and disappear without the influence of any other agency than some kind of emotion. Mental qualities, like drugs, could neutralize therapeutics and they could also increase the effect of drugs. Fear, terror, anxiety and care, grief, anger, wonder and expectation were regarded as the most likely to produce disease." To the criticisms referring to mental therapeutics as being nothing new, Beard replied that he had not implied that psychotherapy was new, but that it had not been carried out in a systematic manner by the profession. Although there was much vigorous critical discussion and skepticism, the brilliant Beard, pioneer in the field, defended his position with confidence and ability. When Beard's famous paper entitled "Neurasthenia (Nervous Exhaustion) and Morbid Fears as a Symptom of Nervous Disease" appeared (1869), his term "neurasthenia" was gradually adopted over the whole world as "Beard's disease," and he was duly recognized as a great pathfinder.

Among the prominent American alienists of the 1880's were Allan McClane Hamilton, Walter Channing, John Chapin, John P. Gray, W. A. Hammond, and E. C. Spitzka. Dr. Hammond, usually considered as a neurologist, also taught psychiatry and wrote a book, *Insanity in Its Medical Relations*, which came into active use as a text. Dr. Spitzka, in 1883, published the *Manual of Insanity*, which included about all that was known and taught of the subject. Although the term "paranoia" (which means "mental disorder" in the original Greek) was introduced into medicine by Vogel in 1764 after which it had rather widespread applications, it was Dr. Spitzka of New York

Downloaded from www.brainvolume.org

who, out of a welter of conditions and names, differentiated it as a specific disorder. It is therefore an American-named psychosis, as we use and understand the term today.

One of the strongest influences to bear upon American psychiatry was the work of Emil Kraepelin (1856–1926). He was professor of psychiatry successively at Dorpat, Heidelberg, and Munich and is generally considered to have been the greatest of all descriptive psychiatrists whose concepts increased and enriched the whole field. He was a systematizer who, following periods of active analysis of data, attempted a synthesis of scattered facts and ideas. Kraepelin had a large amount of clinical and laboratory material with which to work, and he made his studies according to the natural history method, in that he followed the course of mental disorder in the individual cases from the earliest symptoms on through to the termination. By means of this method, it became possible for him to make a new grouping of mental disorders on which some basis for prognosis, therapy, and prevention could be ascertained. He was after the causes, the course, and the outcome of mental disorders with reference to any pathological lesions and processes, and he was interested in any mental trends and clinical pictures that tended to terminate in various degrees of deterioration.

In 1883 Kraepelin published the first edition of his *Psychiatrie* which subsequently passed through several revisions and translations into other languages. The English translation of the book changed the whole aspect of classification of mental disorders in America. His outstanding contributions to the description and delineations of dementia praecox states and manic-depressive conditions have held a central position in psychiatric thought and practice from the time they were first introduced to the present day. His clinical descriptions of the psychoses can still be read with a great deal of profit by the student of psychiatry.

The concept of dementia praecox was later elaborated and expanded into schizophrenia by Eugen Bleuler (1857–1939) in 1911. Among this eminent Burghölzli professor's numerous original contributions which have vitalized psychiatry in all civilized areas are the psychology of dementia praecox (schizophrenia) including the phenomena of ambivalence and of autistic thinking and the delineation of the schizoid and syntonic personalities, and some later biophilosophical theories.

About one year after the birth of Kraepelin, a man was born who was not only to revolutionize psychiatry but to influence the philosophic thought of the whole world, namely Sigmund Freud (1856–1939). After a period of interest in neurology, Freud went to Paris to study under Charcot, who was the outstanding clinical neurologist of his day, and who had developed a system of hypnosis for the treatment of hysteria. After returning home to Vienna, Freud carried out some studies of his own, and in 1895 the *Studien ueber Hysterie* was published, followed by the *Traumdeutung* in 1900. These studies represented a new approach to the investigation of human motivation and to the phenomena of the unconscious. Freud had replaced hypnosis with his method of free thought association and dream interpretation.

Freud's technique made it possible, for the first time, for a physician to devote his time in attempting to understand the innermost working of the patient's mind rather than directing the patient's life in matters that were obscure to everyone involved. For a number of years Freud worked alone, but later, when well on his way to success and despite the great amount of opposition from critical contemporaries, students of the mind began to take an interest in the concepts, and a number of now-well-known names appear in the list of his special pupils, supporters, and co-workers. Among these are Karl Abraham, Sandor Ferenczi, Carl Jung, Alfred Adler, Wilhelm Stekel, Otto Rank, Hans Sachs, Paul Federn, and Ernest Jones.

Jung, Adler, Rank, and Stekel later developed some special modifications of psychoanalysis contrary to Freud's wishes. He insisted that these modifications were not really psychoanalytic and were of such a nature that they necessitated his breaking off professional relationship with these workers. However, these

Reproduced from www.dbraun.org

doctrines all found followers in America and elsewhere, as have the later modifications of some of Freud's theories and techniques such as those of Sandor Rado, Franz Alexander, Karen Horney, and Harry Stack Sullivan among others in this country.

In 1909 Freud made a personal appearance in America to lecture under the auspices of Clark University in Worcester, Massachusetts. It may be said that practically everything that Freud wrote has at one time or another been translated into the English language, but in those earlier years America became rather thoroughly acquainted with the Freudian literature through the efforts of Abraham A. Brill, who first translated Freud's works, and of Smith Ely Jelliffe and William A. White, both of whom were outstanding leaders in psychiatric thought and freely disseminated such knowledge through their prolific writings of books and articles. Psychoanalysis soon gained a wide acceptance and became gradually incorporated into psychiatric thought and procedure.

Psychoanalytic teaching and practice were organized and standardized by the establishment of psychoanalytic institutes and societies directed and supported by highly trained specialists in several large cities in America as well as abroad. The psychoanalytic literature which has accrued over the years reveals a considerable diversity of trends, but in the main they fall into two general categories—(1) that which includes investigations aimed to extend the field of metapsychology where the unconscious structure of the super-ego, the material gained by hypnosis, and the pregenital infantile frustrations are the principal topics, and (2) that which attempts to adapt current theories to clinical confirmation. There are now an ever-increasing number of able workers interested in testing the validity of the libido theory and other concepts pertaining to various psychiatric conditions, in understanding the physiological manifestations of mental attitudes by means of combined studies in cooperation with modern biological laboratory disciplines, and in establishing an interpretation of neurotic symptoms in terms of somatobiological activity.

A group of Fellows of the American Psychiatric Association formed a Section in Psychoanalysis within the Association in 1933, and a year later a symposium was given in this section on the relation of psychoanalysis to psychiatry, which marked the beginning of a new era in the history of psychoanalysis in America. The conclusions were to the effect that the psychoanalytic formulations of Freud were established as indispensable to the procedures of treatment and research, and that requirements of technique, the investigation of unclear or incomplete knowledge, and the application of therapeutic procedures to selected clinical groups were being continually studied and that it was to be expected that modifications of psychoanalytic conceptions would take place to a considerable extent.

Another prominent psychiatric development took place under the leadership of Adolf Meyer (1866–1950). He came to America from Switzerland as a young man, well trained in neuroanatomy, neuropathology, psychiatry, and philosophy. Following services as pathologist in state hospitals of Kankakee, Illinois, and Worcester, Massachusetts, he became director of the New York State Psychiatric Institute on Wards Island where, as early as 1906, he was working on his concept of integration with the total individual as a unit. From the beginning he emphasized the pathological evolution of the symptoms of psychiatric disorders in terms of all of the presenting facts. His was a dynamic system.

Later, in 1912, when Dr. Meyer became Director of the Henry Phipps Psychiatric Clinic and Professor of Psychiatry at the Johns Hopkins Medical School, he formulated through the subsequent years the reaction type of behavior and his concepts of social adjustment. He created a fresh, unique attitude toward the individual as a totality and brought the term "psychobiology" into the foreground. By training many psychiatric teachers in this discipline, he created a school of thought—particularly, the concept of psychobiology—which has had a notable influence on psychiatric developments, particularly in this country and Great Britain.

Early in the 1900's Elmer E. Southard

Downloaded from www.dbraybooks.com

(1876–1920), another great ferment in psychiatry, developed the psychopathic-hospital idea and also brought into the foreground the training of social workers in psychiatry. Adolf Meyer had brought social work into psychiatry as early as 1904, but in 1912 it was Southard who expressed clearly the social aspects of psychiatry and extended its interests into the training of social workers and into industrial hygiene. His famous book *The Kingdom of Evils,* with Mary C. Jarrett as coauthor, was published in 1922 after Southard's death. This book dealt with social case work, presenting 100 case histories together with a classification of social divisions of evil. In 1919 he said, "Social psychiatry is far from the whole of mental hygiene, for mental hygiene includes also the far more difficult and intriguing topic of the individual as related to himself and his organ processes." Here is reflected the keen interest he always had in the organic reactions of the body and brain which were the principal foci of his original researches.

It seems that the term "mental hygiene," in its generally accepted meaning, first appeared in the literature in 1843 in a book entitled *Mental Hygiene or an Examination of the Intellect and Passions Designed to Illustrate Their Influence on Health and Duration of Life* by Dr. W. C. Sweetser, Professor of Therapy and Practice of Physic at the University of Vermont. Dr. Isaac Ray also wrote a book ten years later entitled *Mental Hygiene.* He defined it as the art of preserving the health of the mind, and he emphasized that all methods of preserving mental health came under it. However, many years were to pass before the mental-hygiene movement became a force for psychiatric progress. In 1908 Clifford Beers published his book, *The Mind that Found Itself,* which created a tremendous interest. By his efforts, together with those of Adolf Meyer and others, the National Committee for Mental Hygiene was organized in 1908. Dr. Meyer suggested the name "mental hygiene" for this committee, which has now been changed to National Committee for Mental Health. It began with twelve charter members, among whom three were the prominent psychiatrists, August Hoch, Adolf Meyer, and Frederick Peterson; the famous psychologist, William James; and the Johns Hopkins internist, Lewellys Barker. In 1912 Dr. Thomas W. Salmon (1876–1927) was appointed director.

The chief aims of the Committee were clearly stated: (1) to work for the protection of the mental health of the public; (2) to strive to raise the standard of care for the mentally ill and for those in danger of becoming mentally disordered; (3) to promote the study of all types of mental illness and to disseminate information concerning their causes, therapy, and prevention; (4) to obtain from every available source reliable data regarding methods of dealing with mental disorders; (5) to enlist the help of the federal government to the extent desirable; and (6) to coordinate the existing agencies and to aid in the organization, in each state, of an allied but independent society for mental hygiene.

The dynamic concepts of Freud, Pierre Janet (1859–1947), and Adolf Meyer strongly emphasized psychotherapy. The early workers in America as well as elsewhere had considered psychotherapy in terms of moral treatment, occupational therapy, recreational activities, and similar procedures, but the followers of the exponents of dynamics, such as A. A. Brill, S. E. Jelliffe, and W. A. White, among others, basing their teachings on the concept that mental symptoms are the expressions or symbols of meanings that are obscure and hidden in the unconscious, made a widespread impact on psychotherapeutic practice which proceeded along the lines of what could be learned from a study of what was going on in the deeper recesses of the patient's mind.

Under the influence of some of Janet's ideas and formulations but contributing a number of concepts of his own, was the Boston psychiatrist Dr. Morton Prince (1854–1929) of Tufts Medical School. He worked with what he termed "co-conscious phenomena," adding much to the knowledge of hysteria, multiple personalities, and hallucinations. He never fully accepted the significance of the unconscious in the Freudian sense of its meaning, and he disagreed with Freud's theory of the

Downloaded from www.dbraylibrary.org.in

libido. He founded the *Journal of Abnormal Psychology*. His famous case of a girl with multiple personality was studied for over seven years and published in 1908 under the title *Dissociation of a Personality*; it is probably the most complete report ever made of this phenomenon. Another interesting contribution to the literature was his *Experimental Study of Visions*. He applied psychotherapy within the framework of his personal concepts.

Trigant Burrow (1875-1951), originally a Freudian, organized his own special group of students in what he termed "phyloanalytic" investigations of human behavior and social adjustment. He stressed the defensive distortions of man's natural reactions through the dominance of visual-verbal part functions resulting in internal tensional disorders called neuroses. He developed a system of psychotherapy aimed at the reduction of these tensions.

Paul Schilder (1886–1940), coming to America after having had a distinguished career in Vienna, contributed to the knowledge of several areas of the psychiatric and neurologic fields. His concepts of integration and his development of the body-image significance in various mental states are among the subjects with which he enriched the literature. The work of Harry Stack Sullivan (1892–1949) and his associates systematically developed the theme of interpersonal relationships, which Freud had taken into consideration but did not develop or emphasize in the same way. The basis of some of Sullivan's conclusions stemmed from the assumption that parataxic illusions are derived from earlier anxiety experiences. To Karen Horney and Sullivan, neuroses were products of cultural environment and distorted interpersonal relationships rather than based on the preformed instincts, as Freud thought. Sullivan organized and published the journal called *Psychiatry*, which still serves as a useful medium for psychiatric thought.

In the field of therapy as well as those of pathology and diagnosis, a significant event was the obtaining in pure culture of the *Treponema pallidum* in 1911 by Hideyo Noguchi (1876–1928), and in 1913 Joseph W. Moore (1879–1957), of New York, and Noguchi demonstated the spirochete in the brain tissue of patients dying of general paresis, thus proving that this mental disorder was precipitated by a form of syphilis. Following this laboratory demonstration, general paretics were treated by the arsenicals and other drugs used for syphilitic disorders, but without marked success. In 1918 Julius Wagner von Jauregg (1857–1940) of Vienna announced his now-well-known malarial therapy for general paresis. This treatment, strikingly successful as compared to other known procedures, promptly came into general use, and the first to apply it in America was the staff of the St. Elizabeths Hospital in Washington, D.C., from which the first paper in English on the results of this treatment was published, as far as I am informed.[25]

During World War I psychiatry was brought more prominently into the foreground and received a long-neglected consideration among the other medical specialties. At the beginning of the war the government called upon the National Committee for Mental Hygiene for aid, and this organization was exceedingly fortunate to obtain and recommend the services of Dr. Thomas W. Salmon (1876–1927), who had a remarkable organizing ability. Through his efforts it was demonstrated that psychiatry could contribute a great deal to the efficiency of the armed services by recognizing and treating the war neuroses. Salmon and his associates in the Army, with its numerous civilian as well as military personnel problems, were instrumental in pointing out the relationship of these problems to medical and social disciplines. By extraordinary patience and hard work, Salmon overcame seemingly insurmountable obstacles and problems. He had confidence in the future of psychiatry and was always alert to defend it against any unfair criticism. He profoundly influenced the growth and course of psychiatry in America, and it may be pointed out that what he did for the Army has stood the test of time, as his methods are still more or less in force and, in the minds of some, are still the best available, having been so proved in World War II and in the Korean campaign.

Downloaded from www.dbraulibrary.org.in

One of the most significant and practically important phases of the mental-hygiene movement to the credit of American psychiatry was the creation of child-guidance clinics, which started with William Healy (1869– ) in 1909 in the institute devoted to the study of juvenile problems in Chicago. This was the pioneer child-guidance clinic, although the term was not coined until 1922. The Boston Psychopathic Hospital, opening in 1912, accepted children from the first, as did the Phipps Psychiatric Clinic in Baltimore where a special outpatient children's clinic was active as early as 1913. The Allentown State Hospital in Pennsylvania was also a pioneer in this field, with a clinic under way in 1915. Child-guidance clinics developed rapidly in other cities and areas under such well-known specialists as Lawson Lowrey (1890–1957), David Levy (1892– ), Frederick Allen (1890– ), J. S. Plant (1890–1946), and Douglas Thom (1887–1954) and are continuing to grow in size and distribution, as the needs for the study and correction of the behavior disorders of childhood are still greater than the available facilities.

Researches of many types have been carried on from early times, particularly on nervous-system anatomy and functions, but intensive organized research, as such, on mental disorders is of comparatively recent development. For example, in 1884 Dr. I. W. Blackburn of Philadelphia, an excellently trained pathologist with a particular interest in the relationship between the brain and mental diseases, was appointed special pathologist at the Government Hospital for the Insane (now St. Elizabeths Hospital). He was the first full-time pathologist in a mental institution in America (at least I can find no record of an earlier full-time appointment of this kind). He published twenty-five papers and books during a period of twenty-five years, many of them illustrated by his own hand, since he was a skilled artist as well as a scientist.

Probably the first large-scale stride toward organized systematic psychiatric research in this country was made in 1895 by the establishment of the Pathological Institute of the New York State Hospitals as an integral part of the state hospital system. Located at first in New York City with Dr. Ira van Gieson (1865–1913), a neuropathologist, as director, this institute was later constructed on the grounds of the Manhattan State Hospital on Ward's Island where it remained for many years under the successive directorship of Adolf Meyer, August Hoch (1868–1919), and George Kirby (1875–1935). In 1929 the old institute was replaced by a modern building constructed as a unit in the Columbia-Presbyterian Medical Center and named the New York State Psychiatric Institute and Hospital. During the past sixty years this institute has been unique, since it has been supported for the sole purpose of research.

The Boston Psychopathic Hospital built in 1912 under the direction of Elmer Southard (1876–1920), the State Psychopathic Hospital under Dr. Albert M. Barrett (1871–1936) constructed in 1906, and later the Colorado Psychopathic Hospital under Franklin Ebaugh (1895– ) are among the earliest centers with active research units employing full-time research workers. From these beginnings acting as stimuli, there have been many similar developments in university and hospital centers. Moreover, the philanthropic foundations have devoted large sums of money to train young research workers in the psychiatric field, to support investigators already in key positions, and to finance laboratories where original studies could be carried out. In 1934 the Scottish Rite Masons of the Northern Masonic Jurisdiction began their support of research projects in schizophrenia, which has continued to the present day with accomplishments that have served as an example of the progress that may be expected with the growth of research interests and financial aid.

The work of Sir Charles Sherrington (1857–1952) of England on the physiology of the nervous system and of Walter Cannon (1871–1945) of America on the relationship between the emotions and the vegetative nervous system, as well as the investigations of the followers of Pavlov's (1849–1936) concepts and to a lesser extent those of Kretschmer (1888– ) on bodily conformation have served as a background upon which the struc-

Downloaded from www.pdfbooksfree.org.in

ture of "psychosomatic" or "comprehensive" or "total" medicine has been erected and expanded in recent years. The term "psychosomatic medicine" has been known for at least 100 years, but in the sense of the modern clinical application and theories in psychopathology and medical problems it is rather distinctly an American development in which Adolf Meyer and Smith Ely Jelliffe contributed a great deal.

Here it is well to remember that George Beard of New York described a syndrome in 1868 which he called "neurasthenia" and under which he included pathological fatigues and so-called nervous exhaustion. He said, "While modern nervousness is not peculiar to America, yet there are special expressions of nervousness that are found here only: and the relative quantity of nervousness and of nervous diseases that spring out of nervousness are far greater here than in any other nation in history and it has a special quality." These disorders, regardless of whether there were more of them in America than elsewhere, were the disorders to which Silas Weir Mitchell (1829–1914) of Philadelphia devoted much thought and therapy. He ascribed them to deficiencies in fat, blood, and other elements and recommended complete rest as the cure. From the general interest in so-called functional disorders came one of the special roots now known as psychosomatic medicine.

Forensic psychiatry, as such, has developed slowly in America through the years despite the fact that there have been outstanding pioneers with constructive concepts and writings. Beginning with Isaac Ray's book in 1838, one finds interesting and pertinent references to the relationship between psychiatry and the law, and recommendations for dealing with these complicated problems. In more recent years the publications and personal influence of such authorities as L. Vernon Briggs (1863–1942), William A. White (1870–1937), Bernard Glueck (1884– ), Winfred Overholser (1892– ), and Gregory Zilboorg (1890– ) have made excellent contributions to the subject in ways that have favorably modified some of the practical legal procedures.

Since World War I, industrial psychiatry, school and college psychiatry, and other penetrations of psychiatry into public affairs have made notable strides that have led deeper into the understanding of emotional phenomena. Clinical psychology, occupational therapy, and social-service activities, all of which are valuable psychiatric auxiliaries, have shown remarkable progress. In the field of clinical psychology, the use of the Rorschach and other projective techniques became established and were freely applied to psychiatric problems. The social worker, from the first, proved to be practically indispensable in investigating the home situation, in the problems of hospital patients and of the child-guidance field, and in interpreting the nature of the problem to the family as well as aiding in the readjustment of the improved patient in the community.

Occupational therapy, in the broad sense of its original definition ("any activity, mental or physical, definitely prescribed and guided to hasten recovery from disease or injury"), has always accompanied enlightened, humanitarian treatment, especially in the field of mental illness. It may have begun in the United States with the opening of the Pennsylvania Hospital in 1752, when the board of managers provided wool-carding and spinning equipment "to employ such Persons as may be capable of using the same." Activities ranging from music, games, and arts and crafts to industrial or housekeeping tasks and education were utilized as an essential feature of the nineteenth-century "moral treatment" as mental hospitals opened in Philadelphia, New York, and Boston. Nursing personnel frequently supervised these activities, though no formal preparation for such leadership was available until Susan E. Tracy established a course for student nurses at Adams Nervine Hospital. By 1917, when the Society for the Promotion of Occupational Therapy (later the American Occupational Therapy Association) was formed, two more training centers were functioning. Three other schools, originated during World War I to train "reconstruction aides" for Army hospitals, continued to grow and were among those accredited in 1938 by the American Medical Association.

Downloaded from www.dbtlibrary.com

Graduate therapists, like their predecessors, worked in various hospitals and rehabilitation centers, using a wide range of activities to promote patients' recovery from physical as well as mental illness.

As late as the 1930's it was advocated by many that psychiatry was not a science but an art, since the personality of the psychiatrist bulks so large in the practice of mental medicine, and psychiatry could never free itself from its philosophic elements. Regardless of what was thought and said, an "American school" was developing, and by 1937 it had the following characteristics, most of which have persisted.

The American school had started to use the new shock therapies which later became so widespread in application, and it had also recognized the great possibilities of sociology and cultural anthropology as contributors to psychiatric knowledge. However, this American movement was not merely a composite eclecticism, but it was beginning a positive frontal attack upon the problems of mental medicine which was new, frank, and critical. It advocated treating all behavior, thought, and feeling of an individual as real or actual performance or, in other words, as a personality experience. The differentiation of human performances and capacities is just as much a real dynamic phenomenon as is any feature of somatobiological processes or of social culture. It also emphasized proceeding along the following general lines in dealing with a particular psychiatric problem: (1) the correction of all recognized defects in the soma of the patient; (2) the establishment of adequate rapport between physician and patient; (3) the careful study and evaluation of familial, economic, and social situations; (4) the detailed investigation of the personality problem; (5) the attitude toward and adjustment to reality; (6) the ventilation of conflicts and desensitization of the patient; (7) the institution of re-educational training; (8) the formation of an adequate philosophy of life; and (9) the desirability of follow-up studies.

The American school recognized and attempted with considerable success to correct the lack of adequate instruction and training in psychiatry in many of the medical schools; in fact, in most of the medical centers, psychiatry was inadequately represented. However, despite these educational handicaps, a greater number of medical students sought postgraduate training, and the number of women physicians entering psychiatry became notably larger since earlier strong prejudices against them had subsided considerably. It is a matter of interest to note that in 1890 a law was passed by the New York State legislature authorizing the appointment of at least one woman physician in each state hospital. Obviously, we have come a long way during the last half century. The lack of sufficient knowledge of mental hygiene and of the psychic components of disease on the part of the general practitioners, and the lack of proper psychiatric information among the clergy and the population in general was also well recognized, and movements were started to try to correct these deficiencies.

In recent years, and particularly since World War II, more adequate methods and techniques suitable for attacking vital problems have appeared and are still in various stages of evolution. In scrutinizing the past in an attempt to perceive the simple beginnings and origins of the present-day science of man, one should remember that each worker, regardless of his individuality, is in some degree dependent on the thought and practice of his time, uses to some extent formulations suggested by others, and is stimulated and influenced by the particular interests of his friends and colleagues.

CHAPTER 2

# RECENT AMERICAN PSYCHIATRIC DEVELOPMENTS

## (Since 1939)

George Mora

Downloaded from www.dcaulibrary.org.in

DURING THE LAST TWO DECADES, psychiatry has undergone a more extensive development than any other field of medicine. The challenge of discovering and explaining more of the various aspects of man's behavior, individual or collective, normal or pathological, has nowhere been met with greater enthusiasm than in the United States. Data have been collected in such volume that it would disorient even the most diligent and patient researcher. A brief chapter on this development can throw light only on certain aspects—the better-defined ones—leaving others in shadow. It will achieve its purpose if it conveys an impression of the developmental trends of the manifold aspects of psychiatry. Only the very last part of the chapter will deal with some general issues which go beyond the geographical and temporal limitations of the two decades under consideration. This has seemed a natural conclusion for a chapter which is intended to be essentially a historical account of this field of medicine. As such it aims to represent the dynamics and the historical continuity of a process, to understand the present situation on the basis of the past, and to anticipate some of the future developments on the basis of the present.

One final point of explanation belongs in the introduction to this chapter: in many

sections dealing with special aspects of psychiatry—such as the different schools of psychoanalytic thought, the development of pharmacological therapy, etc.—some of the people who have made particularly significant contributions in these fields have been mentioned. Full source information, however, has not been provided in either text or bibliography. This omission was a deliberate one, first, for reasons of space limitations, second, because the separate chapters dealing with these subjects in detail provide full bibliographic references. It seemed more economical of effort, therefore, to limit the references for this chapter to the points outlined in the note preceding the bibliography.

## ¶ General Trends of Psychiatry

### *National Recognition*

The condition of psychiatry at the end of the third decade of the century presented a characteristic picture of a transitional phenomenon—the end of one period and the introduction of another. The stable structure on which psychiatry was based in this country, from the founding of the American Psychiatric Association in 1844 to the beginning of the century, seemed to undergo a process of intimate revision. For many years the field of psychiatry had been divided into two main schools, the organic and the psychobiologic—the first emphasizing psychological parallelism or reduction of psychic phenomena to organic causes, the second—represented especially by Adolf Meyer and his disciples—emphasizing the importance of environmental as well as biological factors in the causation of psychological disturbances.

It was only in the late thirties that an initial, still timid, trend toward a better integration of psychiatry into the social structure of the American culture started to become evident.

A slow, but significant, development of the administration policies of mental hospitals, an attempt to integrate such institutions into the community through an intensive program of aftercare, a beginning of the recognition of the value of the training of personnel working with mental patients at every level, from the psychiatrist to the social worker, the nurse, and the attendant—all this, even if limited to isolated areas in the country, pointed to a greater flexibility of approach to mental patients and to an initial broadening of viewpoints, harbinger of further developments.

Research in psychiatry also entered into a new phase in the third decade of the century. New fields—especially psychosomatic medicine, shock therapies, electroencephalography, child psychiatry, criminology, alcoholism—became major areas of investigation. Equally significant, even if outside the strict realm of psychiatry, were the studies of psychological tests (especially projective techniques), of the experimental neuroses, of the ecological aspects of psychiatry, to which representatives of allied disciplines contributed in a joint effort. Clinics for mental patients in which psychotherapeutic methods of different kinds were employed more frequently were organized all over the country in a relatively short time. In the thirties, child psychiatry too went through a period of tremendous development, at times more as a response to emotional demands than to scientific demands. The International Congress of Mental Hygiene and the White House Conference on Child Health and Protection, both held in 1930, were representative of this new interest in the preventive aspects of psychiatry in a broader cultural context.

At the base of these new trends was the recognition, brought about by the psychoanalytic school, of the importance of early emotional experiences for later psychological disturbances. It was during this period that a large number of outstanding psychoanalysts emigrated to the United States from Europe, following antisemitic persecution. The impact of their thinking hastened the acceptance of psychoanalysis as an essential part of psychiatry from a genetic and symptomatological as well as a therapeutic viewpoint. The consequence was a broadening of the view of the psychiatrist, decreasing the barrier between

Downloaded from www.cambridge.org

normal and abnormal in psychology and making possible a formulation of the patient-therapist relation that proved to be of high pragmatic value.

These new trends counteracted the tendency of psychiatry to remain rooted in a biological substratum, and brought a new phase in the relationship between neurology and psychiatry. The introduction of the shock therapies in the late part of the thirties revived that perennial problem in a more empirical, yet still obscure fashion, for the psychiatrist as well as the neurophysiologist. Insulin, Metrazol, and electric shock therapies doubtless constituted a major event in American psychiatry, in spite of the different responses they elicited in scientific milieus. The emphasis on psychotic patients raised by the developments of shock treatment counterbalanced the emphasis on neurotic patients brought about by the psychoanalytic therapy, and contributed to create a better integration and a more meaningful platform for further developments.

World War II acted as a catalyzing agent in the growth of psychiatry. Under its impact, new developments took place, as the need of the moment called for the application of psychodiagnostic and psychotherapeutic procedures on an extensive basis. Clinical psychologists and social workers were employed extensively in this program, which was later carried on by the Veterans Administration.

The new techniques of evaluation and of treatment proved to be quite useful even in normal peaceful conditions, and they tended to foster a more flexible attitude toward short-term psychotherapy, in contrast to the long-term psychotherapy of the classical tradition. This was also the result of a general trend toward an interdisciplinary approach to scientific problems. As the boundaries between normal people and neurotics became less rigid, a more cooperative and understanding attitude developed among members of the same staff in relation to individual roles played in connection with the patient. This development was particularly evident in the new fields of child psychiatry, group therapy, and rehabilitation, in which psychologists and social workers took active and determining parts.

From a general viewpoint, the psychological problems posed by the war were carried over and better defined in the transitional period that followed the end of the war. The importance of psychiatry gained nationwide recognition. This fact, aside from some negative aspects arising from oversimplified and unilateral attitudes, soon revealed its first positive consequences. Many aspects of basic importance for the mental hygiene of the country, such as the prevention of mental disorders, the rehabilitation of veterans in need of psychiatric help, the training of a sufficient number of psychiatrists to meet the most essential needs, were recognized by the federal government as problems of national importance. Some of the programs operated by private agencies—such as the Rockefeller Foundation and the Commonwealth Fund—became integrated on a larger national basis.

The Vocational Rehabilitation Act of 1942 constituted a considerable step forward in mental hygiene. But even more important was the National Mental Health Act, enacted in 1946, authorizing the creation of the National Institute of Mental Health in Bethesda, Maryland, in 1949. The program outlined by the National Mental Health Act focuses on three main functions—research in the field of mental diseases, training of personnel, and assistance to the states in developing their mental-health programs. Though the goals to be achieved are still distant, a considerable amount of information has already been gathered by statisticians and social scientists in regard to mental conditions. Another accomplishment of the Institute has been the organization of the National Governors' Conference on Mental Health, to provide maximum educational and training facilities at a regional level. Many states have created a central state board, known as state boards or boards of institutions. Practically all the states have organized divisions of mental hygiene within the departments of welfare or departments of mental hygiene or mental health, and some states have taken a leading position in mental-health programs. New York, for instance, established a Mental Health Commission in 1949 and passed a Mental Health Act in 1954,

Downloaded from www.dbraulibrary.org.in

from which New York City particularly received great advantage.

## ¶ The Mental Health Movement

Mental health, a concept widely accepted since the foundation of the National Association for Mental Health by Clifford Beers in 1909, has been subjected to increasing criticism in an attempt to bring it into a more scientific frame. Various authors have focused attention on the relative definitions of the normal personality and of mental health; on the vagueness of the essential aims of mental-health programs, too frequently resting on assumptions; on the dubious role of ideas; on the inappropriate use of psychodynamic formulations; and, in general, on the uncertainty concerning basic factors—i.e., factors influencing community acceptance, concepts and theories to be employed in the study of mental health, theories of what undermines and of what maintains mental health.

Undoubtedly, the difficulties in the field of mental health cannot be overcome easily, in spite of universal agreement on the value of its three main practical aspects—promotion, prevention, and education. The focusing on these problems is of historical significance, however, in that it allows definition of the direction of future scientific developments, especially in regard to scientific objectivity and controlled experimental conditions. As an example of this trend, the "indexes of mental health" represent a definite achievement, hopefully to be followed by others. The collaborative book edited by Ruth Kotinsky and Helen L. Witmer, *Community Programs for Mental Health*, presents the most recent viewpoints on the above-mentioned aspects of mental health.

## ¶ Research and Methodology

Historically, psychiatry originated as a purely empirical science, and this trend has continued through the development of psychoanalytic practice. This explains the fact that, in spite of a tremendous amount of data gathered under difficult conditions by a large number of researchers, the field still suffers from a fundamental lack of skill, of methodology, and of technique in organization and evaluation of the material studied. This becomes even more evident if psychiatry is compared with psychology, in its clinical and social fields, where methodology of research has been carefully investigated.

This criticism is especially valid today, when psychiatric literature is increasing to tremendous proportions and when many psychiatric centers of different kinds dedicate effort and time to research. The results of a survey, *Collaborative Research in Psychopathology*, published by the Group for the Advancement of Psychiatry, in 1954, are impressive in their emphasis on the basic instrumental deficiency which still weakens a sound program of methodological research. This seems to justify the despairing note sounded by Lawrence Kubie, in 1952, that "research in psychiatry is starving to death."

Of course, the fact that the subject of psychiatry is the individual in its totality is itself responsible for some of these difficulties and for other factors of basic importance in psychiatric research. It is enough to mention as major points the lack of a universally accepted concept of normality of the human being, the semantic difficulties caused by the use of the same symbols with different meanings by different schools or from different viewpoints (phenomenological, structural, genetic, functional), the uncertainties and the ambiguities of the classification of mental diseases (present even in the *Diagnostic and Statistical Manual on Mental Disorders* published by the American Psychiatric Association in 1952). Some variables of psychiatric research, as for example the characteristics of the experimental group versus the control group, the interference of the biological and of the cultural process with the psychopathological process, the emotional aspects of the personality of the researcher (as pointed out by Frederick Redlich and Eugene Brody in an interdisciplinary report[132]) are extremely difficult to control. The above study by the Group for the Advancement of Psy-

Downloaded from www.jsbarlibrary.org.in

chiatry has been very useful in attempting to clarify the different aspects of research in psychiatry. The historical period under consideration has not, however, produced the needed clarification on research and methodology.

## ¶ Psychopathology

### *Anxiety and Related States*

The problem of anxiety has been considered an essential one to human life ever since man first reflected on his condition and on his destiny. St. Augustine, Pascal, Kierkegaard, and many other thinkers of the past have offered answers to this crucial problem of human existence. But only in the last few decades has the problem of anxiety been considered essential for the comprehension of psychiatric conditions, and explanations of it advanced by different schools.

Freud's revised formulation of anxiety (1926) as a signal of danger from within, with symptoms considered to be special types of defenses called out by anxiety, still remains an epoch-making contribution to psychopathology. In following years, psychiatrists investigated the problem of anxiety from different viewpoints on the basis of clinical material. As to the contributions made by neurologists, Kurt Goldstein's description of the "catastrophic reaction" in organic patients as a defense against overwhelming anxiety remains the best attempt made to approach the difficult problems presented by the behavior of these patients.

The contact of American medicine with psychoanalysis, when the latter became more accepted in this country, encouraged the investigation of anxiety on an experimental basis. Both trends of American medicine, the biological and the social, contributed to this development. As an expression of the first trend, Sandor Rado—influenced by the classical work of W. B. Cannon on the physiological changes in pain, fear, and rage—introduced the concept of emergency behavior as explainable in the light of the hierarchic organization of levels of emotional thought and of unemotional thought.

Cultural anthropologists affirm, instead, that anxiety appears when something within the person threatens his relation to significant people, and that the societal pressures under which individuals live are the real causes of repression, resentment, and hostility. Both theories agree that secondary anxiety grows out of the very defenses originally erected against anxiety and that a vicious circle between anxiety and defenses is then created—a viewpoint that has marked importance in the Karen Horney formulations.

Hans Selye's description of the "stress syndrome" or the "general adaptation syndrome" as including all the more specifically induced changes determined by a specific syndrome within a biological system had the effect of directing the problem of anxiety to a more experimental basis. His continuous development of research on endocrinological secretions in relation to stress (hypothalamic-sympathetic-adrenal medullary system and hypothalamic-hypophyseal-adrenal cortical system) constitutes a remarkable example of an effort toward a general systematization of all biological forces of the organism. So far, however, the influence of this research on psychiatry has been limited, in spite of Selye's recent attempt to present it in the frame of a general philosophy of life.

More important for psychiatry have been the observations reported by Stewart Wolf and Harold G. Wolff on the effects of anxiety on gastric secretions as an experimental way of investigating sympathetic discharges caused by fear from parasympathetic discharges caused by anxiety.

Neurophysiological research has continuously paralleled the clinical observation mentioned above. The recent trend of this research has been to investigate both the "downward discharge" from the cortex to the hypothalamus and the "upward discharge" from the hypothalamus to the cortex experimentally (with the use of the strychnine method or neuronography, for example).

Further progress in this question has recently been made by Daniel H. Funkenstein and his collaborators, who studied the different effects

Downloaded from www.pharmapsychiatry.com

of epinephrine and norepinephrine in relation to anxiety, whether this be due to unexpressed anger (anger-in) or expressed anger (anger-out). Other biochemical studies have recently tried to correlate "free anxiety" to the rise of the 17-hydroxycorticosteroids in the blood or to the quantity of hippuric acid secretion.

So far, however, this type of research is indicative more of the complexity of the task than of the results achieved. Two recent methodological papers by David McK. Rioch and Roy Grinker on the experimental approach to anxiety, in animals and in human beings respectively, point out independently the complexity of the variables that must be considered. The present research trend is to study the system of anxiety in transactions with other psychological organizations, either intrapersonal (perception system, endocrinological and vegetative system) or interpersonal (adjustment to groups).

The human—and thus variable—aspect underlying the complexity of the expression of anxiety is perhaps the motivating force which has led several students of this field, among them Kurt Goldstein, Hans Selye, Daniel H. Funkenstein, and Rollo May, to infer conclusions about human personality and its environment on the basis of their own psychopathological concepts. This phenomenon—certainly not a casual one—indicates the need for a better delimitation of methodology of research.

### *Formal Mechanisms*

Whereas the majority of the works on psychopathology deal with the motivations and the content of the symptomatology, a group of authors have stressed the study of the *forms* of the symptoms, in addition to dynamics. According to most of these authors, the *forms* and the *transformations* have to be studied ontologically, phylogenetically, and in relation to the dynamic mechanisms.

As Silvano Arieti stated: "The study of formal mechanisms reveals *how* we think and feel. The study of dynamics of psychoanalytic mechanisms reveals *what* we think and feel and the motivation of our thinking and feeling. Both the formal and the dynamic approaches are necessary if we want to understand psychological phenomena fully." The application of the formal approach, as differentiated from the psychodynamic, to the study of mental patients, is a relatively new development.

Observations on the formal mechanisms, especially of dreams, language, and primitive cultures as related to psychotic patients, had already been made by early psychoanalysts, especially Alfred Storch, who reported on the primitive archaic forms of inner experiences and thought in schizophrenics.

Jacob Kasanin, who introduced the Vigotski test in America, Eilhard von Domarus, who studied the logic of schizophenic patients (a subject expanded later by Arieti), and especially Kurt Goldstein, who described an "abstract" and a "concrete attitude" (the latter prevailing in brain damaged and schizophrenic patients), have made extensive contributions to the study of formal mechanisms. Other contributions to this problem, especially from the psychological viewpoint, were made by H. Werner in his *Comparative Psychology of Mental Development*.

Arieti stressed the importance and expanded the investigation of the formal mechanisms in schizophrenic patients from a clinical viewpoint. This material, important even from a historical angle, presented in his book, *Interpretation of Schizophrenia*, throws light not only on some aspects of schizophrenia so far overlooked but also on the mechanisms of dreams, of verbal associations, of infantile and paleologic thinking. It thus represents a development of considerable importance, especially as it opens a new field of investigation in the borderline area of traditional logic and modern psychology and represents a further clarification of the intricate problem of schizophrenia.

## ¶ The Psychoanalytic Movement

Psychoanalysis was the major influence on psychiatry in the first half of this century. The two theoretical frameworks are now so thoroughly integrated that it is almost impossible to isolate the original psychoanalytic contributions from the total context of psychiatry.

Downloaded from www.dbraum.org

Furthermore, the significant events of the psychoanalytic movement are so close to us in time and so colored by the personal position of the authors and the philosophies of the various post-Freudian schools that one cannot pass a judgment of historical value on this movement. The few historical contributions published so far reflect this provisory character or clearly indicate their derivations from a particular school.

Typical of this, for instance, are such collections as *Twenty Years of Psychoanalysis,*[6] written by the staff of the Chicago Institute for Psychoanalysis as an expression of Franz Alexander's school; *Midcentury Psychiatry,*[145] edited by Roy Grinker as an attempt to intergrate psychoanalysis with the biological and social sciences; Clara Thompson's *Psychoanalysis: Evolution and Development,*[159] written as an expression of the new neo-Freudian cultural schools; and finally, Clarence Oberndorf's *A History of Psychoanalysis in America*[124] which is a more autobiographical and chronicle-like essay. The provisory character of all these studies is also present, although perhaps to a lesser degree, in the extensive literature published in 1956 at the occasion of the Freud centennial. Even the most significant papers of this series, such as the four addresses by Ernest Jones,[82] or the articles edited by Nelson in *Freud and the 20th Century,*[174] must be viewed from such a historical perspective.

The process of historical evaluation has been further complicated by the esoteric approach of the movement in the sense that it developed in part as a reaction to the hostile attitude of the opposers, and in part as a result of the pioneering spirit of the analysts. On the other hand, psychoanalysis cannot isolate itself from the living currents of the American culture if it wants to survive and to contribute further.

The history of the psychoanalytic movement of the last twenty years is in fact the history of a twofold struggle for both identity and integration. Fortunately, the movement has not exhausted itself in this sterile struggle, except perhaps in a few instances, but, rather, has initiated a process of slow integration and of revision of basic psychoanalytic principles in the context of psychiatry in general. The pragmatic orientation of American culture has been an instrumental factor in this process.

It is obviously impossible, within the limits of this chapter, to present the full implications of the manifold contributions growing out of this process. Only the most important trends of the psychoanalytic movement will be reviewed in their historical perspective: (1) the integration of psychoanalysis with the biological and social sciences; (2) methodological and experimental advances; (3) ego psychology; (4) developments in psychoanalytic therapy, unorthodox, and neo-Freudian schools; and (5) the organization of psychoanalytic associations in the United States. This subdivision has both strengths and weaknesses, but it has been maintained because of its practical value.

## *Psychoanalysis and the Biological and Social Sciences: an Integration*

The integration of psychoanalysis with the biological and social sciences represents an important development in both the theoretical and the practical aspects of the psychoanalytic movement. The old schema of nineteenth-century philosophy, essentially materialistic, that had constituted Freud's theoretical bias in the formulation of his concepts gave way to more flexible and pragmatic concepts, for example, homeostasis, adaptation, integration, organization, autonomy, and communication.

Such recent theoretical elaborations as Bertalanffy's dichotomy—"open" systems of the living organisms and "closed" physical systems—and Wiener's cybernetics—based on the feedback mechanism of the nervous system (or the study of the patterns of interaction between cortical and subcortical nervous functions)—have provided an impetus for the re-elaboration of theoretical constructs of psychoanalysis. One can mention, briefly, among the most recent contributions to this re-elaboration: (1) George Engel's studies on homeostasis and behavioral adjustment, (2) Therese Benedek's studies on the organization of psychic energy, (3) Thomas French's work on the integrative process, (4) Sandor Rado's formulations on adaptational psychodynamics, (5) Donald O. Hebb's studies on the organization of behavior, and (6)

Downloaded from www.dbraebrary.org.il

Jules Masserman's work on dynamic integration.

The classical concepts of psychoanalysis—instinct, equilibrium, conflict, topography and economy of the psychic apparatus, anxiety, defenses, psychosexual development, as well as many others—are being reviewed in the light of these theoretical frameworks. Although this process is in an early stage, there are indications that it will exert considerable influence on the psychoanalytic movement generally. A more unitary concept of health and disease, extremely significant for psychopathology, is already evident in the theoretical formulations of such researchers as Arthur I. Mirsky, Roy Grinker, Sidney G. Margolin, M. Ralph Kaufman, Harold G. Wolff, John Romano, and many others. These researchers are attempting to take into account both the biological and the sociological dimensions of the human personality.

## *Methodology and Experimental Advances*

Experimental validation of psychoanalytic principles has been impaired by all sorts of difficulties, both of a technical and of a professional nature. Yet, it was natural that—in view of this country's empirically oriented approach to personality as compared with the more metapsychological approach of the European tradition—attempts would be made toward such an experimental validation. These attempts are still in the initial stage. The difficulty of translating the experimental findings on animals and young children to normal adults, the ethical implications of submitting human beings to stressful situations, the strict confidentiality that surrounds the patient-analyst atmosphere, are all factors contributing to the difficulties of experimental validation.

In spite of the problems, however, the literature of the last two decades reveals a definite trend toward the experimental approach, with both animals and human beings. Among the best-known studies are those of Jules Masserman on the results of different types of "psychotherapy" employed in "neurotic" animals, Neal E. Miller's studies on rats, Howard S. Liddell's research on experimental neuroses, and the very recent experiments by Arthur I. Mirsky on the mother-child relationship in monkeys.

Experiments with infants and young children attracted attention some years ago, especially after the classical studies on sibling rivalry and affect hunger by David Levy, the extensive research by Robert Sears and his collaborators, and the famous observations on hospitalism, anaclitic depression, and autoerotism by René Spitz. Today the interest in this type of research, as well as in dreams and hypnosis, remains active, but its methodological ground is increasingly questioned. Rather, the interest is centered on the problem of anxiety.

There is no question, however, that many of the observations are still fragmentary and need further investigation. As Ernest R. Hilgard stated recently, "Experimental work thus far bears most directly on only the most superficial aspects of psychoanalysis, while many of its deeper problems are scarcely touched."

Of the many authors who have approached the problem of experimental research in psychoanalysis, Lawrence S. Kubie has perhaps been the most active. Kubie has touched upon a series of important aspects: qualitative and quantitative measurement of the relation between conscious and unconscious levels of symbolic activity; careful study of free associations; study of the relation between various psychological levels through unconscious material; validation of interpretations; investigation of the problem of the validity of chronological sequences. Kubie has suggested the creation of a research institute of psychoanalytic psychology for recording the psychotherapeutic process with minimal distortion and analyzing qualitatively and quantitatively the material gathered under these conditions.

## *Ego Psychology*

From a historical viewpoint, Freud's fundamental studies on the ego and the mechanisms of defense constituted the beginning of the development of ego psychology. Metapsychological schemata, as derived from Freud's formulations, comprised the dynamic, eco-

Downloaded from www.dbraulibrary.org.in

nomic, and structural points of view. Even if operationally useful, however, the dynamic interplay of the three basic structures of the id, the ego, and the super-ego, left unsolved the important problem of the genesis of the ego.

Following Freud's formulation of an undifferentiated state of the id-ego, Heinz Hartmann attempted in a number of papers to define the developmental stages of the ego from this matrix. He considers the influence of (1) congenital ego-characteristics, (2) primary instinctual drives, and (3) external realities essential for the development of the ego.

Hartmann defines the ego as the substratum of the personality in terms of its function, especially the control of the apparatus of motility and perception (internal and external), the contact with reality, and the inhibition of primary instinctual drives. This definition implies, besides the genetic, the adaptive point of view—namely, the mediating function of the ego between present reality and needs of other psychic systems—a concept originally anticipated by Herman Nunberg. The adaptive functions of the ego are related to the theory of the ego autonomy to which David Rapaport brought essential contributions. In terms of Rapaport's latest formulations, the optimal functioning of the organism requires the constant balance of mutually controlling factors, ego-autonomy from the id and ego-autonomy from the environment.

Beside these basic developments of ego psychology, other aspects have been investigated in the historical period under consideration. Among the most important are (1) the role of the somatic ego (Willi Hoffer's interplay of mouth-hand, Anna Freud's ego integration) derived from the original concept of body image of Paul Schilder, the process of separation between the self and the environment; (2) the concept of "area of the ego free of conflicts" as a structural function originally started as a defense mechanism; (3) the concept of "ego strength" as an empirical measure of the level of integration and self-realization of the ego; (4) the concept of desexualized and aggression-free energy as "neutralized energy" and conversely, of sexualization and aggressivization of the ego-functions with non-neutralized energy; and (5) the role of introjection and identification in the building of the ego.

Another major aspect for study has been the mother-child relationship as a basic factor in the development of a flexible and adaptable ego. This relationship has been investigated especially in relation to the differentiation between the self and the world which takes place from the original symbiosis of the mother and the child. The contributions of Therese Benedek on the physiological stages of these dual interactions, of Thomas French on the supporting role of confidence in the development of the infant, and of René Spitz on the pathological development of the child following severe disturbances of this dual relationship (hospitalism) are among the most important of the last two decades.

From an over-all viewpoint, ego psychology originally initiated in the strict realm of psychoanalysis and is developing gradually in the direction of classical developmental psychology.

## *New Developments in Psychoanalytic Therapy: Unorthodox and Neo-Freudian Schools*

It was to be expected that *Karl Jung's* analytical psychology, so full of symbolisms and of esoteric material derived especially from the Eastern tradition, would meet great resistance in the United States. In fact, this country has been influenced remarkably little by Jung's complex formulations, in contrast to England where occult and parapsychological sciences have a long historical tradition. Some of Jung's best pupils, such as Michael and Frieda Fordham, are in England. In this country, the study of the unconscious which occupies a great deal of Jung's writings was quickly overcome by the study of the egodevelopment, defense mechanisms, and the transference situation. Only recently has the distribution of Jung's collected works, as well as selections of *Eranos Yearbooks* been initiated in this country by the Bollingen Foundation, perhaps more for scholars than for practical psychotherapists.

Downloaded from www.dbraulibrary.org.in

If one excludes the collective and the foreign presentations (for example, the work of Jolande Jacobi and Frieda Fordham), American original expositions of Jung's doctrine are limited to Ira Progoff and Frances Wickes.

*Alfred Adler's* influence in this country is more difficult to ascertain, especially if one considers not its totality but some of the particularities of his work. Because of the popular character of many of his writings, some ideas which he originated have been integrated in other scientific elaborations or have become part of universally accepted practices. Typical is the approach used in child guidance or the emphasis on discussion of psychological problems in groups—for example, in meetings of the parent-teachers association. Similarly, the short-term psychotherapy as used by Adler is now extensively used by some psychoanalysts, although from a different theoretical viewpoint.

Even more limited not only chronologically but geographically has been the influence of *Otto Rank*, especially since he emigrated to the United States in the early thirties. Specifically, Rank's influence has been strong among the social workers of the Pennsylvania School of Social Work, where he taught for some years. It is from Rank that the so-called "functional school" of social work, represented especially by Virginia A. Robinson and Jessie Taft, has derived. Through his intensive life, Rank's concepts were influenced considerably by the fact that his orientation was essentially artistic. Out of this orientation he derived many brilliant intuitions—but intuitions never validated through scientific investigations. Rank's fundamental preoccupation with the study of artistic intuition became more evident in his latest productions, as Fay B. Karpf shows in the monographic study, *The Psychology and Psychotherapy of Otto Rank*.

Because of their restricted historical influence on the psychoanalytic movement, no detailed mention can be made here of less well-known psychoanalysts who also detached themselves from Freud's school, such as Wilhelm Stekel, Sandor Ferenczi, Wilhelm Reich, and Theodor Reik, the last two of whom emigrated to this country. Of this group, only Reik exerts some influence in this country, especially in New York City. The popularity of his books and the group of lay analysts that he has gathered around his journal, *Psychoanalysis*, and the National Psychological Association for Psychoanalysis largely account for this influence. The volumes by Munroe[121] and Progoff,[128] among others, provide extensive surveys of the viewpoints of the various schools.

At present, the Freudians remain the main group in the psychoanalytic movement. They represent a tradition of seriousness of research and of clinical investigation which continuously influences the whole field of psychiatry. This large group of Freudian psychoanalysts, who constitute the American Psychoanalytic Association, has been subjected to the impact of both forces—biological and sociological—of American culture. The majority of Freudian psychoanalysts, however, continue to be engaged in the classical themes opened by Freud's own contributions. The literature of these authors is remarkable for its deepening of theoretical concepts, refinement of the therapeutic techniques, and clarity of the clinical descriptions, rather than for originality.

In many quarters, there is a feeling that a more radical revision of many concepts advanced by Freud is necessary, not only because of his own *Weltanschauung*, derived from nineteenth-century philosophy but also because of his long-term therapeutic approach. There are signs even among the most orthodox Freudian analysts, of attempts to adapt themselves more realistically to the urgent need with which psychiatry is confronted in this turbulent century.

The literature on the different aspects of psychoanalysis has become so imposing as to justify the task, recently undertaken by Alexander Grinstein, of editing an index of psychoanalytic writings in several volumes. The contributions of the major representatives of the Freudian movement range from theoretical studies on personality development, through descriptions of clinical patterns and of treatment of neurotic and psychotic patients, to excursion in the fields of sociology, metaphysics, and the expressive arts.

Some of these contributions can already be

Downloaded from www.dbraulibrary.org.in

considered of historical value. Although, as mentioned in my introduction to this chapter, the bibliographic sources for this material are not provided, the following listing allows some idea of the variety of the subjects under investigation and the researchers most interested in each:

The psychology of women: Helene Deutsch
Psychosomatic functions of women: Therese Benedek
Psychosomatic disorders: Franz Alexander, Carl Binder, Felix Deutsch, Flanders Dunbar, Thomas French, Roy Grinker, and others
Ego development: Heinz Hartmann, Ernest Kris, Rudolph Loewenstein
Emotional disturbances in childhood: O. Spurgeon English, David Levy, Gerald Pearson, Emmy Sylvester
Family dynamics: Erich Lindemann, Nathan Ackerman
Psychotherapy of psychoses: Frieda Fromm-Reichmann, Gustav Bychowski
Psychotherapy of delinquents: Kurt Eissler
Cultural anthropology: Abram Kardiner
Various clinical matters: Kenneth Appel, Greta Bibring, Phyllis Greenacre, Ives Hendrick, Robert Knight, Lawrence Kubie, Maurice Levine, Bertrand Lewin, Sandor Lorand, Jules Masserman, Karl and William Menninger, Herman Nunberg, Clara Thompson, Gregory Zilboorg, and many others

These contributions are more remarkable for their acceptance of the basic Freudian postulates than for their differences which are certainly understandable in view of the variety of backgrounds and culture found in this group. This acceptance creates a feeling of internal consistency and justifies linking these researchers into a common denomination. Individual differences are present, but not to the extent of creating a definite schism in the movement.

Only *Alexander* and his school have deviated considerably from the original Freudian formulations, on practical rather than theoretical issues. The short-term psychotherapy carried on in the Chicago Institute for Psychoanalysis differs a great deal from long-term orthodox analysis.[6] In spite of these differences, Alexander and his co-workers still consider themselves part of the main Freudian current.

A more decidedly autonomous position has been taken by the so-called "neo-Freudian school" represented essentially by the Washington School of Psychiatry and by the William Alanson White Institute of New York. The impact of American cultural and sociological currents, represented by such men as George Mead, Edward Sapir, and others, had a tremendous influence on the work of Harry Stack Sullivan, Karen Horney, and Erich Fromm. The theories presented by these authors differ considerably from each other.

*Sullivan's* "theory of interpersonal relations" puts the emphasis on the child's early interaction with the mother and other meaningful figures, on the "self-dynamism" of the personality, and on the role of "participant observer" assumed by the therapist. His historical value, however, consists even more in the extension of psychotherapy to psychotic patients, strictly connected with the investigation of the countertransference of the therapist toward such patients.

*Horney's* emphasis, in line with Alexander's school, is on the present situation of the patient, with relative unconcern for his early childhood. Her major contribution lies in the study of the interplay between neurotic defenses and cultural forces, a subject that lends itself rather easily to generalizations and appealing statements which tend to overlook the biological substratum of the personality.

*Fromm's* contribution is a passionate and brilliant dialogue of the author with the central themes of human social philosophy, viewed from the perspective of the American democratic scene. The topics of the personality types, of freedom versus authority, of selfishness versus mature love, among the most significant, emphasize the dynamic relation of man to society, which creates new needs for man and at the same time prevents their fulfillment.

Historically, neo-Freudianism has deviated from the Freudian system much more than seemed probable in the intentions of its supporters. Only portions of the basic Freudian concepts of personality (such as the theory of instincts, the Oedipus complex, the influence of the super-ego, etc.) have remained in the work of these neo-Freudians. But probably the

Downloaded from www.dbraincenter.org.in

sharpest difference between the two schools lies in the neo-Freudians' view of man adjusted to his society—a fundamentally optimistic view—as opposed to the Freudians' pessimistic picture of man struggling between his impulses and the strictures of the super-ego. Although for the moment it is not possible to pass a definite judgment on the future influence of neo-Freudianism on American psychiatry, there is no doubt that this movement has brought a fresh approach to the problem of human personality and has satisfied the need of many American students for a more sociologically oriented type of psychodynamics.

## *The Organization of Psychoanalytic Associations*

The development of the psychoanalytic movement underwent dramatic phases, as illustrated in Ernest Jones' *Life and Work of Sigmund Freud*. Although the details of this development, which covers half a century, cannot be mentioned in this chapter, an examination of it reveals that the main issues constantly involved throughout the years have been those of the establishment of professional standards for psychoanalysts, training of future analysts, and consistency of theory and practice.

The American Psychoanalytic Association's declaration of autonomy from the International Psychoanalytic Association, in 1938, was a natural consequence of the influx of European analysts and of the interruption of relations with European societies caused by the rise of the totalitarian regimes and, later, the war. This move increased the level of professional standards and training and strengthened the ties with other scientific organizations, particularly the American Psychiatric Association. At the same time, the move created favorable conditions for an increasing influence on psychoanalysis of American sociological concepts, a development that ultimately led to neo-Freudianism. This trend toward secession was started by Karen Horney with the foundation of the American Institute for Psychoanalysis in 1941 and probably influenced the further development of the psychoanalytic movement. In 1946 the American Psychoanalytic Association changed the status of the individual societies from constituent members to affiliates, permitted the establishment of more than one society or one institute in any one locality, freed each institute from connection with the society, and finally, in 1951, became incorporated under New York State law. These decisions had the effect of encouraging the founding of new societies, such as the Association for Psychoanalytic Medicine, the Columbia University Psychoanalytic Clinic, and the Psychoanalytic Institute of the State University Medical Center in New York City; at the same time, they strengthened the connection between psychoanalytic institutes and medical schools.

This reinforced even further the feeling of mistrust and rejection which the American Psychoanalytic Association always expressed toward lay analysts, in contrast to the more lenient attitude of such European psychoanalytic associations as the Swiss and the British. The Association has taken an official position of admitting only physicians as candidates for training. Originally only a restricted number of well-known lay analysts, such as Ernst Kris, Berta Bornstein, Beata Rank, and Eric Erickson, were accepted as members.

The question of training analysts has become a crucial one—especially since a professional standards committee was established—and has raised considerable discussion and controversy. Although there is general agreement that theoretical psychoanalytic concepts should be taught to psychiatric residents, there is a difference of opinion as to whether a homogeneous form of didactic analysis should be required for all residents or only for future analysts. Similarly, there is disagreement as to whether institutes for psychoanalysis should be independent of medical schools.

It is apparent from these discussions, however, that it has become more and more difficult to differentiate orthodox psychoanalysis from psychoanalytically oriented psychotherapy, theoretical from practical issues. Certainly, to quote Robert Knight,[88] "The spectacle of a national association of physicians and scientists feuding with each other over training standards and practices, and calling each other orthodox and conservative or deviant and dissi-

Downloaded from www.ultralibrary.org.in

dent, is not an attractive one, to say the least." The impression of a rigid conformism in some expressions of the psychoanalytic societies has been noticed by many. Oberndorf, for example, commented[124] that "the rigorous, somewhat conventionalized training program that developed at the various institutes during the fifth decade . . . sometimes leads to stereotyped thinking and codified, even mechanized interpretations." Appel remarked[13] that "rigidity, dogmatism, assertion, conviction, authority, indoctrination, so prevalent in many psychoanalytic institutes," favors only passive submission on the part of the candidate and satisfies his need of achieving a supposed higher professional status by becoming a psychoanalyst.

Whether the psychoanalytic movement will be able to maintain its original integrity and still become an integrated part of the American culture cannot now be predicted. At this point, the historian can only note the growth of its influence in the past twenty years, and observe, in current terms, the opposition between the tendency toward conventionalism and that toward re-evaluation of basic issues.

## ¶ Therapy

### *Physical*

#### Shock Therapy

The introduction of shock therapies was one of the most important events in psychiatry in the last two decades, and one of the factors that contributed to create a natural chronological subdivision in the development of psychiatry, at least in this country. Shock therapies were introduced here in the following order: hypoglycemic treatment by Manfred J. Sakel in 1938, Cardiazol therapy by J. Ladislas Meduna in 1938, electric convulsions by Lothar Kalinowsky and Renato Almansi (following their training in Rome under Cerletti) in 1939.

A considerable body of data has been accumulated around the subject of shock therapy; the scientific validity of these data, however, has been questioned in many quarters because the original hypotheses regarding the effects of shock—both physiological and psychological—have never been experimentally established.

In general, the concepts concerning the practical application of the shock therapies—particularly insulin and electric shock—have been widely accepted, at least in the absence of other more rational forms of treatment. Much of the available data deals with the problem of the type of patient best suited to shock therapy, and, in the attempt to reach a more valid selection of cases, some special tests were introduced. Technique of administration of treatment has also received much attention, and many variations have been attempted, with rather meager advantages, however, over the original technique. Most hospitals use electric shock therapy rather than deep coma insulin, because the latter involves such high costs. And electric shock can be—and is—utilized even in ambulatory practice.

The data on shock therapies have been gathered, for the most part, by researchers committed to the physiological rather than the psychological approach. In recent years, however, the literature has grown to include some studies of psychodynamics. The psychological importance of the regression on the patient, the close contact between the patient and therapist, the experience of symbolic expiation, death, and rebirth by the patient during treatment, and the importance of other factors in the psychodynamics of the individual case are some of the themes dealt with in the psychological studies that have been published.

*Shock Treatments, Psychosurgery, and Other Somatic Procedures in Psychiatry*, by Kalinowsky and Hoch, remains the basic textbook on shock therapy. Chapters by Cerletti, Sakel, Meduna, and others who have pioneered this field appear in the recent historical volume, *The Great Physiodynamic Therapies*.[138]

#### Psychosurgery

The first lobotomy was successfully performed by Egas Moniz in 1936; then, in the early forties, Walter Freeman and James W. Watts introduced psychosurgery in this country. In spite of the large amount of data reported since that introduction, controversy over this therapeutic technique has raged undiminished on theoretical and practical as well as moral grounds.

Even the specialists in the field have become

Downloaded from www.dbraulibrary.org.in

progressively more selective and restrictive in their criteria for suitability of patients for psychosurgery; this applies to mental disease in general, as well as to severely painful somatic conditions, with the exception perhaps of psychomotor epilepsy. Through the years, a considerable modification of the original surgical procedures has been introduced. The difficulties in collecting good physiopathological data and the scarcity of the postoperative anatomical reports account for this relatively rapid change in techniques. With the rise of tranquilizing drugs, psychosurgery has shown a certain decline. Some authors state that these drugs produce a "functional" lobotomy. Whether, in the future, tranquilizing drugs will entirely replace psychosurgery is difficult to say, although at the moment the trend is in that direction.

Walter Freeman and James W. Watts, John N. Fulton, and Milton Greenblatt and Harry C. Salomon have published important monographs on the subject of psychosurgery. In 1951 the United States Public Health Service published a collection of papers on the subject, and additional papers can be found in *Psychiatric Treatment*.[17] Walter Freeman[51] has presented an important survey of twenty years of leukotomy.

### Pharmacological Therapy

Although pharmacological therapy in psychiatry is as old as psychiatry itself, only in the last few years has the pharmacological approach achieved significant developments, producing substantial modifications in some of the basic aspects of the management of psychiatric patients.

The emphasis on hormone therapy in the second and third decades of this century also had repercussions in the field of psychiatry. The successes originally reported with hormonal therapy have been followed by increasing skepticism, in spite of the extensive research carried on in some institutions (e.g., by Hudson Hoagland and his associates at the Worcester Foundation). A recent review by Roy G. Hoskins[138] recognizes the limitations of the results.

In the forties, under the impact of the war and the need for short and intensive treatment, the emphasis shifted to Sodium Amytal and other chemical compounds. Besides its value for differential diagnosis, its use was especially emphasized in narcocatharsis, narcoanalysis, and narcosynthesis. The use of Sodium Amytal in medicolegal cases to obtain more unconscious material through loose free associations, became a fairly common trend that has drawn increasing criticism from both the legal and the medical professions on ethical as well as scientific grounds.

Of the three major groups of drugs—tranquilizers, sedatives, and anti-depressants—which today constitute the field of psychopharmacology, chlorpromazine and reserpine continue to be used more extensively than the others in a large number of mental conditions, with frequent symptomatic improvement. We actually know little of the mechanism of these drugs, in spite of the wide program of research carried on all over the country—a program reflected in the literature already available.

It is the consensus of many that the extensive and indiscriminate use of these drugs, supported by an overwhelming propaganda campaign, has encouraged a tendency to overlook the importance of psychodynamic factors in relation to psychopharmacology, such as the basic personality of the patient, the importance of oral gratification, the role of interpersonal relationships connected with the administration of the drug. The claim, by many researchers, that the drugs facilitate psychotherapy has been challenged by as many others. Although it is still too early to pass judgment on their value, the historian cannot avoid finding similarities between the recent developments in psychopharmacology and other earlier movements that proposed a basic relation between organic and functional aspects of psychiatry. From this viewpoint, the present discussions about the value of psychopharmacology lose much of their animosity and acquire significance in the broader context of the basic philosophy of psychiatry.

## *Individual Psychotherapy*

Many issues concerning psychotherapy have already been dealt with earlier, in the section on the psychoanalytic movement. Although

Downloaded from www.dbraulibrary.org.in

it must be pointed out that psychoanalysis, first developed as a psychotherapeutic method, laid the foundations for modern psychotherapy, this does not imply that psychotherapy refers only to the Freudian movement. In many quarters, even among orthodox analysts, there is recognition of the value of the so-called "psychoanalytically oriented psychotherapy" as applied by the representatives of different schools or by many considered to be "eclectic."

After the natural enthusiasm of the past two decades for Freudian techniques, the tendency is now toward better differentiation between the conditions that require a long-term approach and those treatable by a more eclectic approach. We find increasing acknowledgment of the fact that psychotherapeutic results are strikingly similar regardless of the theoretical framework followed by each therapist, that the personality of the therapist is more important than his adherence to a particular school of thought, that psychoanalytically oriented psychotherapists are qualified to treat the large variety of conditions that demand a flexibility of approach outside the rigid lines of the Freudian techniques.

No doubt considerable clinical data are available for validating the claim that different psychoanalytic techniques have produced improvements in many patients. Nevertheless, psychotherapy remains an empirical science for a number of reasons: (1) the difficulty in evaluating results quantitatively (a difficulty increased by the resistance of the American Psychoanalytic Association to the experimental approach); (2) the multiplicity of uncontrollable variables, and of objectivizing the personal involvement of the therapist created by the transference situation. It is possible that in the future better tools for research will be found, but so far our measures of human behavior, normal as well as pathological, are too approximate to justify any definite assertion on the value of the different therapeutic techniques. Hoch and Kubie,[59] perhaps better than anyone else, have pointed out the limitations and the uncertainties that characterize the present psychotherapeutic situation.

A reading of papers on psychotherapy (for example, *Progress in Psychotherapy*,[59, 107, 108] *Psychiatric Treatment*,[17] among many others) tends to encourage a position of relativism toward the apparently homogeneous results claimed by the variety of psychotherapeutic schools.

Perhaps such a feeling of relativism should be an essential attribute for any judgment on psychotherapy. To quote Zilboorg[173] "Take your theory, keep it, work with it. But don't be a missionary of your theory. . . . Exclusiveness of one's own theoretical bias is the dangerous factor in the therapeutic situation." Such statements are not meant to support vagueness and eclecticism of approach, but are rather a simple affirmation of the tendency in contemporary American psychiatry, toward integrating classic Freudian principles in a largely eclectic psychotherapeutic approach. It is this common psychotherapeutic approach, tacitly accepted by practically all those engaged in psychotherapy, that makes communication among different psychotherapists possible and that contitutes a neutral ground on which theoretical constructions can be built.

### Psychotherapy and Schizophrenia

American psychiatrists, and especially some of the outstanding psychoanalysts, first attempted to treat schizophrenia with psychotherapy. Following the early work of Sullivan and Federn in the thirties, other researchers, particularly Fromm-Reichmann, Bychowski, Redlich, and Arieti, published data claiming positive results in this area of mental illness.

Although the theoretical formulations they advanced to explain their results present differences, a factor common to all of them is the importance given to the early emotional development of the individual and to his interplay with the parental figures and the social environment. The mother-child relationship is considered the center of this complex interplay of dynamic forces, but is viewed in a broader social frame than that of the English psychoanalytic school led by Melanie Klein. Although the multiplicity of early psychological events is stressed in the literature, the concepts tending to emphasize a one-to-one causality (such as the concept of the "schizophrenogenic" mother) are subjected to re-eval-

Downloaded from www.pbookshop.com

nation and criticism. (Although interesting, John N. Rosen's technique of treatment of schizophrenic patients based on "direct analysis" which aims at a direct interpretation of the unconscious conflicts, aside from any social influence, has elicited considerable criticism.)

The most important aspect of the development of psychotherapeutic techniques for the treatment of schizophrenia lies in a new attitude toward patients created by its fundamental concepts—primarily, in the recognition that the countertransference of the therapist requires careful investigation. The mixed feelings of helplessness, rage, and rejection aroused in the therapist by the apparently absurd phenomena of schizophrenia are finally being analyzed and overcome. Although most therapists are deeply interested in the development of this technique, it has, so far, necessarily been applied to a limited number of cases only. Its broader significance has been its effect on mental institutions, where it has encouraged a tendency toward a more individual, understanding, and respectful approach to the treatment of psychotic patients.

### Brief Psychotherapy

In Alexander's "brief psychotherapy," the treatment emphasis is on creating a "corrective emotional experience," working through the actual conflictual situation of the patient, especially with the help of supportive methods (contrary to the uncovering methods of classical analysis). Alexander's therapeutic approach overlaps to a great extent—as he has stated himself—with the psychoanalytically oriented approach, and therefore the same consideration can be applied to his system. Alexander's outstanding pupils include Maurice Levine, Henry Brosin, Milton Rosenbaum, Martin Grotjahn, George Ham, and Thomas Szasz.

### Hypnotherapy

Hypnotherapy, as a therapeutic technique based on hypnosis, has maintained a definite autonomy. Considered historically as the matrix of the psychoanalytic technique, hypnosis lost importance in psychotherapy in this country until its revival during World War II, in the treatment of acute mental disorders. The success obtained by such short treatment, validated further by the work of English scientists, spurred an increase of hypnotherapeutic practices in this country. The Society for Clinical and Experimental Hypnosis was organized in 1949, the same year that saw the publication of a journal with a similar title. The theoretical basis and the therapeutic techniques of this school—one slightly different from the other—have been discussed by such authors as Margaret Brenman and Morton Gill, Lewis R. Wolberg, John Watkins, and Harold Rosen. In general, one feels that the movement lacks methodological principles, especially in relation to the indications for hypnotherapy, probably because of the vagueness of the theoretical framework.

### Conditioned Reflex Therapy

Many complex factors (heavy influence of psychoanalysis in this country, reciprocal mistrust between American and Russian psychologists, etc.) explain the general rejection of psychotherapeutic techniques based on Pavlov's conditioned reflex methodology. W. Horsley Gantt, who, with such other experimental psychiatrists as John C. Whitehorn, Ernst Gellhorn, Howard S. Liddell, William S. Reese, and David Mck. Rioch, founded the Pavlovian Society in 1955, recently attempted to formulate the Pavlovian principles for psychiatry. This formulation, as well as other presentations of Soviet psychology[148] and psychiatry,[172] failed to explain the very essence of the psychological phenomenon—the emotional condition of the person due to the interplay of internal events and of external resonances. This omission accounts for the disinterest of American psychiatrists in this psychotherapeutic approach, particularly in a historical period characterized by the emphasis on the unconscious processes underlying human activity.

### Communication and Learning Theory

Outside the realm of psychoanalysis, but more in line with the American emphasis on the value of symbolic logic, of language, of interactional systems and the like, are the

Downloaded from www.vidyanidhi.org.in

theoretical formulations by Jurgen Ruesch and Gregory Bateson of communication as the "social matrix of psychiatry." Although these formulations are still too recent to allow any historical judgment, they seem to be an expression of the "operationalistic" tendencies largely diffused in psychological quarters. As such, they are subjected to the same type of criticism leveled against conditioned reflex theory—namely, a lack of understanding of the basic inner condition of the patient. So far, they have met, if not open resistance, an attitude of caution.

### Client-Centered Therapy

A more popular movement is the so-called "client-centered therapy" developed by Carl Rogers in the early forties and expanded by many of his pupils. Rogers' contention is that "the individual has within himself the capacity and the tendency, latent if not evident, to move forward toward maturity" and that the role of the therapist is only to favor such a spontaneous process in a climate of "nondirective" approach. Client-centered therapy has found support in many quarters, especially among clinical psychologists, probably because it has represented a way of overcoming the intransigent attitude manifested by the American physicians toward laymen practicing psychotherapy. The historical value of this therapeutic method lies essentially in the fact that it has made psychotherapy accessible to the many people in need of it. The theoretical postulates of "client-centered therapy," in spite of attempts to present them through systematic research (as in the book, *Psychotherapy and Personality Change*, edited by Carl R. Rogers and Rosalind F. Dymond, and published by the University of Chicago Press in 1954), are rather weak and not too original. The concept of a spontaneous tendency toward maturation in the personality obviously has a long tradition in psychiatry, and the presence of a transference situation in the interaction between therapist and patient cannot logically be denied. Perhaps the contribution of "client-centered therapy" belongs to the field of counseling rather than to psychotherapy and should be considered as such by the historian.

### Group Psychotherapy

From a historical viewpoint, whereas individual psychotherapy is largely the product of European thought, group psychotherapy is, instead, a recent and typical expression of American thought. In a broad sense, group psychotherapy is the result of the interaction between the imported highly individualized psychotherapy and the typical socially oriented expressions of American culture.

This explains the immediate success of group psychotherapy in this country, despite the fact that it was developed on empirical grounds, with almost no theoretical construction. The early "classes" of tuberculous patients inaugurated by J. H. Pratt in Boston in 1905, the lecture classes for mental patients organized by Edward Lazell at St. Elizabeths Hospital in Washington in 1919, the groups gathered by Trigant Burrows in the twenties, the lecture groups initiated by C. Marsh in New York in 1930, the early "impromptu theatre" of J. L. Moreno in the thirties, have all been a succession of empirical attempts, based on different principles, arising out of occasional circumstances.

Only with Kurt Lewin's introduction, in the thirties, of "field theory," did the dynamic phenomena of human groups start to be scientifically investigated. Lewin's pupils continued his work at the Department of Social Relations at Harvard University and at the Center for Group Dynamics at the University of Michigan at Ann Arbor, and the practical results of these new currents have become known in the application of group work to institutions and collective setups of different kinds.

Some main currents of group psychotherapy have crystallized during the past twenty years: analytic group therapy, introduced by Louis Wender and Paul Schilder in New York in the early forties, attempts to apply psychoanalytic technique in the free atmosphere of the group; the "psychodrama" of J. L. Moreno permits the patient to act out his conflicts on the stage through the use of particular techniques (auxiliary ego, mirror, double and role reversal, etc.); group therapy with emotionally disturbed children, introduced by Samuel R.

Downloaded from www.dbraulibrary.org.in

Slavson in the thirties at the Jewish Board of Guardians in New York, allows patients to work out conflicts within the context of the play situation.

Group psychotherapy—either these formalized techniques or other more eclectic approaches—has been applied during recent years to all kinds of groups assembled on different principles (symptoms, therapeutic aims, individual and social roles, etc.). This tendency represents a danger to the original purpose of therapy—for it can dilute the therapeutic effects for the individual if group work becomes a vehicle for examining collective emotional experiences—as, for example, happens in such organizations as Alcoholics Anonymous.

The American Association of Group Psychotherapy and other parallel organizations on an international level attempt to define the boundaries of their field through meetings and through scientific research (especially in the two journals *Group Psychotherapy* and the *International Journal of Group Psychotherapy*). The historical survey by Dreikurs and Corsini[49] offers an accurate picture of the various viewpoints on this technique.

## ¶ Developments in In-patient and Out-patient Facilities

The developments of the last two decades in the field of hospital treatment of mental patients, although obviously connected with the developments in social psychiatry, are, historically, of such significance that they can to a certain extent be compared with those that occurred at the end of the eighteenth century. Once again, because of the influence of many factors still difficult to evaluate, society is reflecting on its attitude toward mental diseases in an attempt to overcome the prejudices that interfere with the understanding of such conditions. This understanding is based, however, on "scientific" as well as humanitarian grounds, a combined approach so typical of American science.

The factors responsible for this new development should probably include the gigantic problem of rehabilitation faced by the Veterans Administration at the end of the war, the educational campaign promoted by mental health specialists at every level of national life, the new concepts of interactional relations developed by group dynamics and social psychology, and finally the psychopharmacological advances in the treatment of chronic mental patients.

The events of historical significance which have initiated this movement include the project for a "day hospital," first outlined by D. Ewen Cameron in 1947, the Mental Hospital Institute organized by the American Psychiatric Association in 1948, the creation of the two sections on Hospital Administration and on Rehabilitation the following year and of the Committee for the Certification of Hospital Administrators in 1953. The psychiatric aspects of rehabilitation were emphasized with the passage of the Vocational Rehabilitation Act in 1954. The program of "family care" for patients able to leave the mental hospital expanded considerably. The program for training psychiatric nurses and, later, aides and attendants working in mental institutions, was enlarged and measures were taken—either through the United States Public Health Service or the National Mental Health Act—to overcome the shortage of nurses, still critical all over the nation. Finally, diagnostic and therapeutic work in psychiatric departments of general hospitals or in out-patient departments has expanded not only because of direct organizational and financial assistance from different sources (medical schools, Veterans Administration, United States Public Health Service) but also because of the more understanding and cooperative attitudes of communities.

On another level, these external events reflect, of course, the profound impact of psychoanalysis on Western culture. For, as psychopathology began to be understood and as self-knowledge increased, the superstitious terror surrounding mental illness was swept away, and the resistance to facing the psychological problems of man decreased.

During the last two decades, a much higher degree of flexibility in the treatment of mental

Downloaded from www.dbraulibrary.org.in

patients has developed. Many of the barriers between them and the community have disappeared. Since the early studies by Stanton and Schwartz—*The Mental Hospital*—and Maxwell H. Jones—*The Therapeutic Community*—the different aspects of the therapeutic community have been studied with the help of scientific methods, including sociometrics—for example, the social implications of "milieu therapy," the system of communication in mental hospitals, the therapeutic implications of "closed" versus "open" wards, the value of techniques of occupational therapy, the relation between the therapeutic community and the outside community, the specific problems posed by particular groups of patients ("chronic," adolescent, alcoholic, addicted, sex deviated, criminally oriented, etc.).

The role of the different staff members (hospital administrator, psychiatrist, psychologist, social worker, psychiatric nurse, chaplain, dietitian, librarian) and especially of personnel more in contact with the patients (psychiatric aides, volunteers) has been given great attention. The importance of the interaction between patients and their families and between patients and staff members has also been stressed from the dynamic, sociological, and cultural viewpoints. The complexity presented by the study of these problems has brought forth an interesting new development—the introduction of sociology in mental hospitals. The program of research carried on by such public and private organizations as the Russell Sage Foundation, especially in some hospitals (for example, the Massachusetts Mental Health Center), is meant to explore this area further.

It is almost impossible to grasp all the implications that this development—at its present initial stage—will have for psychiatry in the future, in relation to psychodynamics on the one side and sociology on the other. The most important aspects of this new field have been discussed by Alfred Stanton and Morris Schwartz, Raymond Fuller, Louis Linn, Milton Greenblatt, Richard York, and Ivan Belknap, among many others, and are reviewed further in the APA reports *Progress and Problems in Mental Hospitals* and *The Psychiatric Hospital*, and in the report *The Therapeutic Use of the Self* published by the Group for the Advancement of Psychiatry.

## ¶ Special Fields of Psychiatry

### *Mental Deficiency*

There has been a move in the past twenty years to define mental deficiency as a symptom common to a heterogeneous group of conditions, independently of its etiology, anatomicopathology, and clinical manifestations. The importance of the concept of "aclinical" or "undifferentiated" defectives as a "subcultural group" in a sociological sense, falling at the extreme left (I.Q. of 70-75) of Galton's curve of the intelligence of the general population, has gained increasing acceptance.

The improvement in the research methodology of mental deficiency, with the application of statistical methods of genetic research to clinically isolated types, has resulted in the clarification of several hereditary forms. Amaurotic idiocy, phenylketonuria, gargoylism, and hepatolenticular degeneration are now considered of recessive nature, and tuberosclerosis and other forms are considered of dominant nature.

In the attempts made toward a better nomenclature and classification of the different forms of mental deficiency, the multiplicity and complexity of the pathogenic factors are continuously stressed. Research on the impact of environmental factors—prenatal, natal, and postnatal in origin—as well as on the influence of different noxiae (avitaminosis, anoxia, X-ray) is being carried on in different centers. The emphasis of the twenties and the early thirties on postencephalitic conditions has now switched to a variety of subclinical conditions (such as toxoplasmosis) in the mother capable of causing mental defect in the offspring. Other important problems, however, remain obscure: the defect due to incompatibility of the Rh factor, the pathogenesis of mongolism, and especially the importance to

Downloaded from www.brainpan.org.in

be assigned to birth trauma in the etiology of mental defect.

The description of the psychological manifestations of brain-damaged children, evolved with the help of special psychological tests based on gestalt psychology, is a relatively recent development, due essentially to the work of Kurt Goldstein, Heinz Werner, Alfred A. Strauss, and Lauretta Bender. The broadening of psychological perspective on many forms of mental deficiency has contributed to the increasing acceptance of the concept of "pseudo feeble-mindedness" as inclusive of all the clinical forms of apparent mental defect due to emotional deprivations, frustrations, and insecurity. At the same time, the study of children's psychoses has focused on the uncertain boundaries between mental deficiency and primary autism.

The progress made in the knowledge of the pathogenesis of some mental conditions is responsible for recent therapeutic achievements, for instance, phenylalanine-free diet in the treatment of phenylketuronics. Independently of the specific pathogenesis, the multiplicity of the factors interplaying in each case has brought psychotherapy into use for mental deficiency in many clinics and special institutions.

Perhaps the most important achievement in the field of mental deficiency, in the period under consideration, has been the more enlightening and practical attitude toward mental deficiency on the part of families, schools, and communities. Many of the old prejudices have been replaced by sound programs, such as the opening of special classes in public schools, the agricultural colonies under public welfare supervision, boarding-home family care, and sheltered shops. This has been accomplished largely because of the acceptance of mental-health principles at different levels, from small group discussions and therapy meetings to national organizations such as the National Association for the Help of Retarded Children. Similarly, employment agencies have become more active in assisting mentally retarded in different ways—qualifications for job placement, and follow-up.

In line with these developments, the *American Journal of Mental Deficiency* has enlarged its interest especially toward educational and sociological aspects. Recent literature in this field includes works by Harry J. Baker (1953), J. Edward Wallin (1949, 1955), Clemens E. Benda (1952), Karl C. Garrison (1950), Merle E. Frampton and Elena D. Gall, Eds. (1956). The American Foundation on Mental Deficiency is the expression of the scientific investigations carried on in this field in many research centers, among which are the Vineland Training School, in New Jersey, the Fernald School, in Waverly, Massachusetts, the Letchworth Village, in New York, the Wayne County Training School, in Michigan, and others.

## *Alcoholism*

Only recently has the problem of alcoholism been faced in its entirety by different groups of researchers, with the recognition of alcoholism as a disease rather than a penal problem. This different attitude toward the problem has been the main factor underlying a number of initiatives of national significance: (1) the organization of the section of alcoholic studies at Yale University's Laboratory of Applied Physiology in the late 1930's, followed by the foundation of the *Quarterly Journal of Studies on Alcohol* in 1940 and the opening of the summer school of alcoholic studies in 1943; (2) the creation in 1941 of the National Research Council on the Problem of Alcohol; (3) the creation of the National Committee on Alcoholism in 1944; (4) the organization of the National State's Conferences on Alcoholism; and (5) the foundation of the National Association for the Advancement of Instruction on Narcotics and Alcohol, in 1951. On a state level, following the example of Connecticut, the majority of the states of the union have organized programs for alcoholics.

Research on alcoholism has covered a great range during the period under consideration, from biochemistry to psychoanalysis and sociology. The interrelation between vitamin deficiency, specific metabolic disturbance, and alcoholic consumption has given rise to a number of hypotheses—all of which are still subjected to a great deal of criticism. The

Digitized from www.dbtulibrary.org.in

introduction in 1949 of Antabuse (subsequently called disulfiram, an abbreviated term for tetraethylthiuram disulfide) has, on the other hand, been considered a landmark in the history of alcoholism.

Most clinicians today, however, incline toward the use of pharmacological therapy combined with psychotherapy. The practical successes of various forms of group therapy, including Alcoholics Anonymous, have pointed out the importance of psychodynamic factors in alcoholism. And a study of male alcoholics and their wives, in group psychotherapy, stresses the importance of interpersonal dynamics. Theoretical explanations of alcoholism from a psychoanalytic viewpoint were advanced several years ago by Robert Knight, Ernest Simmel, and L. E. Wexberg. These explanations have been reformulated by Giorgio Lolli as unsatisfied needs for love and tenderness—unsatisfied because of the taboo on tenderness and because of social isolation and loneliness. Increasingly, the research on alcoholism from a cultural standpoint—its role in divorce, in crime, in industry, in automobile accidents—merely emphasizes the need for a thorough understanding of the psychodynamics of the disease.

## *Child Psychiatry*

Psychoanalysis was the first discipline to focus on the emotional development of the individual personality and on its deviations. The work in the field of juvenile delinquency in connection with the courts and correctional institutions pointed out the need for prevention and early diagnosis and treatment of juvenile offenders. Areas of specific interest for mental hygiene and psychiatry also became progressively better delimited by many family and social agencies throughout the country. These facts, as well as others such as the progress of developmental and educational psychology, brought additional support to the value of the work already accomplished in child psychiatry.

Historical surveys[20,85,119] agree that child psychiatry originated through the efforts of William Healy in Chicago and Boston and was later continued by the Demonstration Child Guidance Clinics and by the Bureau of Child Guidance in New York City. Owing to the success of these enterprises which at least partially met the tremendous need of the communities, many other child-guidance clinics were established. At about the same time, child psychiatric wards began to be opened in some hospitals, and such pediatricians as Charles A. Aldrich and Benjamin Spock became known for their interest in emotionally disturbed children.

In spite of the differences in disciplines and training among the people working with, diagnosing, and treating children, and in spite of the uncertainty of the roles of the members of each clinic, a trend toward a certain homogeneity in dealing with individual cases as well as with problems became more and more manifest. The structures and the functions of the multidisciplinary "team" became better defined. The same differences in background of team members contributed to create a high degree of flexibility in diagnosis and treatment, which was particularly indicated for conditions as variable and plastic as emotional disturbances of childhood.

Through the years, the research and the experience of the specialists have clarified many issues in the psychopathology of childhood. The value of the multidimentional approach in each case has been progressively recognized and emphasized. In line with this, the active cooperation of the parents, especially of the mother, is now universally stressed as a necessary requirement in the treatment of each case. Furthermore, the area of cooperation has been extended to include other environmental aspects of the child's life (school, recreation, camp, etc.).

At the same time, much progress has been made in the techniques of the intake process, diagnostic procedures, play therapy, and case work with parents. The empirical definitions of the severity of the pathological process, of the need, length, and type of treatment, of the personality of the parents, of the prognostic judgment, and of many other variables are being clarified and refined. An aspect once severely neglected—the follow-up of cases dis-

Downloaded from www.ebrahimzadeh.ir

charged by psychiatric centers—is now receiving considerable attention.

Research is being carried on in many specific areas of child psychiatry, only a few of which can be mentioned here. With the recognition of "primary autism," the syndrome first described by Leo Kanner in 1943, there was a focusing on the onset of psychotic conditions in children—a fascinating, but difficult, problem. In another area—that of the neuroses and psychoneuroses—the condition of early emotional deprivation, empirically observed in the past by some pediatricians, has been clarified experimentally by the research of René Spitz and Margaret Ribble. Other researchers are working on the areas of symptomatology (enuresis, reading disability, school phobia, pseudo feeble-mindedness, etc.), etiopathology (patterns of mothering, prenatal and paranatal factors, etc.), family relations, the application of psychological tests. The problem of diagnostic categories in child psychiatry is still under discussion, in spite of the recent attempt (1957) of the Group for the Advancement of Psychotherapy to clarify it.

In the area of therapy, the general methodological principles of Anna Freud seem to have achieved more acceptance in the United States than those of Melanie Klein. The treatment program being carried on by Beata Rank and his collaborators at the Putnam's Children Center in Boston—an attempt to treat "atypical" children intensively—has attracted considerable attention. In the literature, the overall studies by Frederic Allen (*Psychotherapy with Children*), Lauretta Bender (*Bellevue Studies in Child Psychiatry*), and Hyman S. Lippman (*Treatment of the Child in Emotional Conflict*) are of major importance.

The problem of delinquency has also been given increasing attention, especially in certain areas such as New York and Chicago, although at times more under the pressure of public concern than on the basis of sound methodology of research and therapy. Ben Karpman, Sheldon and Eleanor Glueck, Harris B. Peck, A. K. Cohen, and F. J. Cohen have all published important material in this field.

In general, the psychodynamics and psychotherapy of adolescents, including delinquents, have been neglected; up to now only a few valuable studies have been published, for example, *Psychotherapy of the Adolescent*, by Benjamin H. Balser. Many authors feel that group rather than individual psychotherapy is more effective in the treatment of the emotional conditions of adolescence.

After the reports by Fritz Redl and David Wineman (*The Aggressive Child*) and Bruno Bettelheim (*Love Is not Enough, Truants from Life*), the idea of placing severely emotionally disturbed children in residential treatment centers received increased support. It has become evident that the families of many of these children are too disturbed to be able to participate effectively in the treatment of outpatient clinics, and that the child needs separation from his environment and intensive treatment for a prolonged time in order to show substantial improvement. Some institutions of this type have already been opened—for example, the Bradley Hospital in Providence, Rhode Island, the Orthogenic School in Chicago, the Southard School in Topeka, Kansas, the Ittleson Center, in Ittleson, New York—and others are in the process of being opened. Currently, however, the great majority of children with emotional difficulties are treated in psychiatric clinics for children. In 1950, 1,228 of such clinics were functioning, many in the eastern part of the country.

Psychosomatic conditions and psychological aspects of physical and handicapped conditions in children are also under investigation, especially in child psychiatric wards of general or pediatric hospitals. Careful studies on asthmatic children, on ulcerative colitis, on allergic conditions, on psychological aspects of tonsillectomy have already been published.

Although in this country child psychiatry is not recognized as a separate specialty of medicine, as it is in Switzerland and Sweden for example, a number of fourth-year residencies in child psychiatry are available in some centers, with the specific aim of preparing future directors of clinics. These centers, either clinics or institutions, are approved by the American Association of Psychiatric Clinics for Children, organized in 1951 in New York, which functions as a coordinating and evalu-

Digitized from www.wolfsonbrary.com

ating office. Besides this, many child psychiatric centers are approved for the third year of residency, thus offering many psychiatrists an opportunity to gain additional experience, especially in psychodynamics and family relationships. The Academy of Child Psychiatry, representing the outstanding representatives of the discipline, was organized, and finally, in 1957, the American Association of Residential Treatment Centers was founded.

## *Geriatrics*

In recent years the problem of old age has attracted the attention of statisticians as well as of specialists in public health and insurance. The trend toward increase of the average life span has had repercussions even in regard to mental health. The focus on the psychological aspects of geriatrics, however, is so recent that there is still considerable variety of approach to these problems among different authors, partly because of the many socioeconomic issues involved—for example, the question of arbitrary retirement, which is criticized as ignoring the importance of individual differences.

Compared to the increasing attention given to social issues in relation to geriatrics, the knowledge of the physiopathological mechanisms involved in the senile brain disease has not shown significant progress in the period under consideration. An important recent event in geriatrics has been the recognition of the beneficial therapeutic influence of tranquilizing drugs in the management of disturbed, anxious, and agitated patients. This has contributed to a considerable change in the philosophy of hospitalization for old people.

Together with the emphasis on pharmacological therapy, there is a growing trend toward considering the importance of emotional factors related to previous events and personality patterns as precipitating events in the pathogenesis of senile psychoses.

This tendency is reflected in the attempts to stress the value of psychotherapy for old people and to understand some basic issues of the psychology of the aged, such as self-destructive impulses, preparation of the aged for death, and psychological care of dying patients.

All of the research tends to indicate that both aspects—the psychological problems of individual personality and the socioeconomic issues of the aged as a group—are practically inseparable and should be approached from a unitary viewpoint. As a result, we find an emphasis on the psychological aspects of group life and social adjustment rather than on individual personality. Many of the specialists who are working on the problem from a strictly psychiatric point of view also stress the value of group therapy and group work as the best available method of treatment for psychological problems of the aged.

This issue will probably receive more attention on an organized social level as it becomes a growing problem in the community. Even now, such states as California and Florida, which have large communities of aged, and such agencies as the Veterans Administration, which has a static population of twenty million people whose problems of aging will put new strains on the agency's responsibilities, are showing a growing sensitivity to the question.

Detailed information—statistical and economic as well as psychological—is available in the literature already published on the subject. Among the writers who have made contributions in this field are Oscar Kaplan, Susan Kubie and Gertrude Landau, M. Derber, R. S. Kavan, O. Spurgeon English, and Maxwell Gitelson.

## *Military Psychiatry*

The influence of military psychiatry, which was almost unknown at the beginning of World War II, has extended to all the other areas of psychiatry in the past fifteen years. For many physicians, the psychiatric training and experience thrust upon them by the war provided the motivation for entering the field as specialists, and this fact may help explain the pervasive postwar influence of military psychiatry.

As the theater of World War II enlarged to include many nations and fronts, and as the United States began to transform its industrial

Downloaded from www.dbraum.org

machine into a military weapon, psychiatry, too, was called into the service of creating a wartime army. (As to the question of the contribution psychiatry could make, it is significant that 850,000 men were rejected by the Selective Service System during the war for psychiatric defects, and 43 per cent of all Army discharges were for neuropsychiatric disorders.)

Specifically, the utilization of psychiatry in the war was centered on five main objectives: (1) selection of mentally fit recruits for the armed forces (through social service, psychological tests, etc.); (2) detection and separation, at the earliest possible time, of psychiatrically bad military risks; (3) prompt and effective treatment of psychiatric casualties, in both training camps and combat areas; (4) plans for rehabilitation of psychiatric casualties upon their return to civilian life; (5) maintenance of mental health and furtherance of good morale among men in the armed forces.

Of the different objectives mentioned, diagnosis and treatment of military psychiatric casualties deserves special consideration. A definite psychiatric syndrome—"combat neurosis" (so-called by Rogers Smith) or "combat fatigue" or "combat exhaustion"—was intensively studied in soldiers who broke under the impact of unusual stresses. Joseph D. Teicher later suggested the substitution of "traumatic" and "war neurosis" for these terms. Eli Ginzberg and his collaborators later established that the important factor is not a psychoneurotic vulnerability, but the stress and strains previously affecting the soldiers. The psychodynamics of soldiers under stress during combat and after were investigated by Abram Kardiner and Roy Grinker. Other problems, such as chronic alcoholism and sexual aberrations, were the object of studies and discussions in regard to policies and regulations, with slow but steady acceptance of psychiatric considerations. This was largely due to the enlightening work of consultation and advice that many outstanding psychiatrists offered to the Surgeon General during the war.

With regard to therapy of military psychiatric casualties, the contingent necessities of the war (shortage of qualified psychiatrists, need for returning the men to the war theater, lack of adequate facilities, etc.) pointed out the value of "short-term repressive treatment in the total therapeutic atmosphere of the group," to quote Albert Glass. This short sentence summarizes the trends prevailing in therapy: short-term therapy, even pharmacologically inducted (narcosynthesis), and group therapy in its different types, in either in-patient or out-patient departments. This approach was considered especially useful in preventing the syndrome of psychiatric hospitalization.

The favorable results obtained with this approach were tested again during the Korean conflict. The literature on this is considerable and includes many aspects of the problem, including such new ones as the psychological problems of "brain washing" and of disaster.

Chapter 12, "Traumatic Neuroses of War," includes an extensive list of the literature relating to military psychiatry.

## *Legal Psychiatry*

The interest in legal psychiatry has been confined to a limited group of specialists, in spite of the attempts made to bring many basic issues to the attention of a larger audience. Unfortunately, important areas of this field are still controversial, in spite of the progress of the last two decades. The diagnostic category of "sexual psychopaths," the value of psychotherapy to delinquents, questions relating to parole and probation programs and to commitment of mental patients, attitudes toward juvenile offenders, eugenic laws concerning mental patients and defectives—these are some of the issues that have been subjected to research and investigation.

Two main issues persist, however, those of criminal responsibility and of the psychiatric expert's testimony. These were the subject of a thoughtful report in 1954 by the Group for the Advancement of Psychiatry. As far as the first point is concerned, the results of the application of the Briggs Law in Massachusetts, which provides for a compulsory mental examination in a variety of cases involving severe offenders and recidivists, have been very encouraging (Peter B. Hagopian, 1950). As to the second, Zigmond M. Lebensohn, among

Downloaded from www.dbraunlibrary.org.in

many others, has articulated the need for a better relation between psychiatrists and lawyers, and suggestions have been advanced for special training in legal psychiatry. There is the feeling in many quarters, both medical and legal, that psychiatrists could be better employed by courts, correctional institutions, and probation agencies. Encouraging steps have already been made in some cities; in New York, for example, consultive mental-health services for courts have been in operation for some time.

The most important event in legal psychiatry in a number of years, however, was the decision of the United States Circuit Court of Appeals for the District of Columbia in the case of Monte-Durham vs. United States, in 1954. The court decided that, as an expert witness, the psychiatrist is expected to give a full account of the mental condition of the patient, in contrast to the old M'Naghten rule which has been criticized as inadequate and legalistic (the full report of the court decision appeared in *Mental Hygiene*, Vol. 40, 1956, pp. 304-317). This decision stimulated discussion—largely favorable—in many journals.

For more details, the reader is referred to the monographs by David Abrahamsen, Walter Bromberg, Henry Davidson, Henry Weihofen, Manfred Guttmacher, as well as to the general reviews by Ben Karpman and Thomas Szasz and to the collaborative work *Psychiatry and the Law*, edited by Paul Hoch and Joseph Zubin.

In recent years, through the efforts of Gregory Zilboorg, the American Psychiatric Association established the Isaac Ray Award, to be assigned each year to a specialist particularly distinguished in the field of psychiatry and law. Four volumes of lectures already have been published, in the following order: 1953, Winfred Overholser; 1954, Gregory Zilboorg; 1955, John Briggs, Jr.; 1956, Henry Weihofen.

## *Industrial Psychiatry*

Industrial psychiatry was for a long time an almost unknown field of psychiatry, cultivated only by a few pioneers. This was in open contrast to the tremendous development of industry in this country. Several facts can be held responsible for this state of things: the majority of psychiatrists were not available in industries during the war because they were drafted by the armed forces; the average businessman has remained skeptical of the complicated and imponderable formulations of psychiatry; psychiatrists themselves—too busy in private practice—have not been too enthusiastic about working in industries.

A marked interest has now developed in this field, among psychiatrists and individuals employed in industries, at the top as well as the bottom level. The American Psychiatric Association established a Committee on Industrial Psychiatry. The Menninger Foundation has a special team for research in industrial psychiatry (Department of Industrial Mental Health). Conferences on Industrial Mental Health were held at Cornell University in 1955 and 1956 under the auspices of the New York State School of Industrial and Labor Relations. The same school makes available fellowships in industrial psychiatry. Some psychiatrists are already employed full time in industries.

The major areas of interest for mental health in industry are (1) methods for prevention of emotional difficulties, (2) occupational neuroses, (3) placing of the handicapped in industry, (4) psychosomatic conditions, (5) alcoholism, (6) accident proneness, (7) absenteeism, (8) psychiatric role of the industrial nurse, (9) problems of aging workers in industry, and (10) psychological aspects of compensation. Obviously, the psychiatric approach in industry can help considerably to decrease expenses.

Direct psychiatric help to the employee remains, of course, the favored area of work for the psychiatrist; such programs have been in existence for many years in a few industries—at Du Pont de Nemours in Delaware, for instance. Friedrick W. Dershimer, among other specialists in industrial psychiatry, has stated that it is better to treat a patient under stress than to remove him from his job. Rehabilitation of industrial workers constitutes another big area of industrial psychiatry, especially after the Vocational Rehabilitation Acts Amendments of 1943.

Downloaded from www.dbraininstitute.org

In the last few years, following the increasing interest in human relations, communication, and group therapy, psychiatry is getting more acceptance from both executives and labor unions; these days, many issues are dealt with on a psychological rather than a moral level. The psychological problem of communication between managers and labor is complicated by the manifold roles each group must play—leading, for example, to divided loyalties of employees. Group psychotherapy seems to be a useful procedure for treating psychological problems in executives.

More extensive and detailed information is available in the studies by Thomas A. Rennie and his collaborators, Friedrick W. Dershimer, Charles C. Burlingame, and in the report (No. 20) issued by the Group for the Advancement of Psychiatry. D. E. Cameron and H. G. Ross, and W. D. Ross have published significant monographs in this field.

## ¶ Collateral Fields of Psychiatry

The collateral fields of psychiatry have developed, especially in the last two decades, as an expression of the acceptance of psychiatry in many aspects of the national life.

Only a brief mention can be made here of the significant developments in the areas of (1) genetics, (2) neurology, (3) psychology, (4) education, (5) social work, (6) anthropology, (7) sociology, (social psychiatry), and (8) religion and psychiatry.

Although the application of *genetics* to psychiatry has never been too popular in this country—as in some European countries—because of many factors, a considerable amount of data has been accumulated in recent years by the Division of Genetic Research of the New York Psychiatric Institute, under the leadership of Franz Kallmann. The results of his studies, presented in a series of papers and a recent monograph, concern the genetic etiology of schizophrenia in twins. Other mental conditions also have been submitted to genetic investigation, but with less success. Limited interest has been directed to the eugenic aspects of psychiatry, an issue which remains controversial, as one can see from the different legislation in many states of the Union.

The growing interest in the relation of *neurology* to psychiatry can be attributed partly to the results of the application, in chronological sequence, of electroencephalography, then of psychosurgical procedures, and finally of the new psychopharmacological substances. We see today a renewed interest in all aspects of brain physiology and pathology. The problems of the cortical organization, of the brain stem (reticular activating system), and of the limbic system (visceral brain) in relation to the cortex (and functionally to consciousness and sleep); the various techniques of electroencephalography, experimental neurophysiology (electrostimulation, neuronography), and psychosurgery; the biochemical researches on brain pathology, the investigation of the mechanisms of pain; the description of the temporal lobe syndrome are among the most important and frequently discussed topics of the last two decades. Among the researchers who have contributed greatly to these studies are Horace W. Magoun, Wilder Penfield, Herbert Jasper, Ralph W. Gerard, Stanley Cobb, Ernst Gellhorn, James W. Papez, Frederick A. Gibbs, and others. It is the definite impression of many that in the long run, aside from present-day disputes and controversial issues, the renewed interest in brain mechanisms will result in a permanent *rapprochement* between neurology and psychiatry.

In the field of *psychology*, the last two decades have been characterized by the developments in clinical psychology, due especially to the program of research, training, and practice organized by the Veterans Administration during and following the war. The extensive use of psychological tests (especially the projective ones), the elaboration of new theories of personality (as those advanced by Henry A. Murray, Gordon W. Allport, Kurt Goldstein, Raymond B. Cattell, John Dollard, and Neal Miller), the formulation of the relation of dynamic concepts of personality to cognitive ones (namely of unconscious drives to cognitive processes), of the relation of the individual to group-derived and social categories (namely the expansion of social psy-

Downloaded from www.dbraulibrary.org.in

chology, following the early topological concepts by Kurt Lewin)—all these are among the important themes of clinical psychology. The names of David Rapaport, Henry A. Murray, David Shakow, Saul Rosenzweig, Frederic Wyatt, Gordon W. Allport, Clark L. Hull, Gardner Lindzey, O. Hobart Mowrer, Gardner Murphy, Robert R. Sears are prominent for their work in this field.

With the acceptance of clinical psychologists as necessary members of the clinical team, especially in child psychiatric and outpatient departments, and following the emphasis on therapy brought up by Carl Rogers' nondirective approach and by the development of counseling, guidance, and group psychotherapy, the relation of psychology to psychiatry in matters of psychotherapy became a matter for discussion in many quarters, either at an intra- or an interdisciplinary level, but remains highly controversial. The "dialogue" between psychology and psychiatry (to quote David Shakow[144]) is far from exhausted, and is a typical expression of the still undefined aspects of both the professional role of the clinical psychologist and the boundaries of his field.

In *education*, there has been a continuous trend toward the introduction of mental health principles in schools and a greater acceptance of the principles of individual, familial, and social dynamics. The importance of a wholesome school atmosphere, leading the pupil to a greater security and a feeling of belonging, of worth, and of dignity, as well as the importance of the teacher-child and the teacher-family relationships have been generally recognized. Progressive methods of education have been studied in relation to mental health aspects, and such extensive projects as "human relation classes" have been highly successful. Psychiatric attention is being extended to every school level, including colleges and universities. The psychiatric approach to older students, started by Clements Fry at Yale University, has been successfully applied to many other universities, as one can notice from the extensive bibliography by David H. Funkenstein and George H. Wilkie, and from the recent monograph by Dana L. Farnsworth.[50]

In the field of *social work*, greater cooperation between social workers and psychiatrists has developed, especially in set-ups such as clinics, out-patient departments, and courts. The extension of the services covered by social workers and the greater flexibility of roles achieved in many clinics have brought up the important point of the relation between case-work treatment and psychotherapy. This issue has been widely discussed (e.g., in the report of the Commission on Social Work presented at the New York Academy of Sciences by Luther E. Woodward in 1955[12]) but is far from solved. And the difficulties in solving it are illustrated clearly by the contrasting philosophies of "diagnostic case work" and "functional case work."

In *anthropology*, the pioneering work of Ruth Benedict, Margaret Mead, and Edward Sapir stressed the importance of cultural patterns and their variations for the development of the personality and its abnormalities. In spite of the recognized need for better reciprocal understanding between psychiatry and anthropology, the students of this new field still remain limited in number. In the two decades under consideration the work of Robert Linton, Jules Henry, Gregory Bateson, Clyde Kluckhohn, Marvin E. Opler, A. Irving Hallowell, George Devereux, Eric H. Erickson, John Dollard, Cora du Bois, and Abram Kardiner have been the best representatives of this field.

The development of *sociology* in relation to psychiatry (*social psychiatry*), although recent, has been very rapid. From the early work of such sociologists, psychologists, and psychiatrists as George Mead, Ernest R. Groves, Richard Cabot, William I. Thomas, Thomas D. Eliot, Trigant Burrow, Kimball Young, William A. White, Harry S. Sullivan, James L. Plant, Robert E. Park, and Laurence K. Frank, the basis was created for an interdisciplinary approach to sociological problems in psychiatry. Since then, this new approach has evolved in a sounder experimental direction, as illustrated by the ecological study on mental disease by Robert Faris and Warren Dunham. The conferences by the Social Science Research Council in 1950, the establishment of a chair

Downloaded from www.pbainternational.org

of social psychiatry at Cornell University in 1950 (occupied by the late Thomas C. Rennie until 1956), the organization of the Society for the Study of Social Problems in 1951, and, finally, the foundation of the *International Journal of Social Psychiatry*, in 1955, indicate the growing importance of social psychiatry in American research. The emphasis of this field has been directed toward the ecological factors of mental disorders (such as cultural and racial conflicts), the theory of social isolation, the psychiatric implications of social mobility, the influence of civilization, and more recently of social stratification on mental disorders. The basic concepts of personality development and of the clinical psychiatric pictures and even the fundamental concept of psychological normality have been reviewed from this sociological viewpoint. The field is in a typically transitional stage, as evidenced by the collection of papers edited by Arnold M. Rose, *Mental Health and Mental Disorder*, and more recently by Leighton, Clausen, and Wilson, *Explorations in Social Psychiatry*, and by Hollingshead and Redlich, *Social Class and Mental Illness*. For the historian this field is moving toward a further greater development in the near future.

Finally, the *relation of psychiatry to religion*, obviously colored by Freud's strong antireligious attitude, is now being subjected to more objective investigation. The joint efforts of psychiatrists and churchmen in the study of the religious phenomenon, either considered intimately as expressed in consciousness and guilt, or externally as expressed in a system of values, have resulted in the clarification of some basic points. Following the important differentiation made by the Swiss psychiatrist Charles Odier between unconscious and conscious sources of guilt, the borderline areas of interest for psychiatrists and churchmen have been submitted to thorough investigation. The importance of moral and religious issues for the mental health of the patient have been emphasized in a number of publications by representatives of different confessions. This new convergent interest in religion and psychiatry has resulted in the organization of the American Foundation of Religion and Psychiatry and of the National Academy of Religion and Mental Health and the publication of two special journals.

## ¶ Psychiatric Education

Throughout the country, psychiatric principles in undergraduate teaching of medical students have been introduced. This tendency appears to be the result of the emphasis on the study of the "total personality" and of "humanized" medicine.

Efforts are made by the medical schools to select students with stable personalities, and psychiatric help is offered to those who are unable to function adequately. As far as the teaching program is concerned, psychiatry is taught more and more as part of the comprehensive curriculum rather than as a specialty subject. In 1948, a report on medical education by the Group for the Advancement of Psychiatry recommended the teaching of psychiatry during all four years of medical education, with emphasis on personality development, unconscious motivation, and dynamic consideration of clinical cases. Some medical schools (Western Reserve, Colorado, Pennsylvania, Tennessee, and Harvard), with the help of special organizations such as the Commonwealth Fund and the Kellogg Foundation, have embraced in their curriculums a program of "comprehensive medicine." This includes a careful study and appraisal of the personality of the patient in his own environment, achieved through home visits and the application of basic psychiatric and case work principles. Other medical schools have opened departments of "behavioral sciences" (Syracuse) or give courses in "human ecology" (North Carolina). Other aspects of this problem can be found in the report of the first Conference on Psychiatric Education held at Cornell University in 1951 as well as in a curriculum of studies recently outlined by the Committee on Psychiatric Education of the American Psychiatric Association.

In regard to postgraduate teaching, the need

Downloaded from www.libtabriz.org.ir

for organizing a program on a national basis became evident at the end of the war. Training in psychiatry, first carried on by private foundations (Rockefeller Foundation, Commonwealth Fund), especially under the leadership of Alan Gregg, was later taken over by the federal government. The Veterans Administration and some large institutions such as The Menninger Foundation continue to maintain an extensive program of training. As a result, the American Board of Psychiatry—established in 1934—formulated definite requirements for the specialty of psychiatry. A limited number of institutions are approved as accredited training centers in the attempt to make the formal postgraduate three years' training as homogeneous as possible all through the country. This problem is complicated by the fact that many residents are foreign graduates and that some of them return to their original countries after their training. The most important aspects of postgraduate training were discussed at the Second Conference on Psychiatric Education, held at Cornell University in 1952, and more recently by the Committee on Medical Education of the Group for the Advancement of Psychiatry. The reports of these conferences stress the importance of dynamic understanding of cases, of facilities in psychotherapy, and of adequate supervision. Personal analysis, although not a necessary requirement, is recommended as a means of acquiring better insight and self-knowledge, especially in regard to psychotherapy. This has brought up the question of whether analytic institutes should be part of departments of psychiatry or should be independent. Different points on the training for psychoanalytic practice have been discussed in a symposium (published in 1954) in the *International Journal of Psychoanalysis* and in *Psychoanalysis and Psychotherapy* by Franz Alexander. Another symposium dealt with the more general topic of qualifications for psychotherapists. Some states have tried to solve the problem of postgraduate psychiatric training by unifying all the psychiatric facilities existing in the state. Other information on postgraduate education, although partially outdated, is available in the volumes by F. G. Ebaugh and C. A. Rymer, *Psychiatry in Medical Education*, and by H. Witmer, *Teaching Psychotherapeutic Medicine*.

## ¶ American and European Psychiatry: an Appraisal

Because science cannot be limited by geographical or political boundaries, an attempt to correlate and compare American with European psychiatry must be an artificial one. Psychiatry, in particular, was largely a product of European thought and was transplanted to this country either through exchange of literature or through the direct work of some of the best representatives of many European nations permanently established in this country.

There is no doubt, however, that all European scientific movements—including those of psychological and medical sciences—having once arrived in this country, were then influenced by the characteristic pragmatic orientation of American philosophy. This approach explains the benevolent acceptance of new methods and systems in this country, provided they pass the test of efficiency and operational value.

The difference in the philosophical approach to the personality problems, more theoretical in Europe and more practical in America, however, remains quite broad even today. The difficulties of communication (languages), the experience of the war, a typical atmosphere of reciprocal mistrust (from which Freud himself did not escape), and the persistence of prejudices of many kinds, all tend to create a barrier between the two continents. This barrier persists even in spite of the American participation in international meetings, of the extensive program of exchange of teachers and students, and of the considerable interchange of information.

It is not possible, in view of the limits of the present chapter, to consider, even superficially, the causes of this phenomenon. Of the different explanatory attempts made, that by Gordon W. Allport[8] is perhaps the most comprehensive and at the same time the most stimulating. It is based on the following points:

Downloaded from www.dbraum.com

(1) The Lockean tradition (empirical) is dominant in England and in America—the Leibnitzian and Kantian (intellectual), on the Continent; (2) Continental theories tend to focus on the "whole man"; Anglo-American theories, by contrast, are more often concerned with parts of the whole—with traits, attitudes, syndromes, factors of performances; (3) American approaches, more than the British, are marked by a tone of meliorism and optimism, whereas many Continental approaches are characterized by a note of fatalism and pessimism; (4) social interaction received greater importance in American than in Continental theories; (5) Anglo-American typologists are currently more interested in "brain models" than are Continental typologists; and (6) the ideal of rigorous positivism seems to prevail in Anglo-American psychology to a greater extent than it does on the Continent.

No matter how much consent or disagreement Allport's ideas find on both continents, his formulations are remarkable for their clarity and sincerity. Though American himself, Allport, in fact, makes a plea for the importance of basic European contributions to essential psychological issues in different typologies, psychometric and psychodiagnostic methods, developmental psychology, gestalt formulations, and, above all, psychoanalytic theory and practice. This is only one side of the question, however, because the American contribution to these very same issues has been marked, if by less creativeness, then certainly by great enthusiasm and freshness of approach. It is therefore not possible, even in view of recent developments, to pass a judgment of historical significance—even less, a judgment implying a hierarchy of values and of priorities.

Some authors—for example, Henri Ellenberger[44]—have attempted to isolate and describe the main differences between American and European psychiatry. Like all statements of broad significance, these descriptions suffer the defect of generalization, and therefore must be considered as referring to trends and currents rather than achieved positions.

In Europe, the emphasis is still predominantly on diagnostic categories—in Germany as a result of the Kraepelinian tradition, based on the predominance of pathology of the nineteenth century, and in France as a result of the brilliant clinical school of descriptive medicine also of the same period. The differences in historical traditions and national characteristics among European countries have produced equivalent differences in terminology, so it is difficult to compare and equate clinical findings. In America the emphasis is on practical considerations, essentially of therapeutic value, and a standard nomenclature—in spite of its limitations—is accepted because of its pragmatic value. Where European psychiatrists speak of mental diseases, implying by this term definite and static entities, American psychiatrists usually speak of "reactive conditions," a concept which includes a more dynamic and total consideration of the individual in his relation to the environment.

In line with this, certain areas of research, such as psychiatric genetics and constitutional typologies, have been investigated with greater attention through detailed statistics in Europe (especially in the Scandinavian countries, Germany, and Switzerland) than in America. Among the factors which have contributed to this trend are the stability of the population and the relative homogeneity of racial groups. In the United States, the concept of multiple causality is generally accepted, resulting in the multidimensional diagnosis and therapeutic approach used in institutions as well as in clinics. As an expression of this cultural frame, psychiatry—as a science dealing with emotional disturbances—is now accepted without too many prejudices among large groups of the population in this country.

It has therefore been said that psychiatrists in America treat conflicts, whereas in Europe they treat symptoms. No matter how naïve this formulation may appear, psychiatric issues in Europe are still dealt with either in the context of a strict patient-doctor relationship, or in the very impersonal and bureaucratic approach of state institutions. The response of the community to psychiatric problems is still a fragmentary and uncertain one, although the personal attitude toward emotionally disturbed individuals of many people working in the community either at a professional

Downloaded from www.dbraulibrary.org.in

level (nurses, attendants) or at a nonprofessional level (for instance, churchmen) is frequently colored by warmth and charitability of spirit. This, perhaps, helps one to understand why, in spite of limited scientific knowledge and scarce funds for research, therapeutic results in European institutions (mental hospitals, rehabilitation centers, treatment homes for emotionally disturbed children and delinquents) are often superior to those achieved in American institutions. Some approaches, applied in Europe for some time, are not yet used in this country—for instance, the "flying team" employed by A. Querido in Holland to treat acute psychiatric emergencies.

European psychiatry has undergone a considerable development since the end of the war. A review of European literature is impressive for the picture it shows of a ferment of ideas, even though only a few of them will stand the test of time. One has to consider, however, that these developments, especially of the psychodynamic school, are expressions of a restricted group of researchers and a limited number of centers. The majority of European psychiatrists, isolated from the rest of the scientific world during the years of the war, are still anchored to the old-fashioned organistic school and quite indifferent to the insights of the psychodynamic school. Instead, many laymen from a variety of backgrounds, particularly psychologists and educators, have enthusiastically (but at times uncritically) embraced the basic principles of psychodynamics —either Freudian or not—and today constitute a large segment of the European psychoanalytic societies. This is in sharp contrast to the American psychoanalytic societies, which are restrictive toward representatives of nonmedical professions.

Considering the problem in its general aspects, one sees in this country a fairly homogeneous acceptance of the basic postulates of the psychodynamic school, which makes possible a common platform of mutual understanding for practical purposes of clinical diagnosis and treatment. In Europe, on the other hand, a variety of different psychotherapeutic approaches, each using a difficult and at times philosophical nomenclature: "Autogene training" (J. H. Schultz), "*Méthode du rêve éveillé*" (Robert Desoille), logotherapy (Viktor Frankl), phenomenological and existential psychiatry, and, finally, reflexological psychiatry are among these approaches.

It is not possible, in the limits imposed by this chapter, to touch even superficially on the particularities of these different currents. Besides the chapter on existential psychiatry in this handbook, additional material can be found in the monographs published in this country by Ulrich Sonnemann and J. H. van den Berg. Unfortunately, almost all the material so far published, except in rare cases (Erwin Strauss's work on obsession, Medard Boss's monographs on sexual perversions and dreams, Viktor Frankl's work on logotherapy, translated in this country in 1955), has to be read in the original languages. Most of the important clinical contributions by Ludwig Binswanger, Roland Kuhn, and Jakob Wirtsch, the phenomenological descriptions by Eugène Minkowski, Henrious C. Rümke, and F. J. J. Buytendijk (on pain, femininity, and the human movement), the "anthropological" contributions by Viktor E. Gebsattel and by the new Viennese school of "deep psychology" (Igor Caruso and Wilfred Dain), as well as the papers published in the yearbook *Situation* in Holland from 1954 on, still remain outside the reach of almost all American psychiatrists. The same can be said of the important articles that periodically appear in such journals as the French *Evolution psychiatrique*, the German *Jahrbuch für Psychologie und Psychotherapie* and *Psyche*, and the Swiss *Schweizer Archiv für Neurologie und Psychiatrie*.

The essential themes of the existential movement center around a strong defense of the intimate *Erlebnis* of the individual, considered in itself and in relation to the dual modalities of human existence. The individual unrepeatable situations in which the human being is "engaged" in his "being-in-the-world" are submitted to phenomenological investigation. The meaning of individual destiny, of responsibility toward life, and of the "decision" of the subject toward the basic issues of human life—such as freedom, happiness, love, work, suffering—is studied through the "inner biography" of

Downloaded from www.pdfbooksfree.pk

the individual and the deviations of his *condition humaine*. Psychotherapy means the "encounter" of the therapist with the patient in the situation of "genuine presence"—the only path to a fecund "understanding."

It is easy to see from all of this why the existential approach to psychiatry has frequently been criticized for its lack of "objectivity" and has so far played almost no rôle in this country. This seems obvious to the historian, considering the pragmatic philosophy underlying American psychiatry. It is more difficult to predict the future mutual influence of American and European psychiatry. The cultural and historical differences of the two continents—endowed with two different types of creativity[8]—seem to slow the effect of the improvement in communications, which normally tends to demolish barriers and differences of opinions.

These barriers are even higher and more difficult to overcome if one considers psychiatry as currently practiced in the Soviet Union. In spite of the scarcity of the reports,[101, 146, 172] there is ample evidence that the themes underlying Russian psychiatric philosophy and especially psychotherapy—persuasion, re-education, work therapy, rest treatment—are quite different from those underlying American psychiatry. In their complete neglect of unconscious motivations and in their emphasis on the processes of the highest nervous activity, they are perhaps more adequate to the Eastern tradition.

The influence of local cultural and historical traditions is also evident in psychiatry as practiced in other countries, as indicated in the reports which are appearing in the American literature, in particular in the collection *Progress in Psychotherapy*.[59, 107, 108]

No matter how strong these local traditions are, the historian has the impression that a marked movement of confluence is present among the different schools, accelerated, perhaps, by the urgent problems posed by the treatment of great numbers of mental patients in large countries. The similarities of the philosophies responsible for the development of socialized medicine cannot be overlooked. Its influence is evident in all fields of medicine, including psychiatry, in spite of the fact that psychiatry, and especially psychotherapy, traditionally resists any direct attempt toward socialization. During the period considered in this survey, American psychiatry has exercised a leading influence among the civilized nations of the world, with the exception of Russia. It is the hope of many that this influence will continue in the near future and that a better reciprocal understanding will take place, in line with Allport's recent statement that "the genius of both [American and European] regional trends is needed to achieve an optimal integration of psychological science."

## ¶ An Over-all View of Modern American Psychiatry

The impact of the main events of the development of psychiatry during the past twenty years is still so much a part of our daily psychiatric thinking, and the men who have contributed to these events are still so close to us in sharing a common *Zeitgeist*, that the duty of the historian becomes an extremely difficult one. The difficulties of the historian of contemporary events—the inability to detach himself from the stream of events and the tendency to limit himself to the function of a chronicler—are quite obvious. These difficulties, practically impossible to overcome, perhaps explain why over-all historical surveys of the last two decades of psychiatry have not yet been attempted.

A number of historical studies have been published in recent years. In 1944, the centennial year of the founding of the American Psychiatric Association, two volumes[11, 75] appeared, containing important historical studies by Richard H. Shryock, Winfred Overholser, Samuel W. Hamilton, John C. Whitehorn, William Malamud, Albert Deutsch, Edward Strecker, Thomas V. Moore, Gregory Zilboorg, Clyde Kluckhohn, George S. Stevenson, Franklin G. Ebaugh, and others.

These, however, limit themselves to consideration of events up to the end of the third decade of the century, a turning point in the history of psychiatry. Surveys of the last two

Download PDF for www.pdfbooksfree.org.in

decades of psychiatry, considered either in its general trends or in its special fields, are still extremely rare, in spite of the imposing editorial activity of recent years and of the increasing interest in historical issues. The reviews on the general trends of American psychiatry, as for instance, by Nolan Lewis[97] and Paul Hoch,[77] are isolated examples, and do not claim sound historical methodology.

Ilza Veith[163] stated, "It is astonishing that medical historians have so far been rather neglectful in their study of psychoanalysis and its founder." Like another medical historian, Erwin H. Ackernecht,[2] Veith goes on to state that the disinterest in the history of psychiatry is not a temporary, but a traditional, one. And this disinterest has existed as much among psychiatrists as among medical historians.

It has to do with a number of obscure reasons, which psychoanalysis has started to investigate. In a brilliant essay, "A Critique of Psychiatry," Alan Gregg[70] focused on these complex reasons: the horror of mental diseases diffused among all the people of the world and the consequent inference of moral lapses as causes for early pathological signs; the tendency to think of mind or spirit as separate from the body; the ambivalent attitudes of society toward psychiatrists; the isolation of psychiatry from general medicine and from the stream of contemporary culture. Furthermore, psychiatry is so intimately related to the scientific, cultural, ethical, and religious currents that accompany its development that it becomes almost impossible to disentangle the history of the one from the others.

Turning now to studies on the history of psychiatry done by psychiatrists, we find these equally scarce, in spite of the fact that "the historical approach is more important to the study of psychiatry than to the study of any other branch of medicine," according to Mark D. Altschule.[10] There is, however, a growing tendency among psychiatrists to recognize the importance of historical studies.

Bromberg,[31] Farrar,[51] Galdston,[61] Lewis,[96] Riese,[134] Zilboorg[176] and more recently Margetts[104] and Mora[119] have made interesting contributions in the field. Freud's centennial served to focus on the importance of such studies[3, 84, 82, 153, 173] and Jones's monumental biography of Freud[81] helped further to stimulate historical interest among other psychiatrists, although their number is still limited.

The reasons behind this relative disinterest in historical issues are complex and difficult to formulate, especially if one recalls that psychiatry—having for its object the human mind—has traditionally been closer to the humanities—and thus to history—than have other branches of medicine. Originally, traditions in psychiatry stemmed from those of the mental hospital superintendents of a century ago—a tradition of scholarliness, paternalism, and humanitarianism. And from those principles arose the highest expression of "moral treatment," which antedated many forms of modern psychiatry. But, in the last part of the nineteenth century, when emphasis shifted toward classification of disease and the neurological approach to psychiatry, this tradition faded. Psychiatry risked losing its essence in the riddle of generalities (as in the concept of neurasthenia) or in phrenological subtleties, or in the confusing formulations of new esoteric religious groups.

In spite of these dangers, psychiatry survived because of the impact of such factors as studies in psychology and education, and in the psychobiological and social aspects of mental disorders. At the basis of all this is the democratic attitude of American society, which made possible the official introduction of Freud's ideas in this country in 1909. The historical significance of this open-minded attitude cannot be overestimated. The uninterrupted tradition of training, research, and treatment in psychiatry, reinforced by its willingness to incorporate the contributions coming out of European research, made it possible to avoid the schisms in the psychiatric movement that occurred in many European countries.

Today psychiatry enjoys a popularity in American culture—in literature, on the stage, on the screen (as one can see, for instance, in Brosin,[33] and in the more recent collection of papers, *Freud and the 20th Century*,[174]) which has elicited concern among many scientists. On the one hand, there is the danger of over-

Downloaded from www.dbpublishing.com

secularization of psychiatric principles, typically reflected in the mental health movement. To quote John R. Seeley,[42] this movement, "with one foot in humanism and the other in science, seeks to perform many if not most of the functions of the relinquishing institutions," to fill "the power vacuum created by the bankruptcy of other institutions." On the other hand, there is the danger of isolation and overspecialization, expressed by the reciprocal ambiguity of psychiatry toward medicine and the biological sciences and by the timid renaissance of "neuropsychiatry."[99]

The last two decades have produced two contrasting developments: the general conservative attitude of the Freudian schools and the increasing influence of sociological issues on overall psychiatry. Both trends have been attacked vigorously on several grounds—the "great psychiatric revolution" brought about by psychoanalysis by Percival Bailey in his 1956 Academic Lecture at the American Psychiatric Association, the modern sociological influence by Pitirim A. Sorokin.[150]

In spite of the progress made in psychiatry—as expressed in the development of the different fields considered above—the historian's responsibility is to advance a strong plea for meditation on the essential themes of the history of psychiatry. Today, these essential themes (the importance of faith and belief in any form of treatment, the tendency for or against restricting mental patients, and finally the relation between mind and body) represent themselves through contemporary events. It is difficult, however, for anyone to isolate these themes from the complexity of everyday life. From a historical viewpoint, the influence of the criticisms cannot be judged until decades later.

Because psychiatry is both science and art, and the human being is its subject, no matter how important the emphasis on many aspects of psychiatry may be, every real advance is related to the personality of the psychiatrist—to his motivations, his ability to disregard prejudices and preconceived ideas, the flexibility of his thinking, his modesty and his capacity to accept criticism and suggestions, his responsiveness to the issues of his contemporary culture. Freud's life and work remain the prototype expression of the psychiatrist, in the humanistic sense, in spite of the fact that his gigantic stature makes him out of reach for the majority of others.

In him the early stages of the historical trends of psychology and psychiatry—a progressive passage from curiosity to research, to greater knowledge, to adequate responsibility—were expressed at the highest degree. The two decades considered in this chapter could be characterized by the greater knowledge achieved by psychiatry. If this is, indeed, as it seems to be, the long-range trend, then the common hope of the psychiatrist and the historian should be that the last stage, that of adequate responsibility, will soon be achieved by American psychiatry.

A brief list of bibliographic sources of literature in the history of psychiatry and psychoanalysis precedes the bibliography for this chapter. The bibliography itself is a brief selection from published material in three specific areas: (1) historical data of the last twenty years; (2) studies dealing with general aspects of psychiatry—e.g., philosophical foundations of its methodology; and (3) contributions to the understanding of psychiatry abroad, particularly in Europe. The latter two represent material that will not be touched on in other chapters.

CHAPTER 3

# THE BIOLOGICAL BASIS OF HUMAN BEHAVIOR

Mortimer Ostow

Downloaded from www.dbraulibrary.org.in

IT IS HELPFUL to the student of human behavior to become familiar with its biological background so that he can see behavior as one among the several functions of the human organism rather than as a separate and special activity. Besides achieving perspective, he will also find, in phylogenetic precursors of human behavior, discrete homologies which will help him to dissect out and comprehend the unitary elements of human behavior which are otherwise so elusive. In this section we shall be concerned with the central nervous system as agent and behavior as the modality whereby the human organism traverses its span from creation to death.

## ¶ The Instincts

### *Terms and Concepts*

The term "instinct" is derived from the Latin *instinctus*, which means impulse. In prescientific literature the term was invoked to account for the apparent directiveness and purposiveness of the behavior of unintelligent creatures. Among those attempting a truly scientific study of behavior, the term "instinct" fell out of favor because it might be taken for a solution to the problem of the form and motivation of behavior rather than a statement of it.

The principle of teleology (from the Greek, *telos*, end) soon contaminated the concept of instinct. As a principle, teleology implies that all vital phenomena subserve ultimate goals or ends. In its original context the term referred to a philosophic quest for the ultimate purpose of existence. It has also been applied, however, to interest in the fact that living organisms show a tendency to act in such a way as to arrive at end points which, to the human observer, are fixed and stereotyped, as if the organism were guided by a consciously known purpose. Used in the latter way, the terms "purpose," "goal," "end," and "aim" may legitimately be employed to describe a behavioral tendency. Unfortunately, some of the proper scientific op-

position to the earlier use of the term has adhered to the more recent use and has tended to discredit both it and the instinct concept to which it applies directly. Because tendency and internal motivation cannot be ignored in the study of human behavior, the term "drive" was introduced into several modern psychologies, and, indeed, the term "instinct," as used in psychoanalytic psychology, is taken as a translation for Freud's term, *Trieb*.

The student of human behavior will be interested in the discipline of ethology (from the Greek, *ethos*, custom or habit) which has been created by a small number of European biologists during the past half century. It is based upon extensive and meticulous observations of the behavior of animals in their natural habitats. Besides providing a large body of behavioral data, the ethologists have also begun to construct a theory oriented about evolution, survival value, and phylogenesis. In their theory, as in modern psychodynamic theory, instinct is restored to a central place in behavior determination, motivation is seen as internal, motivation responds to external triggers, and motivational forces conflict.[60, 61, 93, 96, 97] In the United States, on the other hand, the study of animal behavior has been concerned with mechanisms rather than with patterns and tendencies, and with the impact of the environment rather than with internal forces (cf. Refs. 6, 7, 47, 66, and 83, and the contrasting views of Ref. 52).

## *Instincts in Animals*

Let us turn to the study of instinct among animals as worked out by the ethologists. Tinbergen[96] (p. 112) defines instinct ". . . as a hierarchically organized nervous mechanism which is susceptible to certain priming, releasing and directing impulses of internal as well as external origin, and which responds to these impulses by coördinated movements that contribute to the maintenance of the individual and the species."

It is known that the central nervous system is responsible for the regulation of many functions of the organism that are determined by the conditions and requirements of the internal milieu. When he says that an instinct is a "nervous mechanism," Tinbergen implies that the regulation of the organism's transactions with his environment, including his conspecifics, is also performed by the central nervous system.

The expression "hierarchically organized" means that each fragment of the behavior pattern is mediated by a discrete structure, and that these fragments, in normal behavior, are integrated into patterns by other structural mechanisms which coordinate the activity of several of these discrete structures. For example, the consummatory thrusts of the coital act are mediated by the lowest levels of the spinal cord, yet the entire body is involved in the coital act, and the proper positioning and activation of each of the body structures is presumably arranged by a superordinate center in the hypothalamus (cf. Hess[43] for a discussion of the motor functions of the hypothalamus). Moreover, the entire coital sequence is called into action only by structures which are concerned with the timing and releasing of instinctual behavior. It seems that animals of each sex are constitutionally endowed with a full set of neuromuscular mechanisms, subserving the behavior patterns of both sexes. The definitive sexual performance is determined by the impact of other constitutional factors, and of hormones, on the central nervous system.[6]

The ethologists distinguish between "priming" impulses and "releasing" impulses. As a result of the former, the instinctual mechanism accumulates *vis a tergo*, or potential to act, whereas the latter permit this potential to discharge in action—they trigger the performance.

Among the priming influences are endocrines. The extent and mode of hormonal influence on behavior are set out systematically in Beach's excellent work *Hormones and Behavior*. His conclusions support Tinbergen's view: ". . . the hormone is to be regarded, not as a stimulus to behavior, nor as an organizer of the overt response, but merely as a facilitating agent which increases the reactivity of specific neuromuscular systems to stimulation."[6, p. 198] Beach also calls attention to the fact that, with ascending phylogenetic status,

Downloaded from www.libtool.com.cn

hormonal influences become progressively less important for behavior determination, while "extraphysiologic influence" increases in importance.

Tissue needs constitute a second source of priming influence in the case of nutritive, excretory, and defensive instincts.[66] These are presumably conveyed to the brain by neural mechanisms or by alterations of concentrations of solutes in the blood. To what extent reproductive instincts, too, may be primed by internal sensory and chemical data (aside from hormones) is not known.

The third source of internal priming is intrinsic activity of the central nervous system. Tinbergen adduces much experimental evidence to substantiate his position that activity may arise spontaneously within neural tissue.[86] Though in 1930 Kubie found it necessary to introduce the concept of a reverberating circuit to account for continuous activity within the central nervous system (see also Ref. 55), it is now generally recognized that nervous tissue beats spontaneously even with no input. It is this internal priming which Tinbergen considers responsible for the internal origin of motivation, that is, for growth of potential for action, apart and aside from tissue needs and endocrine influences.

The instinctual behavior that is set in motion is generally fairly complex and protracted. Goals are achieved by sequences of acts, each initiated at the proper time with respect to environmental opportunity and to the instinctual behavior which has preceded it. The initiation of action, then, depends upon release by sign stimuli, which act as triggers. The sign stimulus acts upon an innate releasing mechanism (IRM) which, it now appears, may be provided constitutionally or by experience.[83] The sign stimuli are relatively simple perceptible configurations inherent in the fixed environment, in prey or predators, or in other members of the same species. The initial searching or appetitive acts alone may be initiated internally without an external trigger, following adequate priming.

Whereas some sign stimuli release instinctual acts from block, others serve merely to orient the animal to its object. The tendency to orient is called "taxis."

Immediately following the consummation of an instinctual act, the releasing sign stimulus is least effective, and to be effective at all it must be specific and ideal. As time passes, the animal's susceptibility to release becomes greater, and the releasing configuration may be somewhat less typical. When there has been no consummation for an unusually long period, the instinctual act may discharge spontaneously, even in the absence of any releaser. This spontaneous discharge is known as a vacuum activity. It is primarily the time course of this readiness to discharge that persuades the ethologists to assume that motivation is essentially internal in origin, and that the external event serves merely as a trigger.

The "coordinated movements" to which Tinbergen refers in his definition constitute the instinctual act itself. The consummatory act is always unitary, discrete, rigid, and stereotyped. The appetitive behavior which precedes it comprises a large number of searching, orienting, and approaching acts, combined more or less flexibly. While in his earlier papers, Lorenz seems to consider the consummatory act itself as the instinctual performance, in more recent writings[61] he accepts Tinbergen's view that the instinctual act is comprised of a series of appetitive acts leading up to and including the consummatory act.

Tinbergen's definition states that the instinctual act "contributes to the maintenance of the individual and the species." It has been created out of the pressure of evolutionary selection and serves a biologic function. It is misleading, in my opinion, to designate as adaptation the fact that instincts have a biologic function. The organism, by means of its instinctual mechanisms, exploits the environment for its individual and species needs—in the sense that a predator exploits rather than adapts to his prey. It is for this reason, I believe, that the concept of adaptation is conspicuously absent from Freud's writings.[76]

How do the ethologists reconcile with their view of instinctual behavior the fact that animals can learn? They believe that learning

Downloaded from www.pnaulibrary.org.in

cannot modify the individual instinctual acts themselves; it can only suggest new sequences and arrangements for acts, expand or narrow the range of adequate releasing stimuli, and fill with data gaps that are constitutionally provided (in the sense that animals seem to have a "faculty to acquire" information about local topography). For a discussion of learning within the context of ethologic theory, the student may consult Thorpe's excellent survey.[93]

Imprinting, described by Heinroth and studied by Lorenz,[56,60] is a process, observed among some birds and fish, whereby the young acquire the image (or rather, its template) which will subsequently come to serve as a releaser of filial or sexual behavior only as a result of confrontation soon after hatching. For example, a graylag gosling, if it is cared for by and exposed to only a human after hatching, will thereafter take humans as parents and ignore other geese. This phenomenon has not been observed among mammals.

An animal may learn to ignore a signal of danger if the signal is never followed by any actual danger. This kind of learning is called habituation.

Simple or classical conditioning is the process whereby an essentially irrelevant stimulus comes to serve as the releaser of an instinctual act after it has been exhibited to the animal a number of times concurrently with an innate or already acquired releaser. For example, in Pavlov's classical experiment, the sound of the bell acquires the capacity to release ingestive acts because it is associated with the presentation of food which is the innate releaser of these acts.

If an animal is rewarded by being given the opportunity to perform a consummatory act, such as eating or drinking, every time he performs some irrelevant act, he will learn to perform the irrelevant act when there is a need for the reward. This kind of learning is called instrumental or operant conditioning.[88] The entire sequence may be made effective only in the presence of some preliminary signal, and a series of acts rather than a single act may have to be performed before the reward is obtained. In any case, a sequence of acquired preliminary appetitive acts is artificially associated with a consummatory act.

An animal may acquire familiarity with his environment under the pressure of only "curiosity" drives, that is, appetitive manipulative and exploratory acts. This process is called latent learning, and the information so acquired may be transferred to the service of other instinctual patterns as orienting information or learned performances.[85]

When an animal observes another animal of the same species performing an instinctual act, it may perform the same act. This phenomenon is called social facilitation.

## *Principles for Extrapolation to Humans*

If the ethologic theory of instincts is to be extrapolated to humans, certain biologic differences must first be taken into account. Although among inframammalian classes and among lower mammals reproductive behavior is regulated by hormonal "priming" of the instinctual apparatus, animals further advanced in the phyletic series show a relative emancipation from the seasonal timing effected by the hormones. Human reproductive behavior seems to be entirely free from such influence and continues at the same level of motivational intensity the year round.

The term "retardation" was introduced by the Dutch anatomist Bolk to denote the fact that the human seems to live out his life cycle more slowly than do his phyletic antecedents. Bolk also observed that the earliest phases of the life cycle of subhuman primates were represented by a disproportionately large fraction of the human life cycle. The term "neoteny" signifies that characteristics of the adult human are homologous with features of the fetal or juvenile animal (Ashley Montagu). For example, the whiteness of Caucasian skin and the Mongoloid epicanthus may be considered to be persisting traits of the subhuman primate fetus.

Although the concept of neoteny was developed to account for physical features, it probably applies to elements of behavior as well. For example, the ventro-ventral position

Downloaded from www.dbraulibrary.org.in

in copulation, which is peculiar to humans in mature reproductive behavior, is also encountered among immature chimpanzees. The shift from the ventro-ventral position to the ventro-posterior one, as the chimpanzee matures, is probably to be correlated with the fact that the vaginal orifice of the immature female presents anteriorly, whereas in the mature female it presents posteriorly.[17] Lorenz[58] suggests that the attachment of the domesticated dog to its human master is a persistence into adult life of the wild animal's childhood attachment to its mother.

Roheim[82] and, more recently, Weyl,[98] have suggested that the neotenic principle may profitably be applied to psychodynamic theory. In other words, although the consummatory acts of adult human reproductive behavior must be characteristic of the mature animal, some aspects of the instinctual disposition of the human adult may be derived from features of the behavior of the juvenile animal. Consider the continuity of human reproductive behavior. Psychoanalytic experience has taught us that there is no essential discontinuity in the motivational basis of the filial, mating, and parental aspects of human reproductive behavior, as there is in the animal (although there is a suspension of the child's sensual desires during latency, his emotional attachment to his parents continues undiminished); nor, in the human, do we encounter the seasonal flourishing and waning of reproductive behavior which many animals exhibit. This continuity may be a consequence of the principle of neoteny, namely that the entire gamut of human reproductive behavior is perhaps driven by the motivational impetus of the filial behavior of the animal. Because of this continuity, features of the behavior of the child will tend to persist and contaminate adult behavior. Hence, the adult requires a special device to suppress obsolete behavior patterns. In my opinion, this is the biologic basis of primal repression.[31] It is by virtue of primal repression that the child foregoes the use of oral and anal activities as the mode of relating to the person he loves in favor of genital and nonphysical (sublimated) activities.

When animals are domesticated, they are protected by man from the rigors of an exposed existence, and many of their requirements are anticipated and provided. As a result, the evolutionary selection pressure for an efficient, tightly organized instinctual apparatus decreases and there ensues what Lorenz[56] calls a "mutational loss of behavior elements." Since the human is also, in a sense, a domesticated animal, two consequences of the mutational loss are important in determining the final form of human instinctual behavior: namely, rudimentation and plasticity.

In the wild animal the consummatory act is a rigidly structured, discrete performance, the individual elements of which cannot be dissociated from each other. In the human, on the other hand, although the final movements of the consummatory act must be retained if his instinctual goals are to be achieved, the full fixed sequence is not necessary. For example, in the animal, mounting, intromission, and ejaculation are inseparable elements of a unitary coital act; in the human, only the final pelvic thrusts and orgasmic contractions are automatic, whereas the preceding moves are variable and separable. This fragmentation and de-automatization of the consummatory act has been called, by Lorenz,[60] rudimentation. Coitus interruptus becomes possible only by virtue of rudimentation.

Instinctual behavior consists of a series of appetitive acts and a final consummatory act, each triggered by the experiences encountered in the course of the performance of the preceding act. The repertory of appetitive acts which are available for any instinctual tendency and their sequential arrangement become much more variable in the higher animal. The result of this variability is plasticity.[60] The application of plasticity to the solution of problems has been called insight.[85] The combination of insight with a greater capacity for latent learning may be considered the basis for intelligence. Learning, insight, and intelligence are therefore not incompatible with instinctual behavior and may, in fact, be seen as derived from some of its essential elements.

Finally, the extrapolation of instinct theory from animal to man must take into account the fact that in man we assume that behavior

Downloaded from www.dbeuniversity.org.in

is expressed in and controlled by psychic function, whereas we do not know to what extent a similar proposition may be true of animals. Moreover, we must take care that we compare with the behavior of animals only the overt behavior of man, and not his psychic function directly.

## *The Form of Instinct in Humans*

If we apply these principles of extrapolation to the instinct theory of animal behavior, we obtain suggestions for a theory of human instinctual behavior which is remarkably similar to that which Freud elaborated on the basis of his clinical experience. Although others, before and since, have suggested that instincts govern human life, only Freud has successfully developed his theory from, and applied it to, human psychopathology. The most complete statement of Freud's instinct theory (except for consideration of the death-instincts, *vide infra*) will be found in his *Three Essays on the Theory of Sexuality*. Whereas Lorenz emphasizes the rigidity and stereotypy of the consummatory act and Tinbergen emphasizes the sequential arrangement of instinctual acts, Freud is concerned, in his description of the erotic instincts, with a persevering tendency of the subject to unite with his object and so to effect a physical contact of erogenous zones. I shall present here, briefly, a version of the psychoanalytic theory of instincts in which I shall try to make the homologies with animal behavior evident. (For a fuller discussion, the reader may refer to my paper on the erotic instincts.)[73]

The fundamental equation for translating from behavior to psychic function is that the instinctual need or tendency is represented psychically as a wish.[53] Whereas Freud dissected the instinct into source, object, and aim (impetus will be discussed below), I shall attempt a somewhat finer analysis of the instinctual wish into subject, object, role, contact apparatus, and technique.

The subject of every instinctual wish must be the self. The instinctual tendency applies to the subject individual himself, impelling him to enter into relations with others.

The object of the instinctual wish is the person or object upon which the subject wishes to act (or by whom he wishes to be acted upon). Whereas for the animal the instinctual object is often an inanimate thing (such as nesting material or vegetable food), the instinctual objects which are significant in human psychopathology are always other humans. For the animal[67] as well as for the archaic ego of the human infant,[68] the object is perceived not as a second individual but merely as a collection or "mosaic" of sign stimuli.

I have suggested[72] that it is useful to distinguish between a direct and an indirect object. Although in the case of the animal it may not be especially enlightening to call the prey a direct object and the predator the indirect object of its own predation (in the sense that the predation is performed for its benefit), in human psychology the distinction is more meaningful. It is important that the psychiatrist be able to distinguish between a sexual liaison which is established out of love for the partner and one which is meant merely to assure oneself of one's own sexual attractiveness. In the latter case, the partner is the direct object of the act, but it is performed for the sake of oneself as indirect object; it is essentially a narcissistic act. Similarly, the parents and, later, the intrapsychic representation of parental authority, the super-ego, are often the indirect objects of acts which are apparently concerned only with the self or with nonparental objects.

The subject may wish to act upon the object or he may wish to be acted upon by the object. In the former case we may speak of an active wish, in the latter of a passive wish. Some wishes concern action upon oneself; they are reflexive wishes. In a medial wish one desires to be something or possess some attribute. These qualities—active, passive, reflexive, and medial—refer to the role which appears in the instinctual wish. Reflexive and medial wishes are called narcissistic.

"Homeostasis" is a term coined by Cannon to denote the tendency of the organism to maintain certain physiologic variables, such as the concentrations of metabolites, within narrow limits. Since some instincts serve tissue

Downloaded from www.brainlibrary.org.in

needs,[49] their success is required for homeostasis. Hence, a significant deviation from a normal homeostatic level may become an important priming influence in generating motivational impetus. One may regard such tissue-need instincts as having the self as indirect object; that is, they are reflexive instincts in one sense, though in another sense they may be transitive. Homeostasis probably plays no role in sexual or social instincts.

I suggested above that one could pass from a consideration of instinctual behavior to psychic function by means of the equivalence —instinctual need becomes wish. Although this equivalence is probably valid for optimal states of psychic function, it is clearly invalid for at least two states, namely, early infancy and psychosis. In earliest infancy (before the age of six months) there is probably no psychic concept of an external object.[91] We believe that the infant is aware only of his own feelings of satisfaction or distress; in other words, psychically he is narcissistic.[68] Yet he performs, with the assistance of a responsive mother, a complex series of transitive acts. In the depressive phase of early schizophrenia, the patient has become entirely narcissistic, refusing to acknowledge the existence of external objects. When he resumes interaction with others in the stage of restitution, it is only by projecting upon others fragments of the image of himself.[68] Thus his actions become transitive, while he remains psychically narcissistic. Some of the narcissism of the infant is given up when the mother is recognized (at six to eight months) as an independent, autonomous object individual.

The consummatory act of a transitive instinct involves the apposition of a surface organ of the subject individual with one of the object individual. Hence a full statement of the contact apparatus of an instinctual wish must include a pair of anatomical structures. The contact apparatus of the subject upon which the psychic wish is projected (as if it were the mouth that wished to suck) was called by Freud the source of the instinct.[32] The initial contact apparatus combination is mouth and breast, the latter entering the wish (as opposed to the act) only to the extent that narcissism has been overcome. In a second phase of infantile development, the sensations attending defecation and its control become the focus of instinctual pleasure so that the anus, the buttocks, and the nose appear in narcissistic and transitive wishes. In a third phase the external genitalia assume the principal role in instinctual wishes. Because in this phase only the genital of the boy is recognized as a definitive structure, the girl's organ being seen as a mutilated one, the phase is called phallic. There follows a period (latency) in which no wishes for physical contact appear in consciousness. Latency is terminated by the advent of puberty when the actual genitalia are recognized and made the central focus of physical desire. It is also true that sexual interest may be triggered by perceptions received by sensory organs and by skin sensations in general, so that sexual wishes may include these as the preferred contact apparatus.

Finally, we must consider the actual act or performance—the method by which the subject relates to the object—the technique. The ethologists distinguish between appetitive and consummatory acts. The latter are the acts in which the instinctual goals are realized—the actual feeding, the actual coitus, and so on. The former include all the acts which lead up to the consummatory acts. With respect to human instinctual techniques, I believe it is helpful to distinguish appetitive techniques, that is, those that aim to find or attract the object; preparatory or approach techniques, that is, those that aim to reach the object; and consummatory techniques. Appetitive techniques would include, for example, searching, investigating, exhibiting, and calling attention to oneself. Approach techniques would include methods of physical approach such as pursuing, trapping, attacking, running, jumping, and climbing; methods of influence such as argument, persuasion, courtship, seduction, and deception; and methods of creation such as agricultural, manufacturing, and testing techniques, logical planning and thinking, and artistic invention. Consummatory techniques include, for example, sucking at the mother's breast, cleaning the infant, coitus, and perhaps also parturition. I emphasize these techniques

Downloaded from www.pbpublishing.org

because I believe they are constitutionally provided elements of instinctual function, and so they appear in dreams, neurotic symptoms, and recreation even in those individuals whose lives are otherwise sedentary and require little physical activity.

Freud's term "aim" includes role, technique, and the contact apparatus of the partner. Thus, the aim of the infant's feeding instinct is to suck at the mother's breast.

One of the most momentous differences between animal and human instinct life is the greater plasticity of the latter. Although it is true that, especially in higher animals, instinctual sequences permit some substitution and flexibility, the degree of freedom for creating novel and original combinations of instinctual elements in humans far exceeds that found in animals. We should expect the plasticity if the assumptions proposed above, about neoteny and the motivational pattern of human instinctual behavior, are correct. It will be recalled that I suggested that, whereas among animals each phase of instinctual behavior had its own separate existence and was driven by a discrete impulse, in humans the entire instinctual structure was derived from the infantile filial relation to the parent, and all instinctual behavior that came into being thereafter was obtained simply by ringing changes on the individual elements of the filial instincts. Hence plasticity is necessary for the maturation of the instinctual apparatus.

However, the virtue of plasticity in instinct life is not only the possibility of maturation with respect to drives; after the full maturation has taken place, the individual has available to him, at the same time, a large number of possible modes of discharging the same instinctual impetus. His versatility arises in two ways. First, in certain circumstances he may resort to modes of behavior that were appropriate in the past but have had to be given up as they became obsolete. This reactivation of old modes of behavior is known as regression. Regression occurs in neurosis, in cases of physical illness or disability, and also, within limits, in normal life. For example, when confronted with frustration in a love attachment, it is common for an individual to revert to the kind of relation he had with one of his parents and treat the partner as he would treat the parents, by seeming to be helpless, by demands, by hostility, and so on, which might or might not be appropriate to the current situation. Again, when frustrated in a heterosexual romance, an individual might return to cultivating homosexual interests he once abandoned. Similarly, when genital activities are obstructed, sexual desire may seek expression in pregenital modalities, which, to a limited extent, appear even in normal love-making.

The second source of versatility in human instinct function is the availability to each instinctual drive of a wide repertory of elements, most of which may be phylogenetically derived from other drives, and which in lower animals are therefore unavailable except in their constitutionally given contexts. Now Lorenz speaks of certain locomotor and manipulation patterns as "tool reactions"[57] because they serve each of several instinctual patterns equally well. On the other hand, there are many techniques (and this is especially true of consummatory techniques) which appear in the service of only a single drive in animals, but in humans can be employed for any of a number of purposes; in other words, in humans almost all techniques become tool reactions. Hence the human has a larger collection of tool reactions than the animal. For example, in lower animals, begging is restricted to the filial feeding situation (though in some species it appears also in courtship), biting to the predatory situation, and sucking to the mammalian suckling situation, yet, in humans, begging, biting, and sucking are techniques used not only in their respective, original patterns, but are also in social, mating, parental, reflexive, and sublimated creative or intellectual activities (*vide infra*).

Impressed by the destructiveness of World War I, by the cruelty of many aspects of human behavior, and by the sadism and masochism evident in all neuroses, Freud, in 1920, suggested that humans, in common with all other animals, were driven by an instinct for destruction and death. Although the instinct was effective internally in the first instance, as a practical matter of survival it was deflected

Downloaded from www.ubralibrary.org.in

outward against other creatures. It is my impression[71] that what Freud called the erotic instincts, namely the reproductive, socially unifying, and generally constructive tendencies, are homologous with the intraspecific instincts of lower animals, whereas the death-instincts are homologous with the interspecific instincts of lower animals, namely, instincts of predation and possibly, also, instincts of defense against predation. The problem of destructiveness among humans seems to arise from the fact that it is not excluded from intraspecific relations as completely as it is among animals. First, predatory techniques such as pursuing and fighting are available to intraspecific tendencies only to a limited extent among animals, but they are without restriction among humans. We say that in humans they are libidinized. Second, although humans as well as animals are influenced by instinctual surrender mechanisms,[58] these seem to be less consistently effective among humans. Third, predatory tendencies, in addition to techniques, can be liberated, among humans, not only in food-getting situations, in instances of frustration or attack, but also as a result of neurosis. If it is true that what Freud called death-instincts in humans are homologous with predatory instincts, then they may truly be said to represent the tendency toward disintegration which pervades living organisms (as well as inorganic material), or at least the struggle against disintegration—a struggle which proceeds by obtaining nourishment at the expense of other living creatures, but which is only partially and temporarily successful.

## *The Execution of Instinctual Activities*

When, in 1923, Freud replaced the concept of the topographic psychic apparatus (unconscious, preconscious, conscious) with the structural model (id, ego, super-ego), he defined id and ego in terms of their roles in the operation of the instincts. The id, he said, is the locus of the instinctual drives, the area in which specific patterns are activated. It is concerned only with the needs of the organism, and it creates the motivation for the instinctual satisfaction of these needs. The ego, on the other hand, is a functioning system concerned with arranging for and presiding over the execution of the instinctual drives activated by the id. It includes the perceptual apparatus which informs it of appropriate opportunities for instinctual gratification, and it controls the entire motor apparatus, which, at its convenience, it bends to the service of the instincts. Freud[30] suggested that this distinction between the source of instinctual behavior and the executive agency of the instinctual apparatus might apply in the study of animal behavior too.

It does not suffice to define the ego in such a way that homologous structures are presumed in animals and human. We must proceed to describe the differences between the ego of the animal and the ego of the human. In the mature human the ego prevents the execution of some of the id drives, out of developmental necessity, as a result of past experience, out of concern with its own feeling of comfort or discomfort, or in deference to the super-ego. In animals, especially lower animals, such inhibition of instinctual action out of internal necessity probably does not occur. This gap between the ego of the animal and that of the human is bridged by a hypothetical phase of ego-function suggested by Nunberg.[68] The ideal ego, he said (p. 126), is the ego of the infant which proceeds to gratify, in whatever feeble way it can, all instinctual needs formulated in the id. As a consequence of maturation, the ego acquires the capacity to interpose obstacles to instinctual gratification. The archaic ego of the lower animal may be considered homologous, therefore, with the ideal ego of the human infant.

Though it is charged with obtaining instinctual gratification, the mature human ego differs from the animal ego in that it precludes the gratification of many instinctual needs and at least modifies most of those that are permitted to achieve gratification. For example, even fully gratified needs, such as those for nourishment, excretory activities, infant care, and coitus, are nevertheless circumscribed by an elaborate etiquette. But the mature human ego does more than obstruct and restrict; it exploits even those instinctual needs that may not be gratified, abstracting from them elements

Downloaded from www.pdfbooksfree.pk

such as impetus and technique, and diverting these to the performance of realistically useful acts for which no phylogenetic provision has been made. By the process of idealization,[28] the child eliminates the sensual components from his wishes for erotic gratification from his parents, and consciously retains only a tender love. By the process of sublimation, he "purifies" his physical desires in such a way that, though the instinctual technique is retained, the contact apparatus is excluded from the wish. Let us return to the example of sucking. Sucking, in lower mammals, is confined, either entirely or mostly, to the act by which the very young animal feeds at its mother's breast. As a result of the plasticity of the human instinctual apparatus, discussed above, sucking can be employed in the service of other instinctual needs. One need not suck at the mother; one may suck at oneself or a mate. One need not suck at the breast; one may suck at fingers, tongue, or genitals. One need not suck at anything animate; one may suck at food, cigarettes, or straws. One need not suck with the mouth; one may suck, or wish to suck, or imagine that one can suck with other of the body orifices. The ego may select among these several possibilities some substitute for the obsolete wish to suck at the mother's breast, a substitue which will provide at least some of the otherwise unavailable gratification. But the ego may go even further, and, by intellectualizing, it may conceive and construct sucking machines such as pumps; it may create the concept of suction or vacuum; it may even act by a process of suction—as, for example, by absorbing impressions. By such processes of dissociation, recombination, and intellectualization, the ego is able to defer the performance of consummatory acts to the end of a long detour path, or to divert some of the energy of a consummatory act to other forms of behavior. Substitutes for phylogenetically provided but repressed instinctual acts, which discharge the energy of these in a manner acceptable to the ego, are called derivatives. The selection, devising, and elaboration of derivatives are functions peculiar to the mature human ego. By derivative construction the ego contributes to character formation, social behavior, vocational and recreational activities, neurotic symptoms, and dreams.

## *The Structural Substrate of Instinctual Activities*

The organic substrates of instinctual function have not been worked out with any certainty or even definiteness. This section will include some guesses and suggestions on the subject.

The problem of the ultimate pathways through which the instinctual act is mediated is not quite so formidable. Some elements of consummatory acts are activated via restricted segments of the spinal cord or brain stem, such as ejaculation—by the lower segments of the cord and its autonomic outflow; or chewing —by the pons. Other acts require the coordination of more than one segment, for example, defecation, vomiting, or fighting. This suprasegmental coordination is probably effected by the hypothalamus.[43] (Although the latter has been putatively assigned a number of different functions in behavior regulation, it is my opinion that, since it is a component of the ventral half of the neural axis, its function can only be motor, and, from the evidence at hand, concerned with the coordination of the several elements of the instinctual acts.)

But to what structures of the brain may we assign the patterning and activation of the instinctual acts? Certainly the patterning and, in lower animals, the activation of the acts cannot be ascribed to the cerebral cortex, for in lower classes of vertebrates there is little or no cortex. Since the striate body is the principal motor nucleus of lower vertebrates and its homologue in humans, the globus pallidus, is concerned with movement, I[75] have supposed that these might directly or indirectly be concerned with instinctual action.

In humans, to a lesser extent in other primates, and to some extent in some of the subprimate mammals, there is a segment of cortex lying anterior to the motor area (the frontal, premotor cortex), stimulation of which produces no immediate behavioral effect, though ablation produces profound changes in

Downloaded from www.dnalibrary.com

behavior. In general, the behavior changes that follow injury to this area include a decrease in interest in all but the most immediate environmental opportunities, a tendency to make little effort, a failure to sustain interest for more than a brief period, complete loss of interest in the presence of delay or detour, and, in humans, defect in planning and thinking ahead, absence of creative fantasy, impairment of initiative and perseverance, and disregard of remote consequences which is indicated by tactlessness, euphoria, and facetiousness. (A review of the literature and more extensive discussion will be found in my paper on the subject.)[74] All of the behavior changes, in my opinion, may be understood as manifestations of a decrease in the intensity of motivational drive, a decrease in the continuity of motivation, and a simplification of behavior patterns. I believe, therefore, that the premotor segment of the frontal lobe deals with continuity of motivation, plasticity of form, and derivative construction. I do not know whether the decrease in motivational intensity results from defective function of this area or from its dissociation from the globus pallidus.

## ¶ Impulse

### *The Concept of Instinctual Energy*

The existence of an internal motivational impulse is a central assumption in instinct theory, both animal and human. The organism is seen not as a passive automaton which is galvanized into action by an impinging, energy-giving stimulus but rather as a spontaneously active entity which develops its own "readiness" (Nunberg's term) to act. The action itself is liberated when a proper environmental opportunity is encountered. Immediately after a consummatory act has been performed, the readiness is minimal. As time passes, the readiness increases, as indicated by the rate of searching and by the amount of obstruction the animal will overcome to perform the consummatory act. Moreover, when a drive acquires impetus but is prevented from achieving consummation, it seems to transfer its impetus to some other drive. Hence, both Freud and Lorenz compare the basis of this instinctual readiness to a fluid, which is discharged from a container by consummation of a drive, which increases in pressure with the passage of time, and which, when one channel of discharge is obstructed, will tend to discharge through whatever other channels may be available.

Freud called this hypothetical fluid psychic energy. Libido is the psychic energy of the erotic instincts; the psychic energy of the death-instincts has no name. Lorenz sees the impetus as a property not of the whole drive but of the individual pattern of behavior—it is an action-specific energy. Tinbergen speaks of "motivational impulse" which he treats as a concept similar to what the neurophysiologists call central excitatory state. The student should understand that although these writers speak of instinctual or psychic "energy," they do not imply that the function to which they refer is a direct or indirect correlate of actual metabolic energy. It is a vital function which impels to action, and in this way resembles true energy. Readiness to execute an instinctual act is not a function of metabolic energy but of priming, of rate of regeneration, and of recency of performance.

Although this distinction has not been consistently carried through, it will ultimately be necessary to distinguish potential, that is readiness, amount of energy, rate of regeneration, and rapidity of satiation. Miller, for example, studying rats who became obese following lesions of the ventromedial nucleus of the hypothalamus, observed that the overeating could be accounted for not by a more avid pursuit of food, nor by perseverance in overcoming obstacles, but more likely by slowness in becoming satiated or by rapidity in the rate of regeneration of hunger.

### *The Supply of Instinctual Energy*

If we grant the reasonableness of assuming the existence of a motivating influence which has certain fluid properties, an instinctual and a psychic energy, how can we use this assumption? To my knowledge, no extensive attempts to develop a system of energetics have been made by the ethologists, although many of Lorenz' formulations seem to anticipate such

Downloaded from www.dbraudiohall.org

an interest (cf. his "initial friction" and "inertia of reaction,"[57] p. 262). Freud, on the other hand, has consistently attempted to utilize his energy concepts in dealing with and explaining clinical phenomena. In my opinion some of the drugs recently introduced in the treatment of mental illness achieve their effects by producing certain changes which are best described as alterations in amount or potential of instinctual energy.[77]

I referred above to Freud's distinction between an id, which is the source of instinctual drive, and an ego, which acts as executive agent for the id. If we assume that all behavior is performed only for the purpose of satisfying instinctual needs, and since we have defined our energy concept so that it is seen as the sole carrier of drive, we infer that no behavior is possible without a specifically assigned quantum of energy. Moreover, we may infer that the impetus which is developed in the id must be transferred to the ego before action can begin. Upon this inference Freud based his theory of repression, namely, that instinctual drives can be denied execution if their impetus is prevented from passing from id to ego.[31] Psychoanalysts have also wondered whether the ego has energy available to it other than that provided by the instincts (Hartmann), though it is difficult to see how such an autochthonous ego energy can be imagined if we take into account our definitions of ego and psychic energy.

The results of ego depletion can be seen in melancholia: inertia, a feeling of emptiness and yet heaviness, retardation of mental processes, preoccupation with one's own feelings of discomfort (primary narcissism) to the exclusion of interest in objects, and also self-criticism and pessimism. The results of a plethora of energy supply to the ego can be seen in cases of preschizophrenic excitement: overactivity, a sense of buoyancy, hurried impatience, rapid-fire thinking, preoccupation with a libidinal object to the exclusion of one's own feelings, self-righteousness, and optimism. The former state can be brought about not only by depression following the abandonment or loss of a love object but also by the administration of reserpine or one of the tranquilizing phenothiazine drugs. The latter can be brought about by an accumulation of libido and also by the administration of iproniazid (Marsilid). Although the ego's energy is derived, in my opinion, ultimately from the drives of the id, the ego seems to have some storage capacity so that it sometimes seems to possess its own resources, as for example when an individual responds to an emergency despite fatigue or melancholia.

## *The Dissipation of Instinctual Energy*

The impetus for the performance of an instinctual act subsides promptly after it has been performed.[32, 61, 96] The lethargy which generally follows coitus or a heavy meal is probably the result of the dissipation of drive energy. Moreover, the tonic functions of the ego, apperception, thought, self-observation, posture maintenance, and so on all probably "consume" energy.

The concept of an energy level in the human ego is a useful one. The level may be raised passively by experience of temptation, threat, or pain, and also, I believe, by sleep. The energy level of the ego may be lowered passively simply by its own activity and as a result of physical disorder. The ego may attempt to raise its own level by attention and by physical activity such as walking. It may attempt to decrease its energy level by diffuse and aggressive activity, by actions which gratify completely or partially the upward striving drives (for example, masturbation, nail biting, fidgeting), and by depressive withdrawals. Freud[20] believed that the mental apparatus endeavored to keep its quantity of excitation "as low as possible or at least constant." Menninger and Mayman[65] refer to this phenomenon as psychological homeostasis and propose a psychiatric nosology based upon the nature of the ego's attempts to reduce its energy potential.

## *Possible Physiologic Correlates of Instinctual Energy*

Magoun[63] demonstrated that, in the central core of the brain stem and extending into the diencephalon, there is a structural system which, when stimulated by any afferent stimulus, brings about signs of behavior and electro-

Downloaded from www.psychiatryonline.org

cortical activation of a quiescent brain, namely, the reticular activating system. Wakefulness and consciousness have both been ascribed to this system, and it has also been proposed as the locus of the action of the tranquilizing drugs. I do not believe that there is sufficient evidence to support such an extension from the experimental findings. The reticular activating system can have no more than an *ad hoc* alerting function. If there is any neural structure which is responsible for spontaneity and drive, I'm inclined to point to the globus pallidus, for the following reasons: First, it is the paleostriatum, the phylogenetically old motor system. Second, the syndrome of parkinsonism, which is attributable to disease of the globus pallidus or related structures, generally includes inertia as a prominent symptom. Third, reserpine and the phenothiazine tranquilizers which, in my opinion, decrease the supply of instinctual energy, also produce, in many instances, severe extrapyramidal movement disorders.[77] I am suggesting that the globus pallidus may be the *fons et origo* of all spontaneous activity.

I should like to suggest, too, that during sleep instinctual energy is regenerated, and, in fact, that the primary function of sleep is the regeneration of instinctual energy. In animals, we see more clearly than in humans that the rate of activity is maximal following sleep, and that it subsides progressively until the next period of sleep. The fact that the human ego has some reservoir properties obscures this simple activity cycle in the case of man. Reserpine and the phenothiazine tranquilizers sooner or later increase the amount of sleep required, I suspect, by decreasing the rate of regeneration of instinctual energy. Dement, Kleitman, and others have recently demonstrated that sleep lightens recurrently four, five, or six times a night, and that each period of sleep lightening is accompanied by dreaming. I interpret these episodes of sleep lightening as the results of upward thrusts of instinctual activity which, in turn, follow from the regenerative function of the sleep. The ego seems to be able to dissipate these premature incursions of drive impulse by dreaming, and thus the dream acts as the guardian of sleep.[25]

## ¶ Affects

### *General Biologic Considerations*

With the consideration of affects we leave the area of observed behavior and must face the far more difficult problem of subjective experience. Although we cannot possibly know what, if any, subjective experience may occur in animals, some careful observers, including Darwin and Lorenz, do not doubt that affects appear in, and influence the behavior of, animals. If we follow them, we must assume the existence of some form of consciousness in animals, since affect can exist only in consciousness. Perhaps the most archaic function of consciousness is to perceive affect.[75] In the most primitive vertebrates the chief exteroceptive input to the telencephalon is olfactory. Hence it may be that the most archaic affects are those which developed as a part of the olfactory sensory system. In fact, it may be that the entire affective system developed first as a component of the olfactory sensory system, and it later became available to apperception by other sensory modalities as well.

A pleasurable experience rewards the individual for arranging for the performance of the consummatory act, and it ensures that the act will be completed.[32,60] It comes to serve as a signal which is associated with and identifies the releasing sign stimulus of the act.

Affects, that is, affective sensations, are always accompanied by autonomic changes and changes in the striated musculature. The ratio of the amount of such changes to affective intensity, and the pattern of these changes, are inconstant from individual to individual. Yet the pattern of changes apparent to others is sufficiently constant to permit members of the same species to recognize the affect which possesses the individual at the moment. These signs of affect come to serve as sign stimuli to other individuals, social releasers, which facilitate coordination and synchronization of group activities.[70] The origin of these characteristic affect patterns is uncertain. Darwin[18] suggested that some of these telltale somatic

Downloaded from www.dbebibrary.org.in

alterations at one time served a useful function, that others represented an attempt to undo the first type, and that still others were manifestations merely of overactivity. Lorenz[87] derives these social releasers from a ritualization of intention movements (this is similar to the explanation of Darwin's first group) and from a ritualization of displacement activities (which is similar to the explanation for Darwin's third group). Freud[88] accepted Darwin's suggestion that the expressive movements accompanying affective sensation were phylogenetic precipitates of what had served archaic progenitors as purposeful acts.

### *Positive Affects*

Positive—that is, pleasurable—affects always accompany the performance of consummatory acts. Some positive affects may be all of what is left of a "rudimented" consummatory act, such as the pleasure of feeling sheltered and safe. Perhaps laughter and the enjoyment of music may also be rudimented consummatory acts in which the affect is the chief or only remaining component.

The anticipation of the consummatory pleasure is itself a pleasurable experience, though it is unsettling, in contrast to the consummatory pleasure which is satisfying. Performance of the appetitive acts preceding the consummatory acts are another source of pleasure. The two together, that is, performance of appetitive acts and anticipation of consummatory pleasure, in human love-making compose what Freud called "fore-pleasure," namely, the pleasure obtained from the erotic play preceding coitus, including touching and looking, and involves erotic zones other than the genitals, as well as the genitals themselves. Human behavior, as distinguished from animal behavior, stresses these two forms of preliminary pleasure rather than consummatory pleasure, which is discouraged and restricted by the rules of our society.

A different kind of pleasure is the pleasure of the satiety following the consummatory act. It is the pleasure of not striving, and is occasioned by the reduction of ego energies. Freud[20] adopted the term nirvana-principle for the finding of pleasure in the reduction of ego energies, and saw in it a manifestation of the death-instinct operating against the individual himself. This state of enervation is pleasurable only as long as the individual is permitted to rest. When the fatigued or melancholic individual is subjected to demands, whether internal or external, he feels both his state and the demands to be painful.

### *Negative Affects*

Among humans there is, in general, a tendency to protract appetitive acts and delay consummation, but some instinctual behavior must be performed as the need arises; for example, the needs to defend oneself against attack, to obtain nourishment, and to eliminate urine and feces. In short, when instinctual behavior is required to provide for tissue needs, it cannot be long deferred.

Let us examine first the instinctual arrangement for providing for the prompt satisfaction of tissue needs. When the physiologic need appears, a sensation reminiscent of that accompanying the desired consummation appears, for example, waves of hunger or of excretory fullness. This sensation acts as a lure to motivate appetitive behavior which will lead to a proper opportunity for consummation. As time passes, this anticipatory sensation becomes painful and more urgent. In addition to the pain, a psychic distress appears which is to be attributed to the flooding of the ego with energy and which, according to Freud's view,[24] is anxiety. There are some acts which conceivably, if performed, would delay consummation in the face of mounting tissue need and subjective distress. The specific quality of pain cannot be transferred to the releasers of these delaying activities, but the anxiety can, and when it is transferred in small amounts to label the potentially harmful situation, it acts as a signal, warning against the development of definitive anxiety. To take an example from neurosis, an individual disturbed by a fear of suffocation will develop signal anxiety whenever he finds himself in a small enclosure.

Because the subjective experience of anxiety seems to resemble none of the specific pains of tissue need more than the distress of being unable to breathe, Freud[24] considered a sug-

Downloaded from www.dbraulibrary.org.in

gestion put forward by Rank. Rank proposed that the subjective prototype of anxiety in the adult is the infant's sensation of being born, that is, of its struggle to get its first breath. We do not know whether subjective experience occurs during the birth process, or whether it can be retained.

A similar mechanism operates to avoid painful experiences. When an attack of some kind produces skin pain, an instinctual tendency to fight off the source of pain appears. When fighting is carried out and the pain is relieved, the problem is solved. When fighting cannot be performed, the accumulated and undischarged energy floods the ego and creates anxiety. The same impasse is the cause of battle neurosis, when inactivity under fire is required. If, as a result of experience, some acts come to be recognized as leading to the situation of unrelieved pain, the releasers of these undesirable acts can be labeled not by a signal pain but by a signal anxiety. The diffusion of anxiety from the ultimate experience of pain, back to all possible precursors, is dramatically demonstrated by the patient with causalgia, who develops anxiety when confronted with any possibility that his sensitive limb might be touched.

Let us consider now, not actual attack but threatened attack, or danger. Danger situations may be recognized by innate or acquired criteria. In the presence of a danger situation, the affect of fear appears. While fear is often confused with anxiety, they are not the same. Fear signals the recognition of danger. When action cannot be taken to remove the danger, the ego is flooded with energy, and anxiety appears as well. Premonitory situations which are associated with potential danger are labeled with signal anxiety. Hence the animal flees from such premonitory situations or acts to avoid them.

How does realistic anxiety, as we have described it, compare with neurotic anxiety? Common to the two is their appearance either when the ego is flooded with instinctual energy, or when it seems likely that such flooding will occur. In the case of realistic anxiety, the traumatic situation and its precursors are imposed from the outside. In the case of neurotic anxiety, the flooding or its precursor results from the escape of poorly repressed instinctual drives. Whereas, in the case of realistic anxiety, the individual is induced to flee from the disturbing element, in the case of neurotic anxiety, actual flight is precluded, and a process similar to flight, namely, repression, performs a similar function. Repression excludes from consciousness ideas and wishes which might generate anxiety and so functions like flight.[24] (In phobias, the source of the anxiety is projected into the environment, so that actual flight can supplement repression.) If I read Freud correctly, it is his view that repression may be considered a consummatory act, analogous to and perhaps a rudimented form of escape or avoidance, which is released by signal anxiety.

In summary, anxiety is a feeling of distress which appears in the ego when a consummatory act is released but cannot be carried out, or when such an emergency can be anticipated. In the former case we have definitive, and in the latter case, signal anxiety. Realistic anxiety motivates flight or avoidance and neurotic anxiety motivates repression, so that the psychic representative of the disturbing drive cannot remain in consciousness and act as a releaser.

With respect to negative, unpleasant affects, an important distinction must be made between animals and humans. In animals, almost all instinctual drives which press for discharge are legitimate and deserve consideration. Humans, on the other hand, by virtue of plasticity, neoteny, domestication, and rudimentation, come under the influence of instinctual drives, some of which are obsolete, others dangerous, others forbidden, and others which threaten the existence of the loved object. It is my impression that the system of negative affects is employed to label such unacceptable wishes after they have been scrutinized. One may say that, in a sense, the flexibility and subtlety of the human instinctual apparatus is purchased at the price of recurrent and inevitable suffering.

Let us consider specific negative affects. Horror is not generally attributed to the repertory of animal feelings. Yet animals do avoid dead or mutilated conspecifics, and Köhler[47]

Downloaded from www.freeutbrain.org

describes the fearful avoidance of toy stuffed animals by chimpanzee and dog. The archaic ego of the human, too, presumably is equipped to react with aversion to sights of mutilation, but when the aversion is clearly excessive or inappropriate, it generally appears that the disturbing neurotic fantasy is one which involves confrontation by mutilated male genitals or by female genitals which, to the archaic ego, are a mutilated version of the male genitalia. A horrified individual shudders, as an animal might, to shake some noxious agent off his body. To the archaic ego, a wound is often seen not only as a mutilation but also as a mutilating agent.

Suspiciousness may be thought of as a negative affect too. Animals normally exhibit a curiosity drive which enforces the exploration of new and unfamiliar configurations.[93] However, when the strange configurations include a mixture of new and old elements, or where there is mutilation or death, the exploration drive is slowed. As exploration does occur, the strange becomes familiar, and the need for exploration disappears.

It does not require too much imagination to see signs of disgust in animals. Dogs, for example, will often refrain from drinking water in which solid objects are floating. Lorenz and Tinbergen[62] point out that when an animal is confronted with the releasers of an act which has just been consummated, it may automatically be forced to fix the releaser, yet turn away from it in a satiated "disgust." Köhler[47] notes that if chimpanzees in captivity inadvertently soil themselves with feces, they will seem to be disgusted (though the very same animal may at another time indulge in deliberate smearing and coprophagy). In human psychology, disgust is used to reinforce the ego's efforts to repress coprophagic or cannibalistic wishes.[68]

Depression is sometimes described in dogs who lose their masters. Köhler[47] saw fury, despair, anorexia, and wailing in a chimpanzee separated from the group. Fear, however, was the dominant response when a young animal was separated. The human infant, separated from its mother, cries, presumably as a result of the anxiety which develops from the ungratified instinctual needs and the threat of failure of gratification. Spitz[91] observed that infants separated from their mothers during the second six months of life show signs of sadness, psychomotor retardation, and depressive weeping. The difference between the earlier and the later response is presumably due to the fact that when the infant is six to eight months old, the mother achieves "the full status of a libidinal object." It is when the infant is able to appreciate the mother as an independent, integrated individual rather than as a conglomerate of releasers that depression replaces anxiety as his reaction to separation.[24,68] From a clinical point of view, it is well to remember that it is the longing for the absent mother which is the prototype for subsequent depression, which may, in reality, follow a loss of love-object or of self-esteem.

The crying of the human infant may be understood as a signaling act which compels the attention of the mother. It is to be compared with the whimpering of other young mammals separated from their parents. Tearing occurs not only in humans, but also in other primates and in dogs.

The depressed individual generally acts and feels as though he were suffering a dearth of ego energy.[68] Freud notes too[27] that in both mourning and melancholia the ego seems to be impoverished. It has seemed to me as though, when a love-object must be given up, depression sets in and drains the ego of energy, lest it be flooded as a result of unrequited desire. The ego impoverishment of depression may have a defensive function.

No one, to my knowledge, has attributed a sense of shame to animals. Darwin[13] notes that shame, in man, is associated with blushing, and both he and Freud[32] believe that it arises out of concern with one's appearance. Specifically, Freud suggests that it is the reaction to the wish to exhibit, and motivates a wish to conceal oneself.

Lorenz states[59] that his dogs showed signs of guilt following behavior which they knew was disapproved. What we call guilt in the human is an unpleasant affect which appears when the behavior profile sanctioned by the super-ego is violated. The super-ego is the intrapsy-

Downloaded from www.pbookshop.com

chic precipitate of the images of the parents. It is by means of this intrapsychic existence that the human parent can continue to supervise the behavior of his child and, in a sense, remain its indirect object. The feeling of guilt is a composite one, including at different times anxiety due to fear of punishment, depression, and longing out of fear of loss of love, and often shame which makes a guilty individual wish to hide.

Affects of pity, mercy, and sometimes sympathy generally signify an aggressive wish, which must be repressed. Suppression of hostile intention is seen in the chivalry reaction of animals described in recent years by the ethologists.[58] When an animal is beating another animal in intraspecific combat, the loser automatically performs a ritualized act which has the force of a surrender gesture and prevents the victor from killing. The young of the species and also the female submitting to copulation are immune from attack. While the vulnerability of the object tempts predatory tendencies, when the object is intraspecific an inhibition sets in which prevents or arrests the attack. It is not unreasonable to suppose that this mechanism obtains in humans too, and is manifest in affects of pity, mercy, and sympathy.

### *Physiologic Basis of Affects*

In recent years a large number of experiments relating behavior to brain stimulation and destruction have appeared in the literature. At this point I can do no more than indicate some of my own conclusions from this material. I believe that the basic experiment relating brain structure to affect is that of Klüver and Bucy. They removed both temporal lobes of mature monkeys and observed an absence of innate wariness, an absence of negative affects such as anger and fear, and an increase in the amount and diversity of sexual behavior. Other experiments have since confirmed these observations. Moreover, the affective sensations that appear during the course of temporal-lobe seizures are generally unpleasant, for example, anxiety, depression, and unpleasant odors and tastes. I suspect, therefore, that some of the structures of the temporal lobes are responsible for the elaboration of negative affects.

At the beginning of the section on affects, I considered the possibility that the affective mechanism may have developed originally as part of the olfactory apperceptive system. The hippocampus, which, in the human, is located in the temporal lobes, is a structure which phylogenetically arose as part of the olfactory system but subsequently changed its connections and came to serve all forms of sensory function. A priori, then, it is a reasonable candidate for the source of negative affects. The amygdaloid nucleus, or group of nuclei, is functionally a part of the rhinencephalic system but structurally a part of the striatum. It may serve the function of modulating ego energy in compliance with affective demands. There is some evidence (Olds) that the septal region may be the seat of positive affects. For a fuller discussion of structural correlates of affective function, the student may consult my papers on the psychic function of the temporal lobe.[73, 75]

## ¶ Apperception

### *The Archaic Ego and the Mature Ego*

I have suggested that the ideal ego of the human infant might be homologous with the archaic ego which Freud attributed to animals. It will be helpful to compare the archaic ego of animal and of human infant with the mature ego of the human adult. It seems to me that there are two essential differences. First, as the ego matures, it seems to acquire the capacity, by means of the repression mechanism and by means of the system of negative affects, to deny entry to some of the drives of the id. (The need for this inhibiting capacity and its *modus operandi* have been briefly given above.) Second, the ego of the maturing human (and possibly, to a much smaller extent, the ego of the primate and even of the other high orders of mammals) acquires a supplement. The supplement contains a systematic arrangement of the individual's store

Downloaded from www.library.org.ir

of memory images, so that in his thinking and planning he is not limited to currently available percepts but may draw freely upon a microcosmic representation of his world. This distinction between an ego-nucleus, which is homologous with the archaic ego of animals, and a supplementary structure, which includes memory images and is peculiarly human, is suggested in Freud's last description of the ego.[30] Whereas the perceptual surface of the archaic ego is exposed directly to environmental percepts, that of the mature ego is exposed only to the ego supplement which may transmit a percept derived from the current environment or one from its own store of memory images. By exercising a function which we call attention, the perceptual surface of the ego-nucleus can examine any of the contents of the ego supplement, as its interests may lead it, except for those that are repressed. (For some interesting physiologic data on attention, see the papers of Galambos *et al.*[36] and Hernandez-Peon *et al.*[41, 42])

If one wishes to distinguish the functions of the ego-nucleus from those of the supplement, one may turn to hypnagogic states, dreams, catatonic stupor, and the automatism of psychomotor epilepsy, in all of which, presumably, the ego supplement is inoperative. In these conditions the subject is aware only of his own feelings and has no interest in, or, indeed, knowledge of the existence of other individuals. When encountered, they are ignored or treated automatically, as if they were merely carriers of sign stimuli. This is primary psychic narcissism[28] and probably resembles the kind of subjective awareness which exists in the archaic ego of animals.[58]

We noted above, in our discussion of depression, that the infant responded to separation from his mother with depression only after he had been able to conceive of the mother as a separate and whole object. It seems that this capacity to conceive of the instinctual object as another individual and not merely as a mosaic (Lorenz' term) of sign stimuli does not exist, in general, in lower orders of mammals or in submammalian vertebrates. I believe that this capacity is provided by the ego supplement. As a result of disease, in fetishism, and in schizophrenia, a sign stimulus is treated as an object. In the former case the patient responds to a part of the object's body or clothing, and in the latter to the words or gestures of the object. The development of the ego supplement probably begins with the separate conceptualization of the mother and the self. With experience, the child elaborates it by including in it a microcosmic reproduction of its entire external world.

In a sense, the ego supplement replaces, for the nucleus of the ego, the external world. The stimuli of the latter fall first on the supplement, which may or may not present them for appereception. Moreover, the ego-nucleus is sometimes content to search for object images among those stored in the supplement without resorting to environmental percepts. Lorenz[57] makes the interesting point that what seem to be voluntary acts of animals are no more than tool reactions which build up action-specific energy rapidly and which are readily released by banal stimuli. Analogously, we may reason that what seem to be voluntary fantasies and thoughts in the human are no more than appetitive instinctual impulses presenting themselves to the ego for execution, and finding appropriate object images in the ego supplement.

### *The Apperceptive Process*

Von Uexküll drew attention to the fact that each animal has its own *Umwelt*, its own range of sensitivities to the external world. This range is adequate to provide for the individual's contact with his instinctual objects, and with probably little to spare, for the only function of perception is the direct or indirect facilitation of instinctual gratification. For example, carnivores are equipped with binocular vision which permits accurate aiming at objects straight ahead. Herbivores, on the other hand, are equipped with eyes set at the sides of the head so that the visual fields scarcely overlap.[40]

The human has the binocular field and frontal position of the eyes, characteristic of the carnivores. He also has a central visual field for searching and watching, and a peripheral field which responds to interesting, unex-

Digitized by www.dbaudiobooks.org

pected stimuli. In the tactile modality, one may also distinguish an exploratory function performed by finger tips and tongue, and the passive alertness to sensation of the rest of the body. No such distinction between a central and a peripheral field exists in hearing, but some sounds are more powerful mobilizers of alertness and interest than others.

For the archaic ego of the animal, apperception seems to be simple. Under the influence of an appetitive drive, the ego scans the perceptible environment, or searches until it finds an object which emits sign stimuli to which it is sensitive. When a match of percept and template image has been made, a positive affect appears, and the archaic ego proceeds to execute the next act in the instinctual sequence.

Whence are the template images of the releasing mechanisms derived? Some, as we have seen, are provided innately; others are acquired as a result of individual experience. The innate sensitivities include those for recognizing the perceptible aspects of the instinctual objects and those for dealing with terrain and materials. In the human the experiences which determine the ultimate collection of releasing templates are probably those which precede latency, that is, the period characterized by the repression of sensual desire, which starts at the age of five, six, or seven, and which terminates with puberty. These acquired sensitivities include those for the images of one's parents, one's name, the sounds of one's native language, one's home, and the trappings of the child's life. The ego supplement accumulates not releasing templates but images of objects. However, the instinctual relevance of these memory images is determined by their associations with, or resemblance to, the innate or acquired releasers (see Klüver[45] on equivalent stimuli); hence instinctual gratification in adult life is governed by the significant experiences of childhood. This is the basis of the repetition compulsion,[20] that is, the need to derive instinctual gratification from repeating in adult life some of the experiences of childhood.

In the mature human, then, the ego supplement intervenes in the process of apperception. I would visualize the process in this way. The percept which appears at the psychic receiving station is not permitted direct access to the releasing mechanisms of the ego-nucleus, as it would be in the archaic ego; rather, it must first find a place in the microcosm of the ego supplement. In other words, the "real meaning" of the percept must first be ascertained. As an instance of the microcosmic element which it matches, the instinctual significance of which has been ascertained from experience, the new percept is now permitted to confront the releasing mechanisms of the ego-nucleus. It is because of this detour in apperception that the mature ego comes to deal with images of real objects rather than simply with sign stimuli.

The process of repression has two aspects. First, it opposes the impetus of the prohibited id drive. Second, those images in the ego supplement which pertain to and would tempt the drive are excluded from consciousness; that is, they and their matching percepts cannot be permitted to reach the releasing mechanisms of the ego-nucleus. This second aspect, namely, exclusion from consciousness, is called denial.[26]

Consciousness occurs, in the course of the apperceptive process, when the percept and its paradigmatic image from the ego supplement encounter an appropriate releasing mechanism in the nucleus of the ego. At that point the form of the conscious experience is contributed by the percept, its real connotations by the ego supplement, and its affect by the releasing mechanisms of the ego-nucleus.

## *Deviations of the Apperceptive Process*

This model of the apperceptive process can help us to understand some of the deviations of apperception which we encounter in clinical work. If we see neurosis as the result of a partial breach of the repression barrier, then we can visualize that in neurosis, even those percepts and ego-supplement images which were to be kept apart from the releasing mechanisms of the ego-nucleus, manage somehow to reach them, and so, in distorted form, to be brought into consciousness. In schizophrenia, the ego supplement loses its control over the apperceptive surface of the ego-nucleus which, as we have seen, regresses to the archaic responsiveness to sign stimuli rather than to

Downloaded from www.dbpublibrary.org.in

objects, and which plucks memory images and words from the ego supplement at its convenience, with no regard to the logical and reality-testing criteria of the latter, treating these images as if they were real objects.

Dreaming may also be seen as a distortion of apperception. On p. 70 I referred to the recent observations of Dement and Kleitman and their associates, who recorded the time course of some of the physiologic correlates of sleep. I suggested that the dreams that occurred with each period of sleep lightening represented the effort of the ego to dissipate premature incursions of id energy, and thus protect itself against being awakened. Freud suggested that the ideal ego of the infant was able to achieve some gratification from hallucination and suggested that in dreaming there was a regression to hallucinatory wish-fulfillment. (The student may profitably consult Chap. VII of Freud's "Interpretation of Dreams" for a discussion of the metapsychology of dreaming.) In terms of our model, we may say that, in dreaming, the aroused ego-nucleus takes the images of the still-dormant ego supplement as external objects, as it does in schizophrenia. It deploys these images in such a way that the instinctual needs, which are thrusting upward from the id, appear to be gratified, and at the same time it appears to discharge the energy which threatens to wake it fully. Dream consciousness appears when the images of the ego supplement encounter the releasing mechanisms of the ego-nucleus. The repressive barriers lie within the ego-nucleus and manifest themselves as the dream censor.

A third situation in which the ego nucleus overrides the structural, logical, and reality-testing organization of the ego supplement is the failure of the ego supplement when it has been cut off from its usual source of sensory supply.[38, 53, 89] Subjects who are deprived of afferent experiences, whether as a result of experimental or accidental isolation or as a result of darkness or blindness, show mental confusion, delusions, and visual hallucinations resembling a toxic delirium. In fact, the phenomena of toxic delirium and of drug-induced delirium[8, 79] may be accentuated by darkness or closing the eyes. Perhaps the toxic condition or the drug operates synergistically with the afferent isolation to impair the function of the ego supplement.

Even in the absence of disease, some percepts seem to act directly upon the ego-nucleus almost with the compelling power of sign stimuli, circumventing the barriers of the ego supplement. The human voice, for example, has a cogency which is not possessed by non-vocal sounds or music. A meeting of the eyes means emotional contact. The response to the facial expressions of others is also automatic. Freud discovered that certain configurations, which were themselves not objectionable, seemed to appear with undue regularity in dreams, myths, and art. He suggested that these were used regularly as substitutes for the repressed images of objects and contact apparatus; that is, that they functioned as symbols. Olfactory sensation, the neural pathway of which is unique in that it does not pass through thalamic nuclei before going to the cortex, is not readily integrated into the ego supplement, and, in its ability to command affective response and escape intellectual examination and manipulation, it probably suggests the subjective experience of the archaic ego when confronted with sensations of all modalities.

## *Sensation*

Schilder[84] and Klüver,[44] among others, have attempted to ascertain the ultimate nature of sensation. Subjective experience has been examined by means of eidetic imagery, tachistoscopic exposure, and alteration by drugs or disease. Perceived images consistently tend to fragmentation, displacement, changes of size and color, and multiplication. Moreover, these changes seem to occur rhythmically. Form seems to be most invariant, and form is probably the basis for the classification of images in the ego supplement.

Now these spontaneous and rhythmic changes, while they are probably the consequence of the intrinsic nature of central-nervous-system function, have value in apperception. If the perceived image fluctuates regularly, its real referent need not match the template exactly, for spontaneous fluctuations

Downloaded from www.dbraulibrary.org.in

will tend to obviate differences. While differences in size, distance, intensity, speed, and number may, for certain instinctual purposes, be irrelevant, nevertheless, percepts that are too large, too loud, too bright, or that approach too rapidly are judged dangerous, no matter what their form. Form and, in some instances, color may be considered essential qualities of percepts, while other qualities may be considered irrelevant parameters except when they exceed certain limits in intensity or extent, in which case they are taken as signs of danger.

In the course of psychic seizures resulting from temporal-lobe irritation, there are often illusory alterations in these irrelevant parameters of perception, as well as illusions of reality or familiarity.[73] I am inclined to infer, therefore, that some structures of the temporal lobe are normally concerned with stabilizing these fluctuating images and making them conform to reality so that they can be incorporated into the ego supplement. The same mechanism could also detect the variations in the nonessential parameters and make them available to the ego supplement as well, as auxiliary data. These functions of the temporal lobe are disturbed by the hallucinogenic drugs. In fact, because the temporal lobe receives information from all of the primary sensory areas,[80] because it is the only area of the human brain from which formed hallucinatory experiences can be elicited,[78] because disorder of the temporal lobe produces sensory illusions, and because I believe there is evidence to support the idea that some structure of the temporal lobe elaborates negative affects in the process of apperception, I would suggest that the temporal lobe is the site of the apperceptive process.[75]

### *The Ego Supplement*

In our discussions of human apperception we have had to refer to the ego supplement a number of times in order to account for differences between human and animal function. Its evolution has obviously been important in altering the mode of instinctual function which man inherited from his progenitors.

While the nucleus of the mature ego, like the archaic ego from which it is derived, is regulated by the pleasure-pain principle, that is, the need to seek pleasure and avoid pain, the ego supplement is concerned only with ascertaining what is real and what is possible so that the mature ego can substitute a reality principle for the pleasure principle. The ego supplement also must distinguish between percepts and its own images—it must test reality.

The ego supplement is probably the locus of thought processes, though the thoughts become conscious only when they are examined by the perceptual surface of the ego nucleus. We noted above (p. 67) how the abstractions with which thought deals, and perhaps even the thought processes themselves, are derived phylogenetically and ontogenetically from instinctual techniques. If these are the only sources of our conceptual and procedural models for thinking, then human thought must, in an ultimate sense, be limited—there will always be some facts about the universe that humans can never know or conceive.[76]

The loading of the ego supplement with information is the basis in humans for what we have described above as latent learning. The supplement also attempts to relate events temporally and causally, so that it will be able to make predictions. This tendency was called by Nunberg[68] the "need for causality." It is an instance of the synthetic function of the ego. By imposing a compliance with reality, logic, and true causal relations, the ego supplement tends to substitute secondary-process thinking for the primary processes of the id and of the ego-nucleus which are concerned only with the prompt achievement of instinctual gratification, ignoring the requirements of the real world.

Because the parietal lobe seems to be concerned with speech formulation, with calculation, and with space and form comprehension,[12] I am inclined to attribute to it the functions of the ego supplement, namely, the formation of images of objects, preconscious memory, thought, and the capacity to predict.

## ¶ Ontogenetic Considerations: Constitution

In any given person, many, if not most, of the organ systems participate in behavior de-

Downloaded from www.pbaulibrary.org.in

termination and execution; these are chiefly the brain, spinal cord, musculature, endocrine glands, reproductive organs, and alimentary system. It is to be expected, therefore, that individual variations in these systems will each contribute an individual component to the total behavior pattern. We may assume, then, that an individual's somatic endowment provides a physical substrate which is modified by experience, and which, in its modified form, constitutes the organic basis for behavior determination. While psychoanalytic data demonstrate daily that adult behavior is given content and perhaps form by childhood, and especially infantile, experience, they also demonstrate that one cannot predict which experiences of childhood will be meaningful to any given individual, or what will be the form, intensity, and duration of a neurotic response to a traumatic situation of childhood or a frustration of adult life. Certain experiences are traumatic to some individuals and not to others. For this reason, Freud spoke of a "complemental series" of cases of neurotic illness in which constitutional predisposition and experience played combined roles in varying proportions.[23]

A priori, one cannot predict whether these variations in constitutional endowment will scatter in a random fashion, or whether they will cluster into modes. Nor is it evident that such variations will necessarily betray themselves in readily observable and measurable indicators. That such clustering into "types" will be found, and that the types will be correlated with obvious physical manifestations has been taken for granted by the earlier students of human constitution. Recently, some psychoanalysts have taken an interest in the problem and have attempted to find recordable indications of variations in endowment.*

The term "constitution," as it applies to organic nature, has been defined in a variety of ways. Bauer, a physician, refers to "the sum total of an individual's characteristics as they are potentially determined at the moment of fertilization." Hebb, a psychologist, thinks of the term as "the factor of heredity." Rees, a psychiatrist, recognizes two definitions, one defining constitution in a narrow sense as related to disease susceptibility, the other as referring to the sum total of an individual's physical, psychological, and physiological characteristics. He emphasizes hereditary determinants and, only secondarily, environmental factors. Constitution is often identified with physique or body type, especially its gross aspects. Clinically, the term is sometimes used as a general unspecified reference to some unknown factor or set of factors responsible for otherwise inexplicable conditions or behavior.

Sheldon asserts that "the adjustments of man to his environment require for their description and explanation the selection and functional analysis of *meaningful* variables at all levels of investigation from morphology to cognition." This defines the constitutionalist's task, namely, the systematic establishment of how the organism is dynamically constituted, necessarily an interdisciplinary undertaking.

Constitution, then, is the organizational pattern potential, the selective realization of which, in respect to degree and content, is modified by physical, psychological, and social environment. The constitutional approach assumes all behavior, variations as well as general tendencies, to have an economy and a significance. While concerned with factors common to all organic life and establishment of scientifically defensible generalizations, science fails to fulfill its responsibility until the single case can be accounted for by defining its characteristics, its deviations from the generalized principle, and by determining the significance of the observed variations.

Historically, stress has been placed in constitutional theory on physical and chemical types, and this trend has persisted to the present. Hippocrates was a constitutionalist five centuries before Christ. His twofold descriptive classification divided people into those who were short, muscular, and strong, that is, *habitus apoplecticus*, and those who were tall, thin, and delicate, that is, *habitus phthisicus*. In his system the temperament of an individual was determined by dominance of a par-

* The following material on typology has been kindly provided by Ashton M. Tenney, Director of the Constitution Laboratory of the Research Facility of Rockland State Hospital, Orangeburg, N.Y., and the summary of recent psychoanalytic and biochemical investigations by Sidney S. Furst, Riverdale, N.Y.

Downloaded from www.libraryofpsych.com

ticular body fluid or humor, that is, phlegm—phlegmatic; blood—sanguine; yellow bile—choleric; and black bile—melancholic. The relation of variations in physique to humoral dominance was not clarified. Six centuries later, Galen, an eminent Greek physician, was concerned with the relation of quality of blood and other humors to temperament and pathology. Dryness, moistness, warmth, coldness, or a combination of these conditions accounted for differences in disease and disposition. Some belief in the temperament types of phlegmatic, sanguine, choleric, and melancholic has continued into our own century. Even Pavlov held that a dog's temperament significantly influences formation of a conditioned response.

Interest in constitutional problems, centering at varying periods in such areas as gross body type, size and shape of internal organs, physiognomy, cranial topography, disease susceptibility, embryonic layers, pigmentation, autonomic responsivity, endocrine balance, temperament, race, chemical types, and mental disorders, have been maintained. Investigations usually have led to either a two-, three-, or fourfold typology, providing a relatively crude descriptive scheme, insufficient to account for the nature and extent of human variation in structure and function or personality and behavior.

The most prominent European constitutionalist is Ernst Kretschmer, a German psychiatrist. Prior to World War II his writings received considerable attention and interest in the United States. He classified people by clinical observation and anthropometry into four body types: the pyknic, described as a compact organism with large, round head, thorax, and abdomen, soft-round, poorly muscled limbs, and a marked tendency to put on weight; the athletic, recognized by his strong skeletal and muscular endowment; the asthenic or leptosomic, a thin, fragile organism with poor bone and muscle structure; and the dysplastic, a mixed type. Kretschmer recognized that the pyknic, athletic, and asthenic components may be intermixed in a given physique.

As a psychiatrist, Kretschmer was particularly concerned with the relation of body type to mental-disease entities and believed that the manic-depressive or cycloid type of mental illness is associated with a pyknic physique and the schizophrenic or schizoid type is asthenic in body build.

Kretschmer's observations and conclusions are provocative, but his descriptive system of morphological variation is inconclusive. A recent German edition, in which he has more extensively explored the nature of biochemical, physiological, and psychological constitution as related to morphology, has added impressively to his thesis. When this is made available in English, a renewal of interest in the problem and Kretschmer's point of view can be anticipated.

In the United States William H. Sheldon, of Columbia University, has made extensive studies of human constitution, including problems of physical variation, temperament, delinquency, psychosis, disease susceptibility, child growth, and their interrelationship. His writings and viewpoint have been subjected to extensive appraisal. With respect to the problem of morphology, he defines three basic components or primary variables which may be evaluated in a given individual. These include endomorphy, characterized by predominance of roundness and softness throughout the body; mesomorphy, in which bone, muscle, and connective tissue dominate the body economy; and ectomorphy, in which there is linearity and fragility of body structure with a lack of either roundness and softness or strength of bone and muscle structure. Sheldon introduced a photographic technique which, by use of a standardized medical photograph of the nude subject, made possible the evaluation of the strength of each of the three postulated components, either by inspectional rating (anthroscopy) or measurement of the subject (anthropometry). This technique also provides a permanent record of the subject, particularly useful in longitudinal investigations. When each component is rated on a seven-point scale, a somatotype or body-type index is provided as a quantified description of the physique.

The extreme endomorph is referred to as a 711 (read: seven, one, one), which means that the subject is extremely obese, with minimal endowment or development of bone and muscle structure and is neither linear nor fragile.

Downloaded from www.vbrajbhan.org.in

The extreme mesomorph is a 171, in which prominence of bone and muscle is manifest, without softness and roundness or delicacy of structure. The extreme ectomorph is a 117, deficient in either softness and roundness or strength of bone and muscle. A mid-range or balanced somatotype is a 444. This tripolar schema of classification makes possible a refined discrimination and description of individual differences in physique for comparative purposes. While human physiques are infinitely varied, there are reasonable descriptive limits for purposes of constitutional analyses.

The problem of temperament and its relation to personality is regarded by the constitutionalist as a primary concern of behavioral science. By temperament, the constitutionalist means the persisting disposition and mode of response of individuals to problems, conflict, and stress, essentially rooted in innate differences. In Sheldon's system the temperament is arrayed and rated in a fashion similar to the somatotype. His components of temperament are viscerotonia, characterized by extraversion of affect or uninhibited expression of feeling and emotion; somatotonia, extraversion of action or uninhibited expression of drive and energy; and cerebrotonia or inhibition of both affect and energy expression. He lists twenty traits for each of these three categories. The resulting temperament type is presumed to correlate highly with the somatotype.

In Sheldon's system of constitutional analysis, observation of exaggerated manifestations of temperament lead to the posulation of three first-order psychiatric components: the dionysian, or the pathological lack of the inhibitory or cerebrotonic component; the paranoid, or pathological absence of affect or viscerotonia; and the hebephrenic, a pathological deficiency of drive, energy, assertiveness, or somatotonia. The meaning and value of these concepts are being explored.

Whether the significant relationship between physique and temperament, as alleged by constitutionalists, is a fact or not, no biochemical or physiological typology, comparable to those describing the varieties of physique and temperament, has been formulated.

Are there biochemical and physiological correlates of physique, temperament, emotion, personality, and behavior? Innumerable explorations, speculations, and proposals have been set forth, but still no conclusive and universally acceptable theory or technique has been established.

Eppinger and Hess proposed a typology of individual differences based on relative dominance of sympathetic versus parasympathetic processes of the vegetative nervous system. Opposing states were termed "sympathicotonia" and "vagotonia." Characteristic of sympatheticotonics is high blood pressure and tachycardia, while vagotonics have low blood pressure, slow pulse, and poor peripheral circulation. It is assumed that these conditions have significance for manifest personality and adaptive behavior. More recently a number of investigators have been exploring the meaning of hormones for personality by studying the effects on blood pressure of adrenalin, noradrenalin, and mecholyl injections in groups of psychotic, neurotic, and control subjects. Differential physiological response patterns have been described; these are significant, but they are inconclusive for constitutional study.

Equally promising are the studies of Adcock, who has conducted factorial research in temperament. He proposes four factors: (1) autonomic lability, a tendency to undue emotional fluctuation; (2) autonomic balance, a bipolar factor dependent on the adrenergic-cholinergic balance of the autonomic nervous system (fear and inhibition are associated with adrenergic balance, dominance and anger with cholinergic balance); (3) drive, possibly associated with hyperthyroidism; (4) tenderness, related to maternal response, based on an appropriate hormone. Adcock analyzes these factors in relation to Sheldon's temperament types in the following manner: the factors of viscerotonia are low autonomic lability and tenderness; somatotonia is dependent on cholinergic balance and drive; and cerebrotonia is related to adrenergic balance and high lability.

Under the influence of dynamic psychiatry and modern psychoanalytic concepts, a new trend in constitutional research has recently emerged. Unlike the older work, this approach is unconcerned with classification into types but is aimed at elucidating the role which constitutional factors play in human behavior and,

Downloaded from www.dbraulibrary.org.in

more specifically, in the true dynamic processes by which these factors influence and find expression in clinically observed behavior and personality. In essence, the method involves detailed longitudinal observation of children and infants, beginning at the prenatal stage, and extending through to adulthood, at times including findings in the psychoanalytic treatment of these older age groups.[18, 34, 104, 105] This approach, which of necessity is phenomenological, is based on the following hypotheses: (1) There are forms and patterns of behavior that are manifest at birth and shortly thereafter, which are genetic or constitutional in origin. (2) These patterns play an etiological role in the process of development, and this role can be ascertained objectively. (3) The behavior patterns delineated for study will have more or less predictive value with respect to the child's later responses and personality development. [This follows from (2).] Far from attempting to provide an answer to the old controversy of constitution versus environment, this approach assumes a situation of intimate, continuous interrelation and influence between the two, in accordance with Freud's frequent emphasis of the role played by constitutional factors in both normal and abnormal development.[19]

One research program being carried out at the Child Study Center at Yale University by Katherine Wolf and her associates[104] serves as an example of this method of approach. They conceptualize each developmental step made by the infant, even in the first days of life, as entailing an "individual solution" (which is essentially genetic or constitutional in nature). It follows that there are various ways by which developmental progress can be made. For example, individualization can be evidenced by the particular, preferred techniques with which the infant deals with situations which threaten to disturb its equilibrium—that is, which produce an increase in "tension." Thus, neonatal behavior may be considered in terms of a "tension-accumulation–tension-reduction" syndrome. Four paradigms of this syndrome that can be observed and studied in the baby at birth are: (1) hunger—food intake; (2) fatigue—sleep; (3) gastrointestinal stimulation—elimination; (4) sensory stimulation—motor discharge. These have been carefully studied in many neonates, and it has been found that the mode and frequency distribution of these tension-reduction paradigms differ so greatly from infant to infant that in each case, they yield a cohesive pattern of the inborn equipment of the child and of the way in which this pattern is expressed in the individualization of the child. Further, it appears that, despite vicissitudes due to external and other factors, these patterns can be traced into later phases of development and can serve at any point as the basis for prediction.

A brief excerpt from a clinical example will serve to illustrate the way in which these concepts are utilized:

> Nancy was born after a difficult labor, was uncomfortable to hold, showed a negative response to lifting, and was jittery, screaming, and tense most of the time. After feeding she was, if anything, more tense, cried, and was uncomfortable. However, her elimination course was regular and smooth, with marked rise in tension toward climax, and relaxation immediately following. Later, at fourteen months, she was noted to be well developed but unattractive. She rated high in performance tests. Her most striking features were her sober, unsmiling countenance, and an attitude of "stay away" both toward her mother and, even more so, toward the examiner. She showed a decided preference for playing with images of things rather than with things themselves. In this case the technique of dealing with the environment by exclusion, which was evident at birth, is shown to influence later personality development. Conversely, other observations showed that from the beginning her relaxation potential was high, but self-gratification was the goal, and this was achieved quickly and efficiently.

A similar approach was utilized by Fries and her co-workers, who studied the amount and type of motor activity which newborns show in response to certain stimuli. From these observations the concept of "congenital activity types" is evolved, and this is shown to play an etiological role in personality development. Specifically, the congenital activity type was demonstrated to exert a determining influence

Downloaded from www.cgu.lib.ny.edu

on the child's relationship with its parents, on its psychosexual and ego development, its preferred defense mechanisms, and on predisposition to pathology. Here, too, the constitutional factor was evaluated in the context of its interaction with the environment.

Mittelmann[67] studied several aspects of mobility in infants, children, and adults with respect to the manner in which they influence the development of ego-functions. He finds that a congenitally determined motor drive plays a crucial role particularly during the second year of life, which is designated as "the motor phase of ego and libido development." During this period, motor activity dominates exploratory efforts, attempts to master the environment, object-choice, and other maturational (ego) processes.

Alpert, Neubauer, and Weil[3] have described unusual variations in the libidinal and aggressive drive endowment of three children suffering from neuroses. Initial variations in the quantity, balance, and distribution of these drive energies were shown to be causally related to ego development, maturational sequences, and ego achievements. These authors assume that a similar situation prevails, in greater or lesser degree, in all children, and that it has a significant bearing on development.

Because of the widespread interest in the physical and chemical basis of brain function, recent advances in biochemical research which have relevance to the subject of constitution should be mentioned. Of these, none is more provocative than Williams' concept of "biochemical individuality." Essentially, this is a statement to the effect that the individual is possessed of a constitutionally determined biochemical endowment which differs in many respects from that of his fellows, and that observed physical, physiological, and psychological variations among humans may be better understood on this basis. Historically, this hypothesis, which was first suspected by Garrod in 1902, is supported by a mass of data from transplantation experiments, blood groups, analytical chemical studies, drug actions, allergies, endocrinological studies, and nutritional and enzyme investigations, all of which have given ample indications that such variations exist between one individual and another with regard to quantitative levels of body constituents, metabolic pathways and requirements, etc.[101] Interestingly, the work of Leo Loeb has established that, the higher the place of a given species in the evolutionary scale, the greater is the degree of intraspecific variability. In a series of recent experiments designed specifically to explore these concepts, Williams and his group have tested twelve healthy individuals with respect to forty-two items, including taste thresholds for common substances, and blood, salivary, and urinary constituents, and have found that the resultant pattern for each individual was wholly unlike the others, and bore no relation to a hypothetical norm. There was one exception—a pair of identical twins. The fact that their patterns were similar but not identical indicates that constitutional factors are responsible for the differences in the large group, and this interpretation was confirmed by similar tests on babies. Williams rather conservatively concludes that these chemical differences must have something to do with observed physical and functional variations among individuals. This principle may be assumed to apply to the brain as well—that is, the variability characteristic of psychic function may be, at least in part, accounted for on the basis of inborn biochemical differences. Direct experimental proof is not yet at hand, but evidence of a preliminary and circumstantial nature has appeared. Many amino acids, for instance, have been shown to transverse the blood-brain barrier in both directions at an extremely rapid rate.[51] In addition, the proteins of the brain were found to be in a dynamic state of constant synthesis and breakdown, and further, this "protein turnover" pattern differs markedly, both quantitatively and qualitatively, from one brain area to another, and also from one intracellular structure to another.[35]

Attempts to evaluate the biochemical basis of behavior must be undertaken with caution. Primarily, it must be shown that a given chemical reaction subserves a psychic event occurring in the brain and not a general metabolic requirement of brain tissue. In addition, it is not unlikely that the chemical reactions which

Downloaded from www.brainlibrary.org.il

underlie psychic function are of an extremely fleeting and subtle nature, in accordance both with the rapidity at which these processes take place and with the view that they require extremely small quantities of energy for their execution. Although these considerations may be taken to indicate that it will probably be difficult to gain direct experimental validation of the concept of a constitutionally determined biochemical basis of psychic function, they do not detract from its plausibility or potential fruitfulness.

CHAPTER 4

# PERSONALITY THEORY

Harry Bone

Downloaded from www.dbraulibrary.org.in

PERSONALITY IS MANY-SIDED and so, also, is the interest it elicits. In addition to the general common-sense, naïve, and amateur attention given to it, there are a number of disciplines which have distinguishable kinds of sophisticated concern with persons and their particular ways of being and doing. To mention philosophers, theologians, economists, political and social scientists, educators, personnel administrators, plastic and pictorial artists, poets, dramatists, novelists, biographers, and historians is to initiate a listing that could be extended. As with every enterprise, the motives which govern an active interest in personality are largely determinative of the methods and results of its pursuit and of their utilization. Recognition of this fact might reduce *some* of the disparities among theories. However that may be, anyone who deals with the subject should indicate his intentions.

This chapter will emphasize psychological or "academic" theories of personality, as distinguished from psychiatric or "clinical" views, which are the concern of other chapters. The distinction is practical rather than neat, however, for though the theories which come out of the universities generally strive to be theoretically precise, inclusive, systematic, and capable of universal application, many "academicians" are clinically sophisticated, some are practicing clinicians, some hold medical as well as psychological degrees, and all make use —some much, some little—of the theories and data of the psychoanalytic schools of thought and practice. Furthermore, intellectual, aesthetic, and practical motives for evolving an articulate viewpoint may combine in various proportions in any theorist. It is frequently informative to notice the nature of the research conducted by the proponent of a theory, and also the area or areas, if any, in which he applies or utilizes the theory.

Our discussion will take the following course: (1) an indication of earlier trends which are discernible in current personality theories, and the major steps by which the psychology of personality became a respectable part of general psychology; (2) representative views concerning acceptable approaches to research in personality; (3) an outline of one instance of current "academic" personality theory, which will serve, incidentally, to make more lifelike the ensuing sections; (4) a mere "pointing at" characterization of a dozen contemporary theories, which may aid the psychiatrist in choosing, among those with which he may

not be familiar, the ones he may wish to explore; and (5) an indication of major issues in personality theory, together with some of the different positions that are taken in regard to them.

## ¶ Some Historical Antecedents of the Present Outlook*

The purpose of this section is to give a brief historical introduction (from around 1900) to the discussion, in the succeeding sections, of current methods, theories, and issues of personality study. We shall first characterize the main currents of the period and then outline the events by which the study of the personality in its total aspects became a respectable preoccupation of general psychology in the universities.

During the earlier decades of this century, behaviorism, gestalt psychology, and psychoanalysis partly displaced and partly absorbed the trends that were dominant at the turn of the century. The introspective experimentalism, of which Wundt and Titchener were the most illustrious exemplars, held that the field of psychology was consciousness, and that the method of psychology was the analysis of states of consciousness into their constituent elements (sensations, images, feelings). The new schools, each in its own way, offered alternatives to those principles. Behaviorism and gestalt psychology were, in large degree, reactions against the unsatisfactory *status quo* in academic psychology. Psychoanalysis was outside of that context and arose in response to clinical needs.

### *Behaviorism*

The background of the trends which came to be called behaviorism was the attitude and scientific practice of mechanistic materialism of the nineteenth century. In Russia, Pavlov and Bekhterev, working independently, established—on a quantitative and objective basis—the concept of the conditioned reflex. Pavlov noted that a laboratory dog responded to his approaching step, as to the meat which frequently accompanied his arrival, with salivation. He found that if a tuning fork were sounded when meat powder was supplied, the dog would come to respond to the former in the absence of the latter; that is, that salivary reflexes could be attached to an originally ineffective stimulus (tuning fork) on *condition* that it accompanied, a certain number of times, the application of the native stimulus (meat powder) for this response. Using a fistula (and later more elaborate means) to collect the saliva for measurement, he studied the frequency of dual stimulation that was required to elicit response by the new stimulus alone, how long the conditioned reflex would continue to operate without repetition of the dual stimulation before it became extinguished, etc. Bekhterev, working with reflexes in human subjects (for example, associating originally ineffective visual and auditory stimuli with the native retraction of a finger from an electric shock), progressively elaborated more complex experiments. Both Pavlov and Bekhterev were physiologists and scrupulously avoided the interpretation of their results in the way that analogous phenomena were explained by traditional mental associationist doctrines. They came to believe that intricate habits, including thinking, might be accounted for as combinations of wittingly or unwittingly acquired conditionings (a technical way of describing "learning by experience").

In the United States Watson attempted to make psychology objective by viewing it as the study of *behavior* without the use of mental concepts or even of consciousness (except for verbal reports by human subjects). His originally modest expectations were profoundly fertilized by his discovery of the work of the two Russians, and he and his followers soon came to believe that his conceptions might be expanded to explain all learning, including the learning involved in the establishment of the central psychological functions. In place of the traditional mental concepts—sensations, images, feelings—Watson utilized physiological concepts—receptor functions, effector functions, learning (conditioning). Unstriped-muscle responses, as well as striped-muscle and glandular

* This section relies heavily on Murphy[26] and quotations are from this work unless otherwise indicated. See also Baldwin,[8] Boring,[9] Müller-Freienfels,[23] and Williams and Bellows.[37]

Downloaded from www.brainpickings.org

responses, and consequently the complex patterns of emotional expression and the characteristic traits of an individual, could, in principle, be objectively explained essentially on the same principles. Important for the learning of many complex responses was the physiology of language. The meaning of a word is the conditioned response to it, including the mouth and throat neuromuscular equipment involved in speech. A word thus connected with a given object or situation will elicit the response which the presence of the object would evoke. Spoken words may be replaced by silent speech (thinking) without basically altering the situation because the same innervations involved in overt speech occur, in reduced strength, in "covert speech." When these are not detectable they are presumed to be present and to constitute the mental aspects of the event.

Experimentation and theory formation based on conditioning procedures were extensively and variously developed by many enthusiastic behaviorists, so that by mid-century, as Murphy says:

> Accurately or inaccurately, "behaviorism" means to many psychologists today any of the following:
>
> 1. The biological approach to animal and human psychology, promising that psychology shall some day make itself as objective as physical science.
> 2. A mechanistic or materialistic view of psychology.
> 3. Watson's personal combination of (1) and (2).
> 4. Other behavior-centered systems, such as those of Tolman, Hull, and Skinner.
>
> In other words, the progeny of the behaviorism of a few decades ago are already very diverse in appearance and in disposition.

During the twenties, and due in large degree to behaviorist influence, United States psychologists were predominantly occupied with the learning process. Since man is a desiring organism, and since human desires are learned (that is, since all inherited tendencies are more or less modified by experience), learning theory may occupy itself with the most important aspects of personality. In fact, it can be—and has been—so employed, by some, as to constitute a virtually complete psychology of personality. Two groups of stimulus-response theories may be distinguished according to whether they chiefly emphasize contiguity (association) as the significant factor in conditioning, for example, Guthrie, or reinforcement (reward), for example, Hull.* Behaviorism and stimulus-response theories, with their austere adherence to operationism (see p. 94ff.), represent, par excellence, the nomothetic, hypothetico-deductive, laboratory-experimental, mathematical, physical-science enterprise as applied to psychology.

## *Gestalt Psychology*

The problem of the one and the many seems to be as old as reflective thinking. Certainly, since the time of the ancient Greek philosophers, there have been thinkers who have sought the ultimate building blocks of the universe and its contents, including man. They hoped better to understand complex entities by a knowledge of the atoms or elements of which they were supposed to be composed. Another frame of mind has stated, in various ways and in various contexts, that the whole is more than the sum of its parts, and that the sum of the parts does not explain the whole —perhaps not the most important aspects of the whole. Of course, those thinkers who have defined the problem at the deepest level have wrestled with the question of the relations between wholes and their parts. Associationism —the doctrine that complex conscious states were nothing but combinations of simple stable elements which were associated with each other in various ways—was dominant during much of the eighteenth and nineteenth centuries. However, there were occasional adumbrations of the holistic attitude during that period which can be viewed in retrospect as harbingers of gestalt, or form, psychology. The viewpoint was initiated in Germany in 1912 by Wertheimer, with his experiment on the perception of movement. The following is Murphy's account of it.

* There are proponents of non-stimulus-response, or cognitive, theories of learning, such as those of Tolman, a connectionist, and Lewin, a gestalt psychologist and field theorist. These as well as the stimulus-response theories are summarized in Hilgard.[17]

Downloaded from www.dbuniversity.org.in

When light is thrown through a small slit placed vertically, and a moment later through a slit inclined 20° or 30° to the right, the interval separating the two presentations may be so chosen that the shaft of light appears to *fall* from one position to the other. Wertheimer proceeded to work out quantitatively those time relations which would give (1) two simultaneous illuminated slits, (2) the experience of motion from A to B, and (3) the sense of temporal succession, the first being followed by the second, but no movement being involved. The central problem was the nature of the experience of movement, the phi phenomenon.

The most likely previous view was that the perception of movement was due to a track of light made on the retina by the successive stimulation of adjacent points (as the flight of Zeno's arrow was composed of a series of its stationary positions) which were successively registered in adjacent points of the brain. Wertheimer's production of the experience of movement by two separate stimuli, the eye being stationary, destroyed that explanation, and he insisted that the perception of movement is essentially different from the perception of a series of static visual stimuli. He attributed it to a brain process which actively interrelated the two stimuli. From this beginning he proceeded to a critical study of the part-whole issue, affirming that organized wholes must be approached directly and that insight into them, the understanding of their structure, might also make possible the understanding of their components. A consequence of this view is the law of membership character, namely, that the elements (tones in a melody, colors in a picture) of a given object or event (form, gestalt, entity) are definable, if at all, in terms of their relationships within (membership in) that object or event. Furthermore, it is well known that wholes are experienced as such, even when details are distorted and when some parts are missing. From this and similar considerations, Wertheimer announced a second law, the law of *Pragnanz* ("goodness"), to the effect that gestalts (structured wholes, organized entities), as perceived, tend toward that which is orderly, comprehensive, and stable, and away from the opposites of those qualities.

Murphy says:

> These two laws, the law of membership character and the law of Pragnanz, are typical of many which rapidly evolved in Wertheimer's thinking. They are, in general representative of Gestalt laws as a whole, laws in which one works not with an infinite number of tiny particles arranging themselves more or less independently, but with a limited finite number of possible modes of stable organization, which because of their orderly, rationally intelligible form are capable of being discovered, and their dynamics understood.
>
> The first task of the perceiver, then, is not to create, but to apprehend the order and meaning which is there objectively in the world. This is, so far, essentially like Platonism. There are, however, many forms or structures to be found, not all of which are of equal relevance to the perceiver. Just as perception moves from the incomplete toward that which is more nearly complete, so there is continuous dynamic selection and integration of forms. We have thus a direct transition from the psychology of perception to the psychology of thought, without involving the need of any essentially different principles. We need to grasp, first of all, the order lying in nature and waiting for our apprehension; and second, that internal order which the thinker manifests as he passes from one to another orderly form, creating new order in the succession and in the integration.

Consistent with his view of perception and of thinking is Wertheimer's view of all the psychological functions. Thinking is primarily recentering—the reorganization of experience into a more accurate and inclusive perspective on the object of the thinking. Affective and conative phenomena are not segmental part functions, except secondarily, but involve the gestalt quality of the total organism.

The work of Wertheimer and his two younger colleagues, Wolfgang Köhler and Kurt Koffka, began to be available in this country in English in the early twenties, and very soon thereafter the younger members of the trio accepted invitations to many American universities to expound their outlook. Their verve, which equaled that of the behaviorists, together with the extensive body of experimental material that had been amassed, won wide

Downloaded from www.freeuniversity.org

attention and acceptance among United States psychologists. By the mid-thirties the method had been applied to all the major issues in psychology, and gestalt psychology had become an established school of thought. Though there were few complete converts, the movement strongly impressed upon all psychologists the importance—and the experimental possibility—of serious consideration of the molar structure and functions of personality.

## *Psychoanalysis*

Psychoanalysis is presented in other chapters of this handbook and so needs only brief mention in the present context. Though its origin antedated behaviorism and gestalt psychology by several decades, its influence on psychology in this country was roughly concomitant with that of the other two schools. It broke in from outside the historic stream of academic psychology; it was strange, unexpected, repellent, and intriguing. Its lack of experimentation and of sharply defined constructs did not commend it to psychologists, who had come to consider these qualifications as essential to scientific psychology. Perceptive and eclectic minds gave it serious consideration from the beginning (see Murphy[25]). Others vigorously rejected it for being "unscientific." To Boring,[9] a historian of psychology, it was worth attentive consideration but was labeled "pre-scientific." For a time textbooks on mental hygiene, adjustment, etc., absorbed certain of its ideas, such as the defense mechanisms, and simultaneously flouted its theories and loose methodology. Today it is widely pervasive in academic psychology, especially where the molar aspects of personality are concerned.* All theories of personality are influenced by it, in greater or lesser degree. Some theorists will not include it in surveys of psychological progress, except indirectly in the form of empirical definitions of the issues it has dealt with by its "unsatisfactory" methodology; not a few stimulus-response theorists, such as Miller and Dollard, include it discriminatingly but importantly in their systems; some, such as Murray, who has announced the value to himself of his personal encounter with it through Jung, make extensive use of it in their systems, though not without considerable selectivity and modification. The chief general contributions of psychoanalysis to psychology are perhaps the following ideas: clinical methods of research (as well as of therapy) of unprecedented penetration; the systematic study of the total personality in its actual life situation; the fact, nature, and extent of unconscious mental processes; the pervasive purposiveness of behavior; the inclusiveness of psychic determinism; the profound influence of childhood experience on the adult personality; and the importance of the interrelations of biological, psychological, and social factors (id, ego, and super-ego) to the understanding of "character" (personality).

Our characterization of twentieth-century psychology in terms of three dominant viewpoints, or rather, three groups of basically similar viewpoints, is grossly oversimplified. The emphases of these schools of thought, together with many other ideas, are held in varying ways and in varying combinations by many psychologists. It seems true, however, that, in general, United States psychologists believe—on the basis of a wealth of experimental and clinical material—that both consciousness and behavior, and also both part functions and whole functions, need to be approached directly in psychological research.

## *The Rise of the Psychology of Personality*

It has been said that, in its struggle for emancipation from theology and philosophy and for acceptance among the natural sciences, psychology lost first its soul, then its self, and finally (with behaviorism), lost consciousness. Certainly, the more the study of psychological phenomena was restricted to the available scientific methodology, the less was it possible to deal with personality as a whole. The investigation of molar issues had to wait on the cumulative development of general psychological methods, theories, and facts; on the construction of adequate molar-problem instruments; and on the more probing clinical procedures of psychoanalysis. The following is

* See Murphy[25] for a differential estimate of the influence of Freud on each of the various areas of United States psychology.

Download from www.psybaulibrary.com

a sketchy indication of how these preconditions of formal personality study were fulfilled.

Although there was some mutual borrowing and combining among the three chief schools, cross-fertilization was limited by the fact that each school was a movement, if not a crusade, and by academic adherence to the classical principle that parts of a system are distorted if wrenched from their proper context and "stuck" onto another system. The child-guidance clinics and the social-work agencies, however, performed the function of a melting pot. These increasingly numerous enterprises were less squeamish about eclecticism because of the practical urgencies they faced and because of the paucity of their scientific resources. In these institutions psychiatrists, social workers, and psychologists, increasing numbers of whom were psychoanalyzed, welcomed ideas from behaviorism, gestalt, and psychoanalysis. Their case histories, which involved the whole person in his real life situation and were replete with facts but limited in meaning, became progressively more structured in terms of personality dynamics. This confluence of events was a main source of the modern conception of personality study.

Concomitant with these primarily organismic approaches, "environmentalists" were making significant discoveries. To take but one illustration, Margaret Mead's publications in the twenties and thirties,—especially, perhaps, her account in 1935, of sex and temperament in three primitive societies in which "masculine" and "feminine" traits and occupations differed strikingly from those of our own culture—demonstrated the profound influence of cultural factors in the structuring of personality. The professional journals had for some time carried hundreds of articles which dealt with the biological and social aspects of personality, but these were generally subsumed under "physiological psychology" and "social psychology," respectively. In the thirties, however, three books on the psychology of personality (Stagner, *Psychology of Personality*, 1936; G. Allport, *Personality: A Psychological Interpretation*, 1937; Murray, *Explorations in Personality*, 1938) dealt inclusively and creatively with the diverse contributions and "pointed the way to an experimental science of personality study. The psychology of personality was being recognized as a subdivision of general human psychology. . . ."

The development of new probing devices for diagnosing personality marked a crucial step. From the turn of the century, attention had been given to individual differences, and it was recognized that the individual *projects himself* into his receptive and assertive relations with the world. Intelligence testing offered an opportunity to introduce scientific method into the matter of individual differences, and, later, psychiatric need for diagnostic aids stimulated the development of tests of other components of personality. Rorschach's ink-blot test, progress toward the standardization of graphology, the interpretation of spontaneous drawing and painting and of children's play with "dolls" representative of important relationships, and, finally, Murray's thematic apperception test in which the subject reveals inner attitudes by "making up a story" from the stimulus of an ambiguous picture—these and many more similar procedures have proved remarkably effective in penetrating into the hidden substructure of personality. "The development of projective testing has done more than any other single thing to give formal personality study a place in psychology, enabling personality research to stand on its own feet as a legitimate inquiry relatively independent of problems of diagnosis and therapy."[28] The limitations of projective techniques—the fact that most of them are cross-sectional only—are slowly being met by systematic longitudinal studies of individuals through many years of development.

A further augmentation of personality study as a science comes from the activities of psychologists in applied fields. For several decades psychologists who were so disposed found opportunities for the application of their science in schools and colleges, industry, clinics, and courts. Although psychotherapeutic application was limited prior to World War II, the war provided unprecedented opportunity and stimulus for that activity, and at the present time psychotherapy is an important integral aspect of psychology. The therapeutic activity of psychologists has significantly invigorated the scientific psychology of the universities by

Downloaded from www.dbraulibrary.org.in

infusing fresh data and problems into the courses and by extending the field of services for which university curriculums are an important part of the training.

Now, at mid-century, *Psychological Abstracts* and *The Annual Review of Psychology* both have sections labeled "personality," and there are journals which are devoted largely or entirely to personality. There are many books on personality theory—academic as well as psychoanalytic—and, increasingly, books which draw impartially on both those historic currents. Books are beginning to appear which present, evaluate, and compare sizable groups of individual theories. There is widespread, if not universal, recognition that part functions are functions of a unified personality which is highly determinative of their nature. In fact, it is now necessary to define what the difference *is* between general psychology and the psychology of personality. Murphy states that, should a psychologist emphasize the more complex functions and expressly desire to see all interrelations within the organism at once, as well as the hierarchy of laws governing those interrelations, he would be occupied with the psychology of personality. "The psychology of personality would then be that particular kind of general psychology which emphasizes the totality and the organic systematic relations which obtain within it."[27] G. Allport, who has always stressed the uniqueness of the individual, goes further: "The day may come when psychological formulations will be regarded as invalid unless they are written to accommodate personal patterns of functioning, personal attitudes, and personal projects. A good general psychology will then be a theory of personality."[3]

## ¶ The Question of Method in Personality Research

We shall present the views of a few representative psychologists regarding ways of studying personality. (No attempt will be made to deal specifically with the imposing array of ingenious and elaborate experimental and mathematical means and instruments currently used by psychologists in research.) The viewpoints chosen for this purpose, because of their explicitness and their variety, are those of Hall and Lindzey, Murphy, G. Allport, Rogers, and Munroe. After their views are stated, the methodological conceptions of several psychiatrists—Freud, Sullivan, and Arieti—will be indicated, and some generalizations will be attempted.

### *Hall and Lindzey*

Hall and Lindzey[16] hold that theories of personality can, and should, constantly strive to conform to the positivistic logic and rigorous experimental methods developed by the physical and biological sciences. They admit the fertility of some theories which do not meet their standards, however, and are lenient toward existing theories because they represent the present elementary stage of personality research. The following is a summary of their position, chiefly in their own words.

A theory is a set of conventions (terms, concepts, definitions), a creative, imaginative organization by the theorist of his observation. It is an artistic, arbitrary product. It is not and can never become either true or false, though its implications may be either. A theory is, rather, useful or not useful—useful if it can generate predictions or propositions regarding relevant events which turn out to be verified (true). Ideally, a theory is a cluster of assumptions systematically related to each other and to a set of empirical definitions. The assumptions, which generally represent the distinctive quality of the theory, should be pertinent to empirical events. They may be general or specific, according to the extent of the area the theorist wishes to embrace. They may be mathematically precise or relatively inexact. Assumptions must be clearly stated and explicitly related to each other and to the other elements in the theory. This is the "syntax" of the theory, and, unless it is clear, derivations cannot be made from it.

The empirical definitions (or coordinating definitions) permit the more or less precise interaction of certain terms or concepts within the theory with empirical data. In this way the theory comes, at certain prescribed places, into definite contact with reality or observa-

Downloaded from www.dbraulibrary.org.in

tional data. Empirical definitions are frequently called operational definitions, because they specify the operation by means of which the relevant variables or concepts can be measured. The investigative purpose of the theory is thus indicated. The empirical (coordinating, operational) definitions may be more or less exact and may be quantitative or qualitative. Precision is preferable in principle but should be relaxed if, in given circumstances, it restricts the theorist to insignificant matters.

Turning from the structure to the function of a theory, the authors indicate three things a theory does. First, it leads to the collection or observation of relevant empirical relations not yet observed. The core of any science lies in the discovery of stable empirical relations between events and variables. The function of a theory is to further this in a systematic manner; it is a proposition mill. Only those derivations or propositions or ideas derived from the theory are open to empirical test. The theory is assumed, and its viability is determined by its utility, not by its truth or falsity. Utility, in this connection, means the verifiability of the propositions derived from it, and its comprehensiveness, scope, or completeness. A theory may be verifiable but insignificant. Ideally, it should make predictions of inclusive scope.

Some theories, which do not observe the principle of constructing empirical definitions and therefore cannot generate research systematically, nevertheless have a heuristic value due to other characteristics, and produce much research. The theories of Darwin and Freud illustrate this.

A second function of a theory is to incorporate known empirical findings in a logically consistent and relatively simple framework. It is a means of organizing and integrating all that is known regarding a related set of events. (Because theories are guided in their inception by what is known, they are in that sense "inductive.") But this organizing of the known is a minor function of theories; their major function is to point out new and unobserved relations.

The third function of a theory is to prevent the observer from being dazzled by the full-blown complexity of natural or concrete events. It is a set of blinders directing his gaze so that he can abstract what is pertinent to his purpose, on the basis of explicit assumptions. A useful theory will give rather explicit instructions as to the kind of data to be collected. This is why a given empirical event may be studied from many different theoretical positions with diverse results.

So much for the structure and functions of scientific theory in general. Applied to personality theory, it means that "a theory of personality must be a set of assumptions relevant to human behavior together with the necessary empirical definitions!" Hall and Lindzey add, "it must be relatively comprehensive . . . should be prepared to deal with any behavioral phenomenon which can be shown to possess significance for the individual."

Viewing their conception of what personality theory should be like in the light of the existing theories (both psychoanalytic and academic) which they expound in their book, they comment as follows: "Our discussion [that is, their theory of theory and of research methodology] is of value in identifying the qualities toward which all theorists aspire and it also gives some idea of what, eventually, personality theories should look like. It is clear, nevertheless, that at the present time they do not look like this." Existing theories, they say, lack explicitness, their assumptions are hard to get at, they are confused regarding what is assumed and what is stated empirically as open to test; that is, the distinction between the theory and its implications or derivations is poorly maintained. Since in the light of this scientific ideal the theories are so seriously lacking, would it not be better, the authors ask, to give up the effort for the present and focus on empirical tools and specific findings? Their answer is, "Not at all!" For since nothing can be done without theory (implicit if not explicit), the abandonment of theory is to give oneself up to implicit or unconscious theory, which is not to know very clearly what one is doing. But, say the authors, poor as they are, the available theories of personality are far from useless: They direct investigation, they provide specific dimensions which are considered important in studying the problems they are addressed to, and their heuristic value is great, since it has led to large

Downloaded from www.objectivelibrary.org

quantities of research and a healthy flourishing of investigation.

## *Murphy*

Murphy has a fine appreciation of classical literary and philosophical psychology, but the general scientific revolution of modern times, which became effective in psychology in the late nineteenth century, receives his most energetic devotion. He believes that we cannot know how far the experimental method can be extended but that where and when it is applicable to psychological problems it wields the final authority. However, he recognizes that most of the crucial issues in personality study are currently amenable to the strictest methods to only a limited degree, and that these issues —to the borderland of psychology and philosophy—should be attacked with whatever methods are available. He recognizes as major research tools "(1) the genetic methods (the cross-sectional comparison of groups at different developmental levels, and the longitudinal-biographical study of individuals); (2) the comparative methods (the phylogentic and the anthropological-sociological); and (3) the experimental method." Statistics may be thought of as a fourth method or as an adjunct of each of the others. The sections of his major contribution to the theory of personality,[27] with his chief sources of information for each, are: (1) organic foundations—the heredity-environment origin and substructure of personality (genetics, embryology, physiology, and comparative psychology); (2) learning—growth, the acquisition of a behavior system, conditioning, complex integrations, conflict (genetic and experimental psychology); (3) the personal outlook—sense perception, imagery, feeling, imagination, and thought (partly experimental psychology, but largely the observations and inferences of the clinic and life histories); (4) the self—the ego, ego defenses, unconscious processes (genetic observations, experiments, interrogations and, in particular, the psychoanalytic methods); (5) wholeness—the interrelations of traits and the organization and functions of the totality (experimental psychology); and (6) individual and group—the implications of the communal nature of personality, situationism, personality and culture, field theory (the social sciences).

## *Allport*

The term "personality" has two meanings—it is a name for a general characteristic of human beings, and it is the name for the uniqueness of each human being. Allport considers uniqueness the most basic characteristic of personality and has repeatedly defended the concept of the person, all of whose manifestations have membership character in his essence, against all forms of scientific reductionism. To one who said that "psychology, as a science, deals with universals, not particulars," he replied that "as long as psychology deals only with universals and not with particulars it won't deal with much—least of all human personality."[2] In one article he discusses the question whether personality is a problem for science or for art, and concludes that both are necessary to do justice to it. Referring to "the four basic provinces of research and learning: the natural sciences, the biological sciences, the social sciences, and the humanities," he says, "Have you ever thought before that it is in the territory of psychology and *only there*, that all these four intellectual winds collide and run a tempestuous course? I suppose it is natural enough that they should do so, for only by the aid of all the inventions and all the resources of the mind can the creative mind itself be adequately explored."[4]

Another of his beliefs is that there are two contrasting outlooks on personality, each rooted in a deep-lying philosophical predilection.[5]

> There is a basic difference in philosophical assumptions regarding the nature of mental life, the Lockean tradition being dominant in England and America; the Leibnitzian and Kantian on the Continent. . . . The Lockean tradition, in brief, holds that man's mind by nature is a *tabula rasa* (environmentalistic leaning); mind does what it is made to do (a leaning toward reactivity and behavioristics); its components are basically discrete (simple ideas), and its organization therefore a matter of cementing bonds (associationism). While not all these doctrines are fully developed by Locke himself, his particular brand of em-

Downloaded from www.brainmaster.com

piricism paved the way directly for Hume, Hamilton, Mill, and later for objectivism. Darwin gave the tradition a functional turn, and borrowing from Freud gave it depth. But the tradition remains clearly traceable. By contrast, the Leibnitzian and Kantian positions have been dominant and, in my opinion, are still dominant on the Continent. They are clearly reflected in present-day characterology. To Leibnitz, as to Kant, the intellect was perpetually self-active (not merely reactive). When Locke said *nihil est in intellectu quod non fuerit in sensu,* Leibnitz gave his famous retort . . . *excipe: nisi ipse intellectus.** To him, the inner and spontaneous workings of the mind were at least as important as its content or productions. His concept of the self-active monad easily became the person who with his entelechtive strivings pursued a unique destiny (cf. Stern's personalism).

These two contrasting *weltanschauungen* "are still reflected . . . in all basic psychological thought." His general conclusions regarding method are as follows:[8, pp. 19, 21]

The scientific ideal which we all share—though we may define it variously—has one serious charge against it. It has produced practically none of the substance for current theories of personality. . . . Excessive methodological purity, as advocated by some Anglo-Americans, can result in bigotry and sterility. On the other hand, if fresh insights, phenomenological deliverances, and hunches are freely allowed, disciplined method can at the proper stage help sift the wheat from the chaff.

## *Rogers*

Rogers' method of deriving his theory of personality is unique among academic psychologists. He created a strikingly original psychotherapeutic procedure, which he and his associates practiced for some years, and finally he formulated a theory based, apparently, entirely on observations of therapeutic phenomena.† He initiates the construction of personality theory by induction based on observation (supplemented by listening to electronic recordings) of his psychotherapeutic interviews with clients. From assumptions generated in this way, he deduces operational hypotheses which he tests by objective measures. The experimental means used by him and his associates in their major research effort[31] at Chicago University included various methods for quantifying psychological variables (Q-sorts, and specially designed rating scales), statistical procedures, and projective techniques (the thematic apperception test, the Stein sentence-completion test, and tachistoscopically given Rorschachs). The molar units of the research were twenty-eight completed, verbatim-recorded cases of client-centered therapy. To these must be added the control cases and the attrition cases (those who did not continue in the therapy). The therapy was conducted for therapeutic *and* research purposes. This school of therapy has certain characteristics which make research of this kind more encompassable by it than by most of the others. (Even so, the time and labor required were enormous.) Clients are generally seen once a week. The length of the therapy, which is determined by the client, is relatively short; one of the subjects in this research completed her therapy in four weeks; the three longest cases continued, respectively, 137, 91, and 78 weeks.

Rogers has reported, in a much-discussed article,[31] how he resolved the conflict between his imaginative flights and his experimental duties. In summary he says:

> Science is a way of preventing me from deceiving myself in regard to my creatively formed subjective hunches which have developed out of the relationship between me and my material. It is in this context, and perhaps only in this context, that the vast structure of operationism, logical positivism, research design, tests of significance, etc., have their place. They exist, not for themselves, but as servants in the attempt to check the subjective feeling or hunch or hypothesis of a person with the objective fact.

## *Munroe*

Munroe's viewpoint roots in her practice of clinical psychology and her close study of the

* There is nothing in the mind which was not [first] in the senses. . . . Nothing except the mind itself.

† It is in keeping with this that his theory of personality should occupy a few pages at the end of a large book devoted to procedure and clinical findings.[30]

Downloaded from www.psychiatrylibrary.org

psychoanalytic schools of thought. She believes that some aspects of the life sciences are amenable to physical-science methodology, but, because organisms are crucially different from inanimate objects, and particularly because the human organism is crucially different from all other objects and organisms, the important aspects of personality can be studied more accurately by relatively "loose" methods. These methods should not be borrowed from other sciences but developed from empirical relations with this unique material, while means for the reduction of error are evolved in the same manner. She writes:[24]

Too often this [theoretical] perspective (should I call it *operationalism?*) has led to efforts at careful definition and measurement in psychological science analogous to the methods of physics. Many of these methods seem to me inappropriate to our essential task. The systems we deal with in psychology are of a different order, and must be studied in different ways. Almost by definition, the exact sciences deal with systems which are repeatable and measurable for the purpose of the investigation (the hypothesis). I shall refer to such systems as "tight."

Fairly tight systems are not unknown in the life sciences, but most of our significant problems are subject to scientific ordering only through recognition of *processes*. Our useful systematizations *should* be thought of as relatively "loose", —as *not* definable and measurable with anything like the precision of physics. Any organism has a *history* peculiar to itself which makes it intrinsically different from every other organism, unlike the atoms which resemble each other so closely that the physicist or chemist can cheerfully ignore variation up to the highest reaches of the quantum theory. By virtue of its especially great flexibility in learning, the human organism is especially variable as a unit that is observed. Its past experience is of crucial importance. Furthermore, it adapts itself creatively moment by moment to the current situation—not as a neatly definable entity, *homo sapiens*, but as an organized personality.

Psychological science *must*, I think, work with processes and trends, with "loose" systems. Exact definition and measurement are helpful tools for many aspects of our problem. For the most part, however, better understanding of a trend (a system) is more feasible and more useful and more *correct* than a finicking precision.

She recognizes that certain pitfalls are indigenous to the traditional method, for example, *reductionism*, the tendency to overgeneralize a useful formulation; and *reification*, the tendency to make a causal entity of a useful dimension or description of dynamic relationships. But she believes that these temptations should be handled by awareness of their existence and by creative vigilance rather than by abandoning the whole approach and replacing it by an alien one borrowed from the physical sciences.

## *Freud*

The source of Freud's theory of personality was clinical—the intensive idiographic study of a relatively small number of cases. The essential methods of the strict scientists—clearly formulated assumptions, operational definitions, and objective or experimental testing—were not employed. Members of the psychoanalytic schools have generally followed, and follow today, Freud's clinical method, though some of them have interrelated theory formation and clinical observation more closely. Freud considered psychoanalysis to be a part of psychology, and explicitly stated his views on method.[15] Hall and Lindzey[16] after quoting him, summarize with admirable accuracy and succinctness his position, which is in sharp contrast to their own.

By choice, then, Freud preferred the more open, informal type of inductive theory-building which stays reasonably close to the empirical supports upon which it rests to the more formal deductive type of theory which starts with sharply defined concepts and carefully phrased postulates and corollaries from which testable hypotheses are derived and subsequently tested. Moreover, as this quotation shows, Freud was fully aware of the importance of the "prepared mind" of the scientist in enabling him to make maximum use of his empirical data.

Digitized by www.psychoanalytic.org.in

## *Sullivan*

Sullivan has declared himself as follows:

> Clinical research in psychotherapy is participant observation addressed to the problem of improving the living of the patient but done well enough and reported well enough to make it possible for others to approximately repeat it—the procedure—when they find themselves in significantly similar inter-personal situations.[36]

Though this quotation does not indicate it, Sullivan made extensive contributions to theory, but, for him, theory and therapeutic procedure and the observed phenomena (of which the therapist was an integral part) constituted an almost indivisible syndrome. It is as though understanding and skill were to be acquired in the richness and imprecision of the practical effort where two whole persons constituted a unified "field," and as though what was learned was to be conveyed (operationally, but not in the usual sense of the term) to one's fellow students who might test it in the same kind of practical activities out of which (with the aid of Sullivan's "prepared mind") it had come.

## *Arieti*

Arieti[7] solves the basic methodological issue with a forthrightness reminiscent of Alexander cutting the Gordian knot. He sees the solution of this problem in recognizing two distinct methodologies which are not to be integrated with each other logically but both of which are to be used, at appropriate points, in personality study:

> The scientific or nomothetic approach studies phenomena in order to abstract the laws which rule these phenomena. The knowledge of these laws is considered necessary to enable the student to interpret, to predict, and eventually to alter the course of the phenomena. . . . This approach is more concerned with quantities than qualities, more with categories than with the individual. The idiographic or historical approach deals more with qualities than quantities, with specific entities and with the sequence of events more than with laws and classes. . . . The pursuit of [the scientific] method in psychiatry has, as a whole, been extremely unsatisfactory. . . . [Furthermore, some psychologists have attempted to utilize this method but] not with great success. . . . Freud . . . revolutionized the methodology in psychiatry and psychology. . . . What Freud and the Neofreudians did was to apply the historical method to psychology and call it psychodynamic. . . . [In general] the psychoanalytic profession has accepted the historical-idiographic method. The longitudinal character of the study, the temporal sequence, the detail, the motivation, the global outlook, the emphasis on the uniqueness, on the autonomy of the individual, are all characteristics which pertain to the psychoanalytic procedure.

A roughly graded series of outlooks on method may be generalized from the foregoing examples.

1. Those who believe that psychology is scientific only to the extent of its use of physical and biological science methods. (If Hall and Lindzey's principles were applied more narrowly and strictly than those authors require, they would speak for this category of theorists.) They are, procedurally when not philosophically, mechanistic and materialistic; they maximize the continuities and minimize the discontinuities between man and the subhuman species.

2. Those who believe that strict methods are, in principle, applicable to personality study, though at present the realization of that ideal is limited (for example, Hall and Lindzey).

3. Those who, while highly valuing the idiographic methods, believe that the experimental methods can and should conquer more and more territory, but that it is for the future to determine how far they can go (for example, Murphy).

4. Those who, while they believe, like most students, in the use of both "tight" and "loose" methods, believe also that "loose" methods are, and will continue to be, the most adequate means of understanding the superior aspects of personality. They emphasize the discontinuities and de-emphasize the continuities between the human species and other species. They also emphasize the uniqueness of individual personality (for example, Allport, Munroe).

Downloaded from www.dbraulibrary.org.in

5. Those who believe in clinical means as the deepest sources of insight into personality, but who believe (a) that scientific psychology affords assimilable and useful contributions (for example, Arieti) and (b) that the checking of clinically derived theories should be done by objective methods (for example, Rogers).

6. Those who rely on clinical methods and have little confidence, or show no interest, in exact-science methods in personality study. Probably only nonacademic clinicians would fall in this category (for example, Freud and Sullivan).

It is clear that there is considerable congeniality between the clinicians and the "right" wing of the academicians. There are differences, however, which are probably due to the distinguishable difference in their occupational aims. The latter are professionally concerned with the systematic advancement of knowledge, whereas the former are professionally concerned with the alleviation of the suffering of individuals.

There is a "method" of understanding personality which is seldom mentioned in academic discussions of method but which is highly valued by many psychologists and psychiatrists. This is the method of understanding personality through self-transformation through growth in self-insight, whether achieved by psychotherapeutic experience or some "natural" equivalent of it. Personality is the one object in the universe which the investigator can study from the inside as well as from the outside. It is the one field of research in which the researcher himself is an instance of the object of his research. Furthermore, self-understanding is never merely the understanding of one's unique, idiosyncratic self; experience seems to indicate that the deeper one enters into his own individuality the more understanding he has of that which is universally human. It seems inevitable, also, that the more truly one experiences personality, in himself and in his relationships, the more truly will he understand objectively acquired psychological knowledge. (The reverse does not seem to be necessarily true—perhaps because objective psychological knowledge may remain a restrictedly cognitive or "intellectual" acquisition.) For these reasons many clinicians and many right-wing academic psychologists consider self-understanding to be the basic psychological, as well as psychotherapeutic, "methodology."

## ¶ Murray's Personology: an Example of Contemporary Personality Theory

Personality is the continuity of functional forms and forces manifested through sequences of organized regnant processes and overt behaviors from birth to death. The functions of personality are: to allow for the periodic regeneration of energies by sleep; to exercise its processes; to express its feelings and valuations; to reduce successive need-tensions; to design serial programs for the attainment of distant goals; to reduce conflicts between needs by following schedules which result in an harmonious way of life; to rid itself of certain persisting tensions by restricting the number and lowering the levels of goals to be attained; and finally, to reduce conflicts between personal dispositions and social sanctions, between the vagaries of antisocial impulses and the dictates of the super-ego by successive compromise formations, the trend of which is towards a wholehearted emotional identification with both the conserving and creative forces of society.[29*]

The psychologist's objects of concern are individual human organisms, or persons. (Groups are the sociologist's objects of concern.) But a person is an emergent entity *of* and exists *in* a certain physical, social, and cultural milieu and cannot be properly represented in isolation from it. The superordinate governing institution of the human organism is the personality, or mind. The brain is not

* This quotation is the summary at the end of the fifty-page exposition of his conception of personality by Murray, with the collaboration of his anthropological associate, Kluckhohn. It indicates the major themes but will be more meaningful in the light of the epitome which follows here, and very much more meaningful still if one reads the complete original exposition. In the epitome the phrases of the authors will be used as much as possible, but space-saving curtailment will eliminate most of the examples, logical development of the ideas, and excellent style and wit. The greatest violence to the text will be the omission of the authors' qualifications of many of their assertions: for instance, ". . . it seems best to think of the id as consisting of . . ." will become ". . . the id consists of . . . ," etc.

Digitized from www.libtibrary.com

the personality, but it is its anatomical center and main constitutional determinant. Because so little is known of the psychophysical correlates, we will forget the brain and restrict ourselves to the psychical-behavioral level of analysis and formulation.

The establishments (a person's knowledge, value system, vocational goal, etc.) and the processes (his transient perceptions, emotions, intentions, etc.) which constitute a personality are out of sight and must be inferred from the facts of his behavior and his reports of his mental content. Hence, in actual practice, the personality is an abstract formulation composed by the psychologist.

"Regnant" refers to momentarily governing processes at the superordinate (regnant) level of integration in the brain field. It may be perception, apperception, intellection, expectation, etc., and it may be conscious or unconscious.

Personality is always in process: the history of the personality *is* the personality. For convenience the waking hours of a person's life may be divided into a sequence of temporal segments or proceedings of personality, some of which are mostly internal and some mostly external. An external proceeding, an instance of a person coping with some aspect of his immediate physical or social environment, is the psychologist's simplest real entity. It is the thing he should observe, analyze, try to reconstruct, and represent, if possible, with a model, and thus explain; it is the thing he attempts to predict, and against which he tests the adequacy of his formulations and hypotheses.

A person's behavior cannot be adequately characterized by a list of adjectives, because the situation he is in at a given time is a determinant of his behavior. Thus the environmental situation which is an integral part of every external proceeding (real entity) must be, in its more relevant portions, described or symbolically represented.

In an interpersonal (dyadic) proceeding—the psychologist's most significant type of real entity, or transaction—the other person constitutes the ever-changing situation of the subject, and vice versa. Consequently, both sides of the equation must be given equal analytic consideration.

The result of a proceeding can be roughly indicated by representing the structure of the field (the instantaneous total situation) at the beginning and at the end of the transaction. For a more exact understanding it is necessary to conceive of a proceeding as a succession of instantaneous fields, each of which determines the action that ensues at the moment. The behavior of a person is in terms of the external situation (the other person) as he sees it. This is the beta situation, as distinguished from the external situation as it really is (the alpha situation), which should be ascertained, whenever possible, by direct inquiry.

Every proceeding leaves some trace of its occurrence, so that gradually (sometimes suddenly) a person changes. As a rule the psychologist looks for uniformities among events, but he should not overlook exceptional occasions, which may be fateful.

Many actions, though temporally discrete, are resumptions of similar previous actions and anticipate future resumptions of them (for example, skill learning, enduring relationships). Such a functionally connected but temporally disconnected series of proceedings is a serial. Various actions, especially serials since they often express inner initiative, may be called proactions, in contrast to reactions, such as are denoted by the old stimulus-response formula. Generally, proaction is not merely homeostatic (serving to restore a normal psychological homeostasis) but superstatic (aimed at growth, development, creation). Serials are important because of their interrelations with the ego system and with means-end learning, skill learning, value learning, and emotional development.

Certain specific objects or kinds of objects which become more or less enduringly attractive or repellent to a person are, respectively, objects of positive cathexis (positive value) and of negative cathexis (negative value). When the object is both liked and disliked, it is ambivalent. A positively cathected object is said to have final or intrinsic value when it is enjoyed for its own sake, instrumental or extrinsic value if it is merely a means to an intrinsic value. Parental and other family figures are important cathected objects, because the interactive patterns or themas established

Downloaded from www.dbraulibrary.org.in

with them influence later relationships. A cathection which is too binding, which should be outgrown in order to permit a more appropriate cathection, is a fixation.

Personality is both the ground and product of activity. Its particular perceptions and apperceptions determine its view of the world, and hence, through numerous trials, failures, and successes, the personality evolves and changes. Generally this is gradual, but sometimes (probably not without latent incubation) it is sudden. Different kinds of serials are dominant at different periods of life, others merely holding their own, some possibly regressing during a given period. Since the establishments of personality change with time, the description of them must distinguish different long periods in the life course—infancy, childhood, etc. Any one of these should be studied by means of closely observed representative short periods.

There are three major types of activity: (1) ungoverned, or process, activity and (2) governed activity, of which latter there are two forms: (a) modal, or formal, activity and (b) directional, or instrumental, activity. Process activity is both effortless and aimless. During the early dependent and irresponsible period, the infant's needs are satisfied by the mother, to the mere cue of a cry. The mind is left free for random processes, which consist in the transformation of percepts into images and also, later, into words (symbols) and fantasies.

Modal activity, like process activity, is of intrinsic value but is more organized. It involves the achievement of excellence or form. The most obvious illustrations of it are participation, expressively or receptively, in storytelling, and in dramatic and musical performances.

Most dynamic psychologists have neglected process and modal activity and have assumed that the most important thing to observe in a person's career is its major directionality of activity. Since directional activities vary in respect to their intensity and duration, their degree of coordination, and their definiteness of aim, it is customary to conceptionalize a directing superordinate "force" in the brain region. It has been variously named—tendency, drive, need, propensity, instinct, urge, impulse, desire, wish, purpose, motive, conation, resolution, intention, etc. We use the term "need" or "need disposition" to refer to the roughly measurable "force" in the personality which is coordinating activities in the direction of a roughly definable goal; and we use the term "aim" to refer to this need's specific goal (to be achieved perhaps in association with a specific object in a specific place at a specific time). Thus, "directionality" means the trend of the activity, and this can be defined only in terms of its aim, or goal, or intended effect. Since Freud, the aim may be conscious or unconscious. The habit of American psychologists to take the hunger and sex drives as basic illustrations is not adequate for the study of "higher-order" human motives.

The infant's mind is not acting most of the time as the instrument of some urgent animal drive (as many psychologists assume) but is preoccupied with gratifying itself. Among these purely mental gratifications of early life is the need to dramatize everything, to invent another world that is more exciting and hence more "real" than the reality of sheer perception. This inner world of childhood provides the basic stuff out of which are shaped forms of play, myths and religious rituals, songs and dances, folk tales and poetry, and even, at a later date, philosophies, scientific theories, and technical inventions. The child—and the adult—not only enjoys imaginative activity but enjoys also the imaginative products of others. The human mind is inherently a transforming, creating, and representing organ; its function is to make symbols for things, to combine and recombine these symbols incessantly, and to communicate the most interesting of these combinations in a variety of languages, discursive (referential, scientific) and expressive (emotive, artistic). In short, the mind lives in two worlds—the world of imagination (religion, art, and science) and the world of perception and practical action. In some areas the two may coalesce; in other areas they may be poles apart. It is the former which is peculiarly human, as distinguished from the predominantly practical lower organisms. In insanity a person does not go "out of his mind," but wholely "in his mind" (Santayana) and out of the external world. Creative mental needs

Downloaded from www.dbraynard.org

have no clearly envisaged goal; step by step, they realize something that never existed before.

A need is not a discernible fact but an intervening variable, hidden in the head, which must be inferred from certain criteria. Hence needs must be diagnosed. They are sometimes obvious and sometimes extremely obscure.

Happiness, though emphasized by most great thinkers of the past, is generally neglected by psychologists. Actually, satisfaction is an affective state which is likely to manifest itself objectively as well as subjectively. It is no more difficult to diagnose than anxiety or anger. We propose a variable, *H* (hedone), which is rooted in the brain (possibly the thalamus) and which varies along a continuum, the hedonic scale. At the lowest end of the scale, *H* manifests itself subjectively as a feeling of extreme dissatisfaction (dejection, depression) and objectively by readily distinguishable postures, etc.; at the highest end, by extreme satisfaction (elation, joy), combined with its objective signs. Indifference is represented by the center of the scale. Every occurrence which moves *H* down the scale is hedonically negative; up the scale, hedonically positive. The aim of all needs is hedonically positive (in the imagination). The person may, however, be in error in his expectation, which means that goals (values) are something that must be learned. This conception is not psychological hedonism, for people never deal with pain, or pleasure, in general. Rather, what is required is the elimination of a certain kind of dissatisfaction or the achievement of a certain kind of satisfaction. Need, then, is the fundamental variable, and the degree of satisfaction (hedone) the best indicator of its state or progress.

The concept of "role" is strategic to the integration of two levels of theoretical analysis, psychological and sociological. Every self-and-body must perform certain individual roles (functions)—biological, psychological, and interpersonal. Every group (social system) must perform a number of social roles to maintain, govern, defend, reproduce itself, etc. By extending the conception of role (social role) to personal roles, a psychological action system and a social action system can be represented as roughly homologous, at least in certain respects. All social roles require one or more kinds of actions (the habitual production of one or more kinds of effects), and these effects (goals) can be classified in the same manner in which needs are classified. At times the individual need-aim and the social role-aim may exactly correspond, namely, when the individual wants to do what his group wants him to do. The extent of this happy harmony is limited by the necessity for concerted action, the requirement that the action be performed at a fixed time. In view of the role action needs of the personality, most individuals try to conform to the group's schedule of role functions.

A need is a general disposition which commonly becomes associated (through "focalization," or "canalization," as Murphy would say) with a number of specific entities (for example, a certain doll, or dog, or person, or group, or town, or theory, or work of art, or religion, etc.) and, through "generalization," with a number of kinds of (semispecific) entities (for example, French wines, or horses, or women, or music, or novels, or philosophies, etc.). As life proceeds, some attachments are outgrown and some new ones are acquired. Certain permanent attachments (for example, mother-fixation) are problematic. So also is the inability to remain loyal to anybody or anything. In addition to provisional maturational or age-level needs, there are diffuse (free-floating) needs and focal (enduring) needs. The distribution in any personality of different kinds of cathections (evaluations, sentiments, attitudes) are correlated with the three vectoral dispositions (Horney): moving toward people (positive goal objects), moving against people (negative goal objects), and moving away from people (noal objects). Positively cathected goals and goal objects (kinds of values) are of two classes: (1) goals which have been experienced rather regularly and (2) goals which attract but have not been attained. By "learning" American psychologists almost always mean means-end learning. More important are goal and goal-object learning, that is, the acquisition through experience of valued goals and goal objects.

Social psychologists, concluding that much human thought and behavior is value-oriented, took "attitude" as their key concept (Allport).

Downloaded from www.brainvalley.co.in

They view personality as a relatively integrated system of attitudes, each of which is a relatively permanent disposition to evaluate some entity negatively or positively. The general or specific entity (object of the attitude) is a value, positive or negative, or has value (power to attract or repel). Incidentally, "attitude" and "sentiment" are synonymous. "Value" is synonymous, in one sense, with "cathexis" and "valence" and, in the other sense, with "cathected entity" and "object with valence." There is always a representation (image) of the valued or cathected entity *in* the personality. Most social psychologists see a gap between attitudes (vaguely defined dynamical forces) and needs (or drives): the former are "higher" and the latter "lower" and "segmental"; the former are "pulls from in front," the latter "pushes from the rear." Actually, the concept of attitudes must be broadened to include all affect-invoking entities from feces to the Fallen Angel. Also, they must be connected with directional activity (the concept of need), so that it may be known how strongly and in what ways a given interest is pursued. As for needs (for example, aggression), not only must the object of the need (for example, brother) be specified, but also the value (for example, one's freedom) in the service of which the need has operated. This means that both action tendencies and valued entities must be classified. Following Levin and Erikson, we call action trends vectors, each of which is a physical or psychological direction of activity, such as (1) rejection, (2) reception, (3) acquisition, (4) construction, (5) conservation, (6) expression, (7) transmission, (8) elimination, (9) destruction, (10) defendance, (11) avoidance. Valued entities (more difficult to classify) might be: (A) body (physical well-being), (B) property (useful objects, wealth), (C) authority (decision-making power), (D) affiliation (interpersonal affection), (E) knowledge (facts and theories, science, history), (F) aesthetic form (beauty, art), (G) ideology (system of values, philosophy, religion). (These are the six components which form the basis of Spranger's typology, with the addition of "body.") Note that each value vector is a need. Such a scheme permits a high degree of concreteness. It can also be used to distinguish the action trend (*need-aim*) in the subject and the action trend (*press-aim*) in the object. In sequence they constitute the thema of a proceeding. For instance, the proaction of the subject (s) could be that of *expressing* (6) an *idea* (E) and the reaction of the object (o) might be that of *rejecting* (1) the *idea* (E): Thema: sE6—oE1. For a more complete statement of the thema, other variables (cathexis, status, conformity to role) must be added to each side of the formula. (The authors state that this scheme is still in process of construction and not yet ready to be applied to the topics which follow.)

Before Janet and Freud, the mind was equated with consciousness. But with the recognition of unconscious establishments and processes, in all people, the conception of mind was greatly expanded. The id is not merely the repository of unacceptable dispositions, in conflict with the "rational" ego; rather, it consists of all the basic energies, emotions, and needs (value vectors) of the personality, some of which are wholly acceptable when expressed in a culturally approved form, toward a culturally approved object, in a culturally approved place, at a culturally approved time. Thus the function of the ego is less to suppress than to govern instinctual needs. Criteria of ego-structure (ego-strength) are in terms of certain specified capacities of three ego-functions. For instance, one of three criteria of A, perception and apperception, is *external objectivity*—the ability to perceive human actions and events without distortion, to analyze and interpret them realistically, to predict the behavior of others. One of three criteria of B, intellection, is *concentration, directionality*—the ability to apply one's mind to an assigned or selected topic, to direct one's thoughts along a chosen path, to persist when bored, to inhibit daydreaming. One of nine criteria of C, conation, is *conjunctivity of action*—the ability to schedule and organize one's activities, to make a plan and follow it, to live an ordered life. The power of the ego, relative to other ego systems, requires some knowledge of the strength of the id. Some "egos are astride a docile pony, others astride a wild broncho." The chief criteria of id

Downloaded from www.dbraum.org

strength are: (1) intense energy, zest, spontaneity, and enthusiasm; (2) intense needs and appetites; (3) intense emotions; and (4) abundant, vivid imaginations.

Freud's oversimplified account of the super-ego must be radically revised. The super-ego develops by stages, stratum upon stratum. In its most primitive form it consists of no more than projections of the child's own oral, acquisitive, and aggressive tendencies, represented, say, by a vampire, werewolf, or gigantic biting animal, such as Moby Dick himself, or, possibly, by a child-devouring witch or deity such as Kronos. In the child's imagination "totem" animal figures are gradually replaced, as they were in the evolution of religions, by human figures, first, perhaps, by an affrighting God-father image, and then usually by a more kindly symbol of moral authority. Here we are speaking largely of the lower layers of super-ego formation, marked by archaic, semihuman, and mostly punishing images. As socialization proceeds in Western cultures, these strata, overlaid by others, become unconscious, and in later life are manifested only in dreams, artistic productions, and insane delusions. Contemporaneous with the development of these imaginative, figurative, mythological, or religious aspects of the super-ego, one finds the gradual structuration of behavior according to certain abstract moral imperatives which are transmitted by parental example, suggestion, persuasion, promises, rewards, threats, or punishments. According to the given parent, these may consist of arbitrary and inconsistent pressures, or a fairly rational ordering of ethical principles. In either case, conflict is bound to occur with the rise of the second major source of super-ego constitutents, the reciprocative and cooperative interactions among members of the individual's peer group. An additional class of super-ego determinates is literature, which exposes the youth to a great variety of contrasting moral judgments. Most mortals cannot make order out of such diversity, and, as there is no central authority among most Western religious groups, wide agreement on basic assumptions and their rationalized derivatives is found only among members of totalitarian systems, such as Communist, Fascist, etc. As a result of these several factors, there is, in contemporary America, more and more adjusting of behavior to the evaluations of one's peers, while the inward Puritan conscience has lost its "charm." The deterioration of the religious and ethical super-ego is made clear by comparison with the intellectual or scientific super-ego, which is increasingly self-exacting. In childhood the chief conflicts are between id tendencies and parental restraints. Later, if socialization advances, many conflicts are between id and super-ego (internal standards). During these years the ego is hardly more than a battleground, or puppet, dominated alternately by the id and super-ego. Eventually, however, under favorable circumstances the ego may become strong enough to arbitrate to some extent between id impulses and super-ego imperatives. Ideally, the super-ego is an inviting conception of an ideal, or at least better, future world; the ego-ideal an inviting conception of an ideal, or better, future self. If integrated with the super-ego, the ego-ideal will portray an individual who is promoting in some small or large way the development of a better world. If not so integrated, the ego-ideal may consist of images of the "master criminal" or of any other wholly egotistical "successful" person.

Following their discussion of the major structures and functions (establishments and processes) of personality the authors continue with two sections which we will merely note. Under "Formulations of Personality" they describe how their scheme is to be used in the actual practice of assessing a personality. Under "Major Functions of Personality" they justify their choice of functions and describe in detail those listed in the "Summary" which we quoted at the beginning.

Murray's "Personology" is among the most broadly based of personality theories. It draws on biology, academic and clinical psychology, psychoanalysis, and a wide humanistic culture. The inclusiveness, discrimination, and operational definition of the various facets of personality are apparent even in our bare outline. The schedule of needs and of press which Murray has painstakingly elaborated, and other items omitted here, may be found in *Explorations of Personality* and other writings listed in the bibliography.

Downloaded from www.obeikandl.com

With this single but illustrative example of a theory of personality in mind, we have a concrete basis for considering the various items which should be dealt with, in some manner or other, by any theory which intends to be inclusive. Before passing to issues in personality theory, however, we will take brief note of a few other current theories.

## Notice of Some Important Current Theories

### *Lewin*

The structure of Lewin's widely influential field theory[20] stems, ultimately, from the nineteenth-century electrogenetic field theory of physics and Einstein's theory of relativity, and, proximately, from gestalt psychology. His view is that the context in which behavior occurs is an inherent determinant of the behavior, and that understanding proceeds from the inclusive field to its constituent parts, including the individual. He strove to establish concepts which would make possible the mathematical description of a given individual in a given situation.

### *Allport*

The manner of Allport's psychological theorizing[1, 5] illustrates a central tenet of his outlook, namely, the ultimately unclassifiable uniqueness of the individual, which he believes science can never fully absorb. Yet this "self" theorist's conception of the self is complex and "loose" in order to include in it both the continuities and the discontinuities between child and adult and between normal and abnormal. He has given much attention to the traditional question of traits but in a very untraditional manner. He is less formally precise than empirically rich, and the membership character each contribution has in his total work is more organic than systematic.

### *Maslow*

A number of the great minds of ancient and modern philosophy have contributed to the organismic or holistic conception which has been an organizing factor for a number of scientists, psychologists, and psychiatrists, such as Goldstein (see Chap. 65) and Meyer (see Chap. 64). Maslow and Lecky and Angyal all emphasize holistic principles; in true gestalt fashion they see the meaning of parts as being largely determined by their relation to the whole. Maslow[21] terms his organismic outlook a holistic-dynamic point of view. He laments the fact that psychology has neglected half its rightful province, that it has analyzed the morbid and the miserable aspects of man and neglected the healthy and the happy aspects. Man's inborn nature is essentially good, and if it becomes neurotic or bad it is because of social ignorance or pathology. He has studied effective persons intensively and found certain characteristics common to all of them.

### *Lecky*

With Lecky,[19] as with Adler who originally inspired him, the individual personality is seen in sovereign terms, and all psychological manifestations are in harmony with it because they are manifestations of it. His key concept is self-consistency.

### *Angyal*

Angyal,[6] like Lewin, extended holistic principles beyond the organism to include the organism-in-environment whole. He originated concepts to describe the elaborately differentiated structures and functions of organic existence that would do justice, simultaneously, to their separateness from and relatedness to the whole. The whole which he envisages transcends, includes, and integrates biological, psychological, and sociological phenomena.

### *Sheldon*

Sheldon[34, 35] has taken as his province an area, constitutional psychology, which has been relatively neglected, in its molar aspects, by American psychologists. By means of an original and elaborate methodology of anthro-

Downloaded from www.dbaulibrary.org.in

pometrics, he has distinguished three components of physique—endomorphy, mesomorphy, and ectomorphy—and three corresponding components of temperament—viscerotonia, somatotonia, and cerebrotonia. The former, in various combinations, yield eighty-eight empirical types.

## *Eysenck*

From the psychometric study of individual differences and the factor analysis of Spearman, originally emphasizing intellectual factors but later expanded to include other dimensions of personality, finally emerged a number of theories of personality. Among these, Hall and Lindzey[16] select for exposition Eysenck and Cattell, because of the "explicitness and extensity of application" of factor analysis in the development of their respective theories of personality. Eysenck,[14] in his "seventy journal articles and five books," has dealt with various topics, but in his personality theory proper he has depended chiefly on the unusual combination of two concerns, namely, psychometrics and psychiatric phenomena. By means of factor analysis, a highly sophisticated mathematical technique intended to discover the significant underlying variables which determine empirical (observable) variables, he has distinguished and described three dimensions of personality structure—introversion, neuroticism, and psychoticism—which provide a basis for the typing of individuals.

## *Cattell*

Cattell's comprehensive factor analysis study of personality[11] exemplifies the growing tendency of researchers who prefer scientific rigor —quantification and mathematical treatment of data—to tackle the molar psychological problems. His approach is in terms of traits, but, unlike Allport, he works chiefly with common traits; unlike Eysenck, he strives to establish a score of traits rather than only a few; and unlike Murray, he emphasizes experimental more than clinical methods. His theory is elaborate, and the relations between constructs and data are close-knit.

## *Dollard and Miller*

In the thirties the question of how learning takes place became a major preoccupation of psychologists in this country. Stimulus-response theories (as distinguished from "cognitive" theories) of learning may emphasize conditioning by association (contiguity) or by reinforcement (reward, law of effect). Hull[18] represents the latter, and Dollard and Miller[13] have elaborated and applied Hull's theories to the most complex issues of personality, including psychotherapy. Psychoanalytic, social, and anthropological theories and data also inform their theory and experimentation.

## *Sears*

Sears, who is outstanding in his interest in the experimental testing of psychoanalytic concepts,[32] is a stimulus-response theorist who has become critical of the study of the individual in isolation and advocates dyadic units —the individual in relation with another, or others—as the unit of study.[33]

## *Mowrer*

Mowrer,[22] also a stimulus-response, reinforcement, learning theorist, has overcome a limitation that is very widely characteristic of nonpsychoanalytic theories by recognizing that anxiety, as well as primary drives, may constitute a form of reinforcement. He has also occupied himself with problems of language and of psychotherapy.

## *Rogers*

Unlike most nonpsychoanalytic personality theorists, and as much as any analytic theorist, Rogers[30] focused originally and still focuses closely on the psychotherapeutic process. In client-centered therapy (originally nondirective therapy) the main function of the therapist is to communicate his continuous imaginative empathy with the vicissitudes of the client's feelings. Rogers' explicit systematic theory of personality appeared after extensive clinical

Downloaded from www.vbraulibrary.com

experience, and since that time the development of theory and of therapy have been kept intimately interrelated. The viewpoint is a phenomenological, organismic, self-theory, and the chief concepts are the organism (the total individual), the phenomenal field (the totality of experience), and the self (a differentiated part of the phenomenological field which consists of the individual's picture of and evaluation of himself).

### *Murphy*

Murphy has made extensive contributions to general, historical, and social psychology. His wide sympathies and encyclopedic knowledge are manifest in the creative eclecticism of his theory of personality[27] which, as Hall and Lindzey say, "includes most, if not all, of the common and familiar concepts, principles, and postulates of modern psychology." At the opposite extreme from purely psychological theories (for example, Lewin), his "biosocial approach" not only makes extensive use of biological, social, and anthropological findings but, as far as possible, interrelates them with the psychological phenomena, topic by topic. Methodologically, he prefers rigorous experimental methods where they are available or applicable, but he encompasses the most inclusive issues with whatever less rigorous means are available.

### *Buchler*

Buchler[10] is technically a philosopher rather than a psychologist. He is listed here because his philosophy is, among other things, an elaborate theory of personality. Furthermore, it has a "field" emphasis which makes it congenial to many psychological theories of personality. His "proception" and Allport's "propriate functions" both emphasize the dynamic-process aspects of what other theorists call the "self," as distinguished from its static structural aspects. Both are attempts to account for the integrative functions of the personality without resorting to reification, without the positing of a homunculus. Buchler's "proceptive domain" and Angyal's "biosphere" are similarly homologous; both are conceptual means of representing the psychological world of the individual and thus taking account of the inextricable wholeness of organism-environment.

## ¶ Some Major Issues in Personality Theory

### *Scope*

Theories of personality vary widely in scope. Theorists who strive to be thoroughly comprehensive and systematic (for example, Murphy, Murray) deal explicitly with the score or more of major issues which have emerged in the history of personality study, and interrelate the positions they take regarding them in a coherent fashion. Others concentrate on the issues they consider most important and subordinate or neglect the others, or fill the gaps with borrowings from other theories. Early psychiatric and psychoanalytic theories were theories of various mental conditions—they did not pretend to be theories even of the *abnormal* personality. Psychoanalysis, however, developed into a theory of personality. Because it sees neuroticism as ubiquitous, it considers its principles applicable to both abnormal and normal personalities. Psychoanalysts have been accused of too readily applying their "abnormal psychology" to normal persons. The socially oriented analysts (for example, Fromm, Horney), who believe with L. K. Frank that "society is the patient," consider that statistical normality in our pathogenic society is, from a transcultural point of view, abnormal. Rank, and many others since, considered the neurotic to be humanly superior to the "normal average" individual on the grounds that the latter has accepted the truncation of his personality in the interest of adjustment whereas the former was still struggling for fuller selfhood, though unsuccessfully. Some academic theories of personality apply chiefly to normal personalities; others attempt to explain both normal and abnormal personalities by the same set of principles (for example, Murphy); still others (for example, Allport) are based on the

Downloaded from www.dbaudiolibrary.com

assumption that the differences between the abnormal and the normal are great enough to require a high degree of differential consideration.

## The Definition of Personality

A definition offered by a theory of personality is a summary of the theory, and the whole theory is an attempt at a more complete definition. Allport[5] was able to collect fifty significantly different definitions, which he grouped into classes and analyzed. For general purposes it would be useful to have a definition on which all would agree, but this is impossible to achieve. For instance, Stagner ("Personality" in the *Encyclopaedia Britannica*) proposes the following: "Personality is the characteristic way of thinking and acting which identifies each person as a unique individual." At first blush this definition would seem innocent enough to secure universal acceptance. Yet many would say that it deals with only one of the two different but indispensable references of the term; that it embraces the particular but not the general aspect of personality. Furthermore, many believe that only the general aspects of personality are amenable to scientific study. Then, extreme behaviorists might consider that "thinking" is superfluous since "acting" (behavior) is all-inclusive, or misleading because behavior alone can be approached by rigorous methods.

Although it is generally accepted that no definition of personality is generally accepted, the fact is variously explained. There are those who believe that it is due to the immaturity of personality science; others believe it to be a permanent state of affairs due to the nature of personality or to the irreducible differences in philosophical outlook (Allport) or basic psychological structure (Jung) on the part of personality theorists.

It may be that one definition of personality is more useful than another for a given kind of preoccupation with personality. Certainly one definition is preferable to another for epitomizing a given theory. Thus, a definition of personality is less a source of knowledge of the truth about personality—even the most general and essential truth—than an indicator of the outlook and ability of its author.

## Structure and Function

These two aspects of living organisms are recognized by all theories, but some emphasize the one, some the other. The structural emphasis tends to go with a cross-sectional interest in the interrelation of traits at a given moment or period of life; the functional emphasis tends to correlate with an interest in developmental stages that distinguish one age level from another. A complete theory will deal fully with both and will integrate them closely.

## Unconscious Processes

Biologically minded theorists tend to think of unconscious processes as physiological rather than psychological activity. Those with a cultural, interpersonal, or psychological emphasis consider them psychological in the sense of their being more usefully describable in terms of conscious mental processes, the essential difference being the fact that they are not in awareness. There are differences also regarding the extent and importance of unconscious processes as compared with the activity of consciousness, some theorists emphasizing one and some the other. Then, there are those who believe that unconscious processes are extensive in neurotic but not in normal personalities. The content of unconscious processes may be thought to include various combinations of the following: (1) native instinctual tendencies which are enduring, while it is their expression which is modified by experience; (2) relatively plastic tissue tensions which are basically modified by experience; (3) unsymbolized notions which took form before the advent of speech and so cannot be cognitively recalled; (4) bad impulses, or (5) good impulses, or (6) both, which are repressed or dissociated.

## Organism-Environment

Differences exist according to whether personality is conceived of as being structured

Downloaded from www.idealibrary.com

primarily by biological or by environmental influences, but all theorists recognize both factors as influential. In practice, one or the other sometimes does not get explicit consideration. The way the interrelation of the personality and its environment (including, especially, other personalities) is represented by a theorist is a large and important part of the theory.

## *Learning Theory*

For several decades, learning theory has probably attracted more sustained and ingenious attention from psychologists in the United States than any other aspect of personality. Varieties and subvarieties of learning theories are numerous, and experimentation is voluminous.[17] The lack of attention to the learning process among psychoanalytic theorists and sometimes among the more clinical-minded academic theorists is more apparent than actual. The fact seems to be that academic theorists (other than the clinically minded ones) deal microscopically and experimentally with learning, while clinicians deal with it macroscopically and clinically. The latter are occupied with learning—whether the term is employed or not—when they trace the molar sort of learning of attitudes and traits to various sorts of familial attitudes and atmospheres that are experienced during the formative years. (This emphasis on molar aspects of personality, as distinguished from molecular aspects, characterizes this group rather generally, for example, the theory of developmental stages. Compare Sullivan and Erikson with Gesell.)

## *The Identification of Motives*

We will mention only two issues involved in the all-important matter of motivation—the basis of motivation and the question of the number of motives posited. A fundamental source of various secondary divergences between different theories is the issue (often not explicitly formulated or dealt with) of how profoundly and permanently the organic inheritance is modified by postnatal experience. On the one hand there is the assumption that the instinctive equipment is "tough" and persistent in its structure and that a psychological layer of personality is grafted on to it, by experience. The alternate view is that the inherited "preferences" of the tissues are "tender" and highly malleable, though within limits. The former put more emphasis on the constitutional determination of personality and the latter on the social. The latter, consequently, view the psychological level of existence as a genuine emergent, though not necessarily, nor often, in the sense of historic vitalism (cf. Ref. 27, p. 35).

In the past, motives were considered to be rooted in a limited number of instincts which were modified by experience. Social psychologists, particularly, felt the need of lists of sentiments (McDougall) or basic wishes (Thomas and Znaniecki) to explain, by their combinations and modifications, the varieties of human activity. Today only a few psychologists attempt to specify a definite list of motives, and when they do, they usually classify environmental need-satisfiers as well (cf. Murray). Many theorists assume one need—the vital need of the organism to maintain and enhance itself, or an unspecifiably great number of highly individual needs that are structured by the interplay of the particular organism with its particular environment. This situation is the result of the general contemporary realization that the inner sources of motivation are numerous; that they are, for the most part, impossible to locate anatomically; that they have many permeable boundaries between them, so that they are partly separate and partly convergent; and that their relation to each other may change momentarily or with time. But this is not all; the matter is further complicated by the fact that motives are organism-environment integrations. A motive is the integration of an inner impulse with a specific environmental object or class of objects, or qualities; it is learned, and it may be temporary or permanent.

## *The Psychological Environment*

There are as many psychological environments as there are individuals because the psychological environment of a particular individual is the world as perceived by him. This

Downloaded from www.cambridge.org

is the world he acts upon and to which he reacts. All theorists take account of this, but some give it much more attention than do others. In the relatively healthy personality the psychological environment and the objective environment are relatively congruent, and the mentally healthy person can progressively correct errors in his psychological environment by experiencing the frustrations which are caused by his misperceptions. In the neurotic or psychotic individual the disparity between the world as it is and the world as perceived is great, and since it is great because the individual has an urgent need for his psychological world to be as it is, clinicians emphasize the need of self-correction by psychological means rather than by logical confrontation with the real world. This is probably a reason why some clinical theorists have a strong phenomenological outlook and give little explicit attention to the objective world. Psychiatrists and psychoanalysts seldom use the term "psychological environment," but the concept is inherent in their concepts of projection, transference, parataxic distortion, etc. In fact, the psychoanalytic emphasis on such phenomena, together with the success of projective diagnostic tests, is a major reason why the psychological environment is recognized as important in most theories of personality.

### *The Self*

The concept of the self was abandoned (as well as the soul and other synonymous terms) by experimental psychologists during the early decades of scientific psychology because of its association with theology and philosophy and because of its unamenability to experimental studies. It was left to philosophers and to European—and some other—psychologists who made no sharp break with philosophy. Its prominent place in United States psychology today is a testimony to the emergence of the psychology of personality as a field of scientific endeavor. Some theorists use the term "ego" as others use the term "self," some use both terms, and some use both terms in a manner directly opposite to their use by others. The concept (or concepts) under consideration refers in all cases to central, integrating structures and functions of the personality, and the problem is to define it so that it will perform that service without the reification of a more or less integrated group of functions—that is, without positing (whether explicitly or not) a homunculus, and without making it impossible to explain segmental and part functions and, particularly, molar conflicts and multiple personalities.

### *Field Theory*

Psychological field theory was borrowed from the field theory of physics. Its characteristic feature—the representation of phenomena as a field of forces, constantly changing, according to laws of process—renders it capable of vividly and economically representing, simultaneously, the intra-organismic field, the extra-organismic field, and the processes which take place between them in the field which includes both. Several factors—the extreme complexity of personality as currently viewed, its constant change in minor structure and continual though more gradual change in major structure, and the constant, intricate interaction of organism and environment (including other organisms)—have led many psychologists to utilize field theory to conceptualize psychological processes. Some, however, make more use of it than do others, or are more explicit in the use of it.

## ◧ Bibliography

The following list includes the titles of several books each of which surveys a number of theories of personality, including the theories of the psychoanalytic schools. Since this handbook contains separate chapters on the major psychoanalytic schools of thought, books restricted to the exposition of a particular psychoanalytic school are not included here. Consequently, the list consists chiefly of volumes each of which presents a single influential "academic" or nonpsychoanalytic theory current in the United States today. The list is highly selective, consisting generally of only one or a few volumes on each theory. The principle of selection was comprehensiveness and recency.

As for the surveys, Munroe[24] presents excellent empathic expositions and critiques of Freud, the major "Freudians," Adler, Horney, Fromm, Sulli-

Downloaded from www.dbraulibrary.org.in

van, Jung, and Rank. Hall and Lindzey[16] present excellent expositions of Freud and the other psychoanalytic schools mentioned above, except Rank, and most of the nonpsychoanalytic theories represented in the following bibliography. They give a biographical sketch of the author of each theory, indications of the major research inspired by each theory, the chief criticisms directed against it, and finally a summary of general trends in personality theory today. In *Perspectives in Personality Theory*, edited by David and von Bracken, twenty-two leading authorities survey various psychological topics and methodologies as well as summaries of personality theory in Germany, Switzerland, Britain, Italy, and France. Gardner Murphy's *Personality* presents his individual contribution to personality theory, but it should be mentioned along with the surveys because, in accordance with his principle of creative eclecticism, he draws widely and explicitly on all the schools, including the psychoanalytic (up to 1947). The *Annual Review of Psychology*, published since 1950, has a 20- to 25-page section on personality. The authors of this section (listed below) are, in chronological order, 1950–1956: Sears, McKinnon, Eysenck, Bronfenbrenner, Child, Nuttin, and McClelland. The monthly, *Psychological Abstracts*, which epitomizes psychological books and journal articles on a comprehensive and international basis, has a section on "Complex Processes and Organizations" which includes a subsection on "Personality."

CHAPTER 5

# THE FAMILY OF THE PSYCHIATRIC PATIENT

John P. Spiegel
Norman W. Bell

Downloaded from www.dbraulibrary.org.in

IN A VERY REAL SENSE it may be said that the study of the family as a significant system in its own right has no history, no body of commonly accepted concepts, and no established findings. This is especially true in regard to the topic of the family of the psychiatric patient. This does not derive from any lack of concern or activity. Social workers, psychoanalysts, psychiatrists, psychologists, marriage counselors, educators, sociologists, and anthropologists have all taken an interest in the family of the patient, but, despite the strong interest, the family as a unit has consistently failed to come into focus. Isolated aspects of the total picture—selected traits of the relationship of parent and child, or of siblings, selected situational or psychodynamic factors —have been extensively investigated, but such subrelationships are almost always dealt with out of context, as if the family-as-a-whole did not exist. Thus this topic cannot in any sense be described as an organized field of research, of practice, or of conceptualization.

## ¶ Introduction

We feel that it is important to view this paradox of the lack of identity of the patient's family as a *field of inquiry* coexisting with the topic's widespread appeal to various disciplines in the perspective of American society and its culture. The United States has always been a nation that was youth-centered and, in a romantic way, family-minded. In the last century these interests were embodied in a quasi-scientific form under the guidance of G. Stanley Hall.[86] "Genetic psychology" did not last as a movement among the enlightened public, but the underlying values remained, reappearing as a concern with the child and his family by various family-service societies,

and more recently the child-guidance movement.

The themes of service and welfare have also been important. These sprang from the idea that it was the charitable duty of the wealthy upper classes to help immigrant and impoverished families by teaching them the values of thrift, hard work, and independence. It sprang, too, from the idea, largely implicit, that people can be changed by changing their environment. This environmentalist point of view is expressed not so much in explicit formulation and theory as in active attack, usually through organizational effort, on whatever aspect of the social milieu is presumed to be the cause of unhappiness or disability. This active amelioration tended to be in conflict with the organismic viewpoint, also held, that human distress can be alleviated only through the modification of the physical and psychological processes within the isolated individual.

## *General Historical Background*

The history of the development of this still uncrystallized field reveals these divergent themes. A brief review of this history will give a better understanding of the current situation. In the first decade of this century, Adolf Meyer, protesting against the organic and nosological rigidity of nineteenth-century psychiatry, advanced the revolutionary idea that mental illness was a failure in the adjustment of the person to his situation. In a broad but vague way he called for more attention to the patient's family in the diagnostic work-up,[140] in treatment,[141] and in post-hospital settlement.[139] His "common-sense approach," however, never was formulated as a specific theory of psychopathology and its treatment. With no conceptual guides to link the person with his situation, individual psychiatrists were left to center their attention on the disturbance in the one or the other. This was the beginning of a characteristic polarity in American psychiatry. For example, the work of William Healy initially concentrated upon the individual delinquent or disturbed child. Later, as information about the causes of delinquency accumulated, there was a swing in attention to the home, the family, the neighborhood, and the school.[89]

During the second decade of this century, social work carried the burden of interest in the family. Psychiatrists, occupied with individual patients in private practice or in mental hospitals, were able to ignore the patient's family, but social workers were early forced to recognize the impact of the family when they tried to help clients adjust to their environment. But even in the practice of social work, the significance of the family was less than fully established, and integration at the level of theory was lacking. Mary Richmond,[178] in her well-known monograph *Social Diagnosis* (1917), scolded her colleagues for paying insufficient attention to the family-as-a-whole. Much earlier, in 1890, Zilpha D. Smith had enunciated the idea of the family's significance, saying "Most of you [referring to the general run of social workers at the time] deal with poor persons or defective persons as *individuals*, removed from family relationships. We deal with the *family* as a whole, usually working to keep it together, but sometimes helping to break it up into units, and to place them in your care"[178] (p. 95). Despite these practical principles, social workers, too, tended to lose track of the family unit as interests swung from the environment to the individual and back. When, in the early 1920's, psychoanalysis was introduced into the curriculum of schools of social work, social workers underwent another, and very significant, reorientation in their thinking and techniques with respect to the family. This reorientation brought the family case worker closer to the interests and methods of the psychiatrist.

The child-guidance movement, born in the early 1920's, reflected these swings of interest. In the early stages social workers, the most sophisticated members of the therapeutic "teams," played an important role in giving a dynamic focus to emotional problems and in having the empirical techniques for investigating the environment. The approach at that time was for the guidance clinic to make a diagnosis and then work out a plan with the family and community agencies, through

Digitized by www.cdrajbanyan.in

which the problem was to be relieved.[215] Only later, when this approach proved inadequate, was direct psychotherapy with the child attempted. By this time the psychiatrist had emerged as the member of the team with the most authority and responsibility. As the movement progressed, a compromise between the environmentalistic and the organismic poles developed; this was the principle of working with the parent. In practice this meant that some relationship with the mother was established. The father was seen infrequently, if at all.[165] Once again partial and arbitrarily selected subrelationships within the family were dealt with, while the family-as-a-whole was neglected.

The reasons why the family was continually being recognized as significant but was always eluding the grasp of theoreticians and practitioners alike are very complicated. The problems of the forced and inhibiting compromise between attending to the individual and attending to the family at the procedural level, and the lack of adequate conceptualization of the interrelations between the family and the individual at the theoretical level, are undoubtedly part of the picture. There seems, however, also to be some resistance among investigators which makes it difficult to maintain the focus on the family unit. This resistance is illustrated in the first round-table discussion of the American Orthopsychiatric Association. A psychiatrist, a social worker, and a clinical psychologist spoke, in this panel discussion, about treatment of behavior and personality problems in children. Alone among the three discussants, the social worker, Charlotte Towle, dealt with the problems and the family in a dynamic fashion. She was articulate and direct concerning the family, saying in part, "Treatment cannot be given to any member of the family without affecting the entire group. In some cases the entire family must be drawn into treatment. Approach to this or that member, or centering treatment on a certain individual, cannot be a random thing"[225] (p. 582). The prolonged discussion that followed dwelt largely on whether notes should be made in front of the patient. No reference to Towle's ideas was made at all. The whole issue of the dynamic formulation and handling of family relationships simply dropped out of sight.

By 1930 the main features of the variety of approaches to the family of the patient which have come to characterize the literature were already in evidence. There were two significant areas—psychoanalytic theory and sociological theory—whose interaction has had a profound influence on the present state of the field.

## *The Influence of Psychoanalytic Theory*

The continually growing interest in psychoanalytic theory has had a definite but very complicated and ambiguous influence on professional attitudes toward the family of the psychiatric patient. The complexities are in part due to the ambiguities within the theory itself, in part to the various ways in which professional groups have responded to psychoanalytic theory, and in part to the general American cultural tendency, already described, to become concerned with the possibility of environmental reform through organized action.

It is always difficult to discuss psychoanalytic theory briefly because of the great variation it has shown in the course of its own growth and development. Considering only the notions of Freud himself on the origins of psychopathology, ambiguities and discrepancies are detectable in his writings on theory, his case histories, and his writings on applied psychoanalysis.

Freud called attention in several ways to the impact of the family upon the potential for healthy or pathological development of the child. The theory of psychic trauma held that intense feelings of rage, love, or fear—precipitated in the course of interfamilial events—could become the focus of neurotic symptom-formation. In the theory of psychosexual development, the actual responses of parents, siblings, and other family members to the behavior of the child in each phase could, presumably, influence the ability of the child to resolve the pressures of conflicting internal forces. A third formulation was the concept

Downloaded from www.pdfbooksworld.in

of the Oedipus complex which, according to Freud, was the nucleus of every neurosis. Finally, the concept of identification stated that the development of the super-ego and, in part, of the ego took place through a process of internalization of the parents and other family members as objects of libidinal or hostile cathexis.

These four concepts would suggest that the actual configuration of the family and the behavior of its members would have an overwhelming effect upon the development of the child. In his theoretical writings, however, Freud took the opposite viewpoint. The seeming paradox was resolved by the importance given by Freud to the effect of the conscious, and more so the unconscious, fantasies of the child. The mind of the child could not accurately reflect the reality of the family environment, he felt. Rather, it reflected a highly elaborated and inaccurate version of that reality, distorted by the wishes generated by the unconscious instinctual forces which proved so difficult to control. Thus, while the influence of the actual reality of the family constellation was not ruled out entirely, it assumed only a secondary and contingent importance in Freud's formulations. The final effect of "accidental" or situational factors was always regarded as contingent upon their influence on the unconscious fantasy life of the child. Even the process of identification was, according to Freud, not the result of the internalization of a true and objective version of the parent but of a version of the parent created in fantasy.

While Freud, in his theoretical writings, tended to tip the balance in favor of the unconscious fantasy life of the child as the primary etiological factor, his case histories give a quite different impression. In one case[73] the details of the adolescent Dora's family setting included a mother with a "housewife's psychosis," an intermittently depressed philandering father, a hypochondriacal aunt, and a husband of her father's mistress who made sexual advances to her. It is difficult not to wonder how Dora would have turned out had she lived in a less complicated family milieu.

Similarly, in his more speculative and philosophical writings in the area of applied psychoanalysis, Freud[72, 74] frequently gave the impression that the disposition to neurosis could be laid at the door of the environment—whether pictured in terms of the family, the community, or the culture. Here, Freud tried to be impartial in assessing the part played by man's instinctual endowment and that played by the environment, but his ambiguity, indeed ambivalence, shows through. The finger of blame lingers longer on the external environment, and mysterious hints are dropped about the possibility of improving the hostile social milieu.

It was then perhaps inevitable that, with these ambiguities in the theory, psychoanalysis should have had an inconsistent and confused impact upon various professional groups in this country—especially in the area of their thinking and techniques with respect to the family. Psychoanalysts with adult patients found that the theory validated what they were already inclined to do—ignore the families of their patients. The psychiatric social workers in child-guidance clinics saw in it the confirmation of their views regarding the significance of the parental environment of the child. It explained the difficulties they were experiencing in persuading parents to adopt the recommendations made by the clinic after the diagnostic work-up of the child. It sanctioned their inclination to concentrate upon the mother as the person whose emotional problems were chiefly responsible for the social worker's difficulties. For those interested in mental hygiene, it justified the organizational energies which they wanted to expend on the public. Finally, it had a mild but definite impact upon those social scientists who were becoming concerned with the status of the family as a dynamic group. It is with this professional group that we must now concern ourselves.

## *The Influence of Sociological Theory*

The family has long been a topic of great interest to sociologists and other social scientists. As early as 1909 the *American Journal of Sociology* devoted two full issues to papers on the institutional forms and social problems of the family. The interest in institutional

Downloaded from www.pdfbooksfree.org.in

forms—their origin and evolutionary development—was the traditional concern of family sociologists in the nineteenth and early twentieth centuries. Some facets of this social Darwinist interest struck responsive chords in American sociologists who were concerned with social problems and reform. In approaching the problems of low wages, urbanization, factory labor, women working, freer divorce laws, etc., sociologists were strongly and clearly committed to the environment as the explanatory factor and the area for active ameliorative attack.

At the time, families were seldom studied directly. Since no dynamic theory of personality was then available, there was little concern with the impact of the environment upon individual personalities or the intimate inner life of the family. Even if sociologists had been more interested in processes within the family than in its institutional forms, and if they had had the skills to carry out investigations in this area, the sentiment that the privacy of the family was inviolable, that "a man's home is his castle," would have deterred them. However, some concern with the fate of the individual and with the quality of family life was emerging.

During the first two decades of this century, social psychologists were grappling with the problem of how to explain the order and dynamics of social behavior. Lacking any sophisticated psychology, and oriented to the environmental rather than the organic pole, they developed the equivalent of instinct concepts in social instinct and imitation theories. Early in the century a philosophical and scientific interest in social explanations of personality-formation and behavior emerged.[42, 138] The culmination of these interests came in Thomas' formulation of the "definition of the situation."[220] These definitions of the situation, in the formation of which the family played a crucial part, were seen as the principle immediate determinants of behavior.

These developments, more social-psychological than sociological, were crystallized in an influential paper, "The Family as a Unity of Interacting Personalities."[31] Though Burgess was a sociologist, he formulated the "essential characteristics" of the family as "sentiments," "conceptions of itself," "social images," "super-personality"—all social-psychological qualities. This paper was widely read and established the chief themes in family sociology for the next twenty-five years. Burgess' paper appeared in a social casework journal, and it was eagerly taken up by social workers, who found it easy to fit into the psychoanalytic framework which they were developing. Academic social psychologists and sociologists were led more in the direction of the empirical study of selected narrow aspects—one might almost say traits—of the family through the medium of the questionnaire.

At the same time, American sociologists were becoming familiar with psychoanalytic theory.* The rather naïve, oversimplified version they assimilated seemed to fill a gap in sociological theories concerning the motivating forces of social behavior and social groups. Psychoanalytic theory seemed to contribute much to the understanding of the social problems in which sociology was deeply interested, such as delinquency and crime, labor unrest, and prostitution. This coincidence of interests was extended, and a new branch of sociology, labeled "social psychiatry," was developed.[190]

A few of the sociologists who became interested in psychoanalytic theory applied it to conceptions of the family.[69, 84] As with social workers, the tendency was to interpret psychoanalysis as contributing to an environmentalist position. Thus there was common interest between psychoanalytically oriented sociologists and social-psychologically oriented sociologists, and psychoanalytic conceptions became part of the language and tools of family sociologists. Psychoanalytic notions were added in an eclectic fashion and used as needed. No integrated theory was forthcoming, however. American sociology has had a strong antitheoretical bias, putting more value on sensitive empirical accounts than on systematic studies and theory building.

The economic depression of the 1930's threw into bold relief what had been seen throughout the 1920's—the problem of the adjustment of families to the social order.[150] In the case of

* Eliot[57] gives a comprehensive historical review of the early interests.

Digitized by eGangotri www.dspace.gangotri.org.in

the depression, however, the fault lay more clearly with the social order. Studies of adjustment were focused primarily on the concrete external problems of unemployment, poverty, poor housing, etc.[11, 15, 36, 115] This interest in adjustment to stress, shorn of its evolutionary implications, was dominant up to World War II and continued through the war.[96, 116]

During the same period in the 1930's, social psychological interests and methods remained strong, particularly in the field of marital adjustment.[32, 218] In pursuit of the practical goals of counseling married or engaged couples, questionnaires were widely used. These questionnaires consisted essentially of lists of traits that had been found to be statistically discriminating. Any theoretical grounding was absent.

In the postwar period some concern began to be shown over the fact that the study of the family had been tied so intimately to the problems of the day that no general conceptions and knowledge were being developed.[47] By this time the anthropological approach to cultural forms, functions, and values, and a range of comparative materials were widely familiar to sociologists. More sophisticated versions of psychoanalytic theory were also known. It became clear, then, that knowledge of many aspects of the family could be advanced only by the collaboration of psychologists, psychiatrists, sociologists, and related specialists.[80] For the sociologist the social-psychological bias is still strong, but these established conceptions and methodologies are being challenged.[29, 59] Some sociologists have become concerned that the sociological aspects of the family are being neglected.[95] Accordingly, more interest has recently been devoted to the family as a small group with determinate structures and processes common to all small groups. Attempts have been made to analyze the family in such a fashion and systematically to relate it to psychic processes, personality development, and broader social groupings.[159]

In many ways, sociological interests in the family have been analogous to the interests of psychiatrists and related professionals. The demands of doing something about specific problems have overridden the need for developing theory to organize observations and guide action. There has long been an awareness that the family is a group with a unity and a reality of its own, but this awareness has not been systematized. Despite its social-psychological bias, the stressing of the environment and the interest in marriage have provided a useful counterpoint to the psychiatric stressing of the organic pole and its focus on personality development. Throughout their recent histories, both disciplines have had a strong interest in the causes of mental disorder. Recently, as interest in the social context of illness and of medical organizations has developed, sociology has been in a position to make contributions more specifically pertinent to psychiatry.

## The Family as the Etiological Agent in Mental Illness

As a result of these cultural and historical processes, the general impression was gained in this country that the family was in some way responsible for the disposition toward mental illness. The interaction between the typically American tendency to blame the environment for the production of personal unhappiness, the culturally conditioned response to psychoanalytic theory, the family-welfare societies, the growth of the mental-hygiene and child-guidance movements, and the influence of the theory and applied procedures of the social scientists produced an intense convergence of interest on the family as the agent of mental illness. As a result, from the 1920's to the present, there has accumulated an extensive literature seeking to assess the nature of the etiological relationships within the family. This literature has been found very difficult to appraise[173] because of the lack of consistency in its methods of procedure, its conceptualizations, and its findings. After an extensive review of the literature, we have reached the conclusion that its subject matter falls naturally into three groups: (1) the characteristics of parent-child relationships presumed to be productive of mental illness; (2) the structural aspects of the family, such as birth order and number and sex of siblings, presumed to

Digitized by www.dbraulibrary.org.in

be correlated with psychopathology; and (3) the influence of genetic or constitutional factors within the child, and the family's response to it. Each of these groupings will be discussed in order.

## *The Influence of Parent-Child Relationships on the Adjustment of the Child*

Of the three groups mentioned above, this has received the most extensive investigation. We have reviewed and abstracted 85 articles in this area. This does not constitute an exhaustive coverage, but we believe that it is representative. It would be meaningless as well as impossible in the space available to discuss all these articles. We shall therefore limit ourselves to citing references illustrative of general trends and concentrate mainly on the problems inherent in the area.

There has been a tendency among the investigators to regard the psychopathology in the child as produced by, or correlated with, certain pathogenic characteristics in the parents. Whereas this has been the general point of view, the studies have varied along a number of dimensions. In approximately half of the articles reviewed, the investigators have attributed the difficulty of the child to one or more traits in the parent, which are seen as unchanging, permanent aspects of the mother's or father's personality and behavior. These traits are usually described by an adjective

TABLE 1. **Partial List of Pathogenic Parental Traits Identified in 85 Parent-Child Studies Published since 1930**

| | |
|---|---|
| Abusive | Overprotective |
| Cold | Overtly rejecting |
| Controlling | Passive |
| Covertly rejecting | Poor self-adjustment |
| Dependent | Poor social adjustment |

labeling the undesirable or pathogenic element in the parent. As can be seen from Table 1, the partial trait list culled from our sampling of the literature is long and varies in accordance with the specificity or diffuseness of the behavior presumed to be etiological. This table does not show, however, that most traits have been found by someone or other to be associated with every type of disturbance.

In the other half of our sample, the investigators have viewed the pathogenesis of the child's disturbance as the result of a process of on-going events between parents and child, and, in a few instances, of the dynamics of the interrelations throughout the family. For example, schizophrenia in a child is described as the product of a symbiotic process set up between mother and child, in which the mother regards the child as an extension of her own body or personality. As a result, the child is not able to regard himself as a separate, independent person, with his own identity, and is thus fixated in an oral stage of psychosexual development. These studies also vary, as in the previous group, in relation to the generality or specificity with which the pathogenic process is described. An interesting, though not unexpected, finding is a change in the distribution of these studies over the past three decades. Although the figures in Table 2 are only suggestive, because of the unknown relation of our sample to the total body of writing, they indicate that, whereas between

Downloaded from www.dralibrary.org.in

1930 and 1940 the number of trait studies was about equal to the number of process studies, between 1940 and 1950 the trait type of study gained ascendence, only to have this relationship reversed in the current decade. They further appear to indicate a slight trend toward greater specification of the behavior of the parent in recent years, but the vagueness with which both traits and processes are identified remains one of the most prominent problems encountered throughout these studies.

Another factor contributing to the inconsistency of findings is the variation in research methods used in the investigations. The variation is so great and the methods in general are so questionable that it is difficult to know how to interpret the findings. We have distinguished three dimensions of variation in the articles we reviewed: (1) the use of large numbers of cases (30 or more) versus the study of the single case or at best a very small number of cases; (2) the use of subjective impressions derived from clinical case studies versus the use of objective or test measures; (3) the use of selected control groups versus studies in which no control group was reported. Unfortunately, we were unable to make these dichotomous discriminations with respect to all the articles reviewed, since some authors say nothing about the numbers of cases involved, while others say little or nothing about their methods. For this reason, the raw figures in Table 3 give only the most sketchy and inadequate view of the methods used. Nevertheless, they suggest that certain trends characterize the entire sample, while others differentiate the trait studies from the process studies. For example, in the whole sample, clinical studies far outnumber objective methods of study, and the studies lacking a control group are much more numerous than those in which a control group is used. On the other hand, trait studies use large numbers of cases more frequently than do process studies, and objective methods are, apparently, not used at all in process studies. In the trait studies, as the behavior characteristics in the parents become more specifically defined, the proportion of large to small number of cases rises, as does the proportion of objective to clinical methods of study. Most of these trends seem to be exactly what one would have expected from the nature of the research materials; the only surprise has been the finding that the process studies are equal in number to the trait studies and are apparently on the increase.

TABLE 3. 85 Parent-Child Studies Published since 1930, by Methodological Characteristics*

A. Number of studies by sample size

| | LARGE SAMPLE | SMALL SAMPLE† | TOTAL |
|---|---|---|---|
| Trait studies | 20 | 18 | 38 |
| Process studies | 6 | 24 | 30 |
| Total | 26 | 42 | 68 |

B. Number of studies by nature of data

| | OBJECTIVE | CLINICAL | TOTAL |
|---|---|---|---|
| Trait studies | 13 | 30 | 43 |
| Process studies | 0 | 40 | 40 |
| Total | 13 | 70 | 83 |

C. Number of studies by use of control group

| | CONTROL GROUP | NO CONTROL GROUP | TOTAL |
|---|---|---|---|
| Trait studies | 15 | 28 | 43 |
| Process studies | 2 | 40 | 42 |
| Total | 17 | 68 | 85 |

* Total numbers vary because of indeterminateness of characteristics of some studies.
† Small is defined as less than 30.

To report the actual findings of the studies of parent-child relationships and to evaluate them is, as we have said, extremely difficult because of the lack of systemization in the literature. Where trait studies are concerned, it would appear that the investigators have engaged in two lines of inquiry, each failing to interact with the other. Some investigators have attempted to identify the pathogenic traits in the parents of patients belonging to a particular symptom group. The parents of patients with schizophrenia, or with a neurosis, have been studied to determine what traits they possessed. A much smaller number of investigators have studied groups of parents exhibiting the traits so specified. There is little evidence in any of the studies of awareness of the nature of the over-all research problems being created by these procedures. Each investigator, with few exceptions, seems to have

Downloaded from www.vidyanidhi.org.in

been content to start off on a line of inquiry which was provoked by his own clinical observations or which had been stimulated by a previous publication. In view of this almost random development of the literature, the most systematic plan of reporting the findings appears to be that of describing first the investigations connected with inquiry into the various symptom groups, as the dependent variable, and then describing the findings of the investigations of parental traits as the independent variable. Because the traits do not work out consistently for any symptom group, this will introduce much overlapping, but it seems the most orderly procedure. The symptom groups to be considered are psychosis, neurosis, delinquency and acting-out disorders, and psychosomatic illness.

Many different behavior traits have been ascribed to the parents of schizophrenic patients. Kasanin, Knight, and Sage[109] found parental overprotection and rejection to characterize 60 per cent of the parents of a group of 45 schizophrenic patients. Maternal depression, repeated traumas of separation, and inability of the mother to gratify the emotional needs of the child were found in a single case studied by intensive clinical methods.[172] In a study of 25 mothers of schizophrenic patients the mothers were found to be insecure, superficial, rigid, and domineering.[228] The fathers in this study were described as good providers but passive, and though aware of the mother-child problem, unable to do anything about it. Reichard and Tillman,[175] reporting 66 cases from the literature plus 13 of their own, found that parents fell into three categories:

1. Schizophrenogenic mother—overtly rejecting type.

2. Schizophrenogenic mother—covertly rejecting type. In this group the mothers dominate the child through overprotection, which occurs as a defense against the underlying hostile, rejecting attitude toward the child.

3. Schizophrenogenic father. This group of fathers is characterized by domineering, sadistic attitudes toward the child. Such attitudes represent both a defense against underlying weakness and a gratification of passive, dependent attitudes toward the wife and of rivalrous attitudes toward the child. The wife in such cases is overtly passive and dependent and ineffectual in handling the husband and child.

In none of the studies so far reported was a control group used. Interestingly enough, in two studies making use of control groups, the findings were opposite in direction. Prout and White[170] studied mothers of 25 male, hospitalized, schizophrenic patients and contrasted them with the mothers of 25 normal male subjects. They found very little difference between the mothers in the two groups. They were not able to find any difference with respect to overprotectiveness or oversolicitousness, but found that mothers of the normal controls showed a more frankly critical attitude toward their child, and a more gregarious and outgoing attitude toward life. In the other study[136] the mothers of 100 hospitalized, male, schizophrenics were compared with the mothers of 100 male medical cases. The mothers of the schizophrenic group showed a more restrictive, controlling attitude toward their sons, and tended to exhibit either cool detachment or excessive devotion.

Many of the above-mentioned traits appear in studies of parents of neurotic patients. In a study of the mothers of 25 children with conduct disorders and neurotic traits,[94] it was found that these mothers had experienced an unhappy childhood, exhibited neurotic, infantile traits, were generally inadequate as parents, had poor marital adjustment, and rejected their children without compensatory overprotection. In another study 142 neurotic patients were compared with a normal control group.[22] The parents of the patient group were rejecting in that they were unable to show love or affection toward the child or to receive it from the child. In addition, there was more conflict between parent and child and between parents in the patient group. In an investigation of the parents of 50 children manifesting stuttering and other articulatory defects, which made use of objective methods, it was found that the mothers were neurotic, submissive, and self-conscious, while the fathers did not differ from the fathers of normal controls.[237] A study of 12 children with school phobias found the

Downloaded from www.psychiatryonline.org

family life to be characterized by emotional instability and conflict. The mothers were neurotic and fearful and the fathers were passive and dependent.[229]

In the area of delinquency and acting-out disorders, fewer studies of parental traits have been carried out. However, the results vary but little from the above groups. In an article entitled "Parents as the Makers of Social Deviates,"[23] Bonney states that rejecting parents cause various forms of deviance in the child. The parents of delinquents discriminate against them in favor of another sibling, while alcoholics have stern fathers and overprotecting mothers. A statistical study of 500 cases carried out at the Michigan Child Guidance Institute[94] correlated three behavior patterns in the child with the behavior of the parents:

1. Unsocialized aggression, in which the child showed violence, cruelty, malicious mischief and open defiance of authority, was correlated with parental rejection.

2. Socialized delinquent behavior, in which the child was on good terms with a delinquent gang but opposed the norms of adult society, correlated with parental negligence and exposure to delinquency patterns.

3. Overinhibited behavior, characterized by seclusiveness, shyness, and apathy, correlated with repressive overcontrol in the parents.

In contrast to the finding in Group 2 of the Michigan study, an investigation of the parental behavior of 21 adolescent socialized delinquents, using a questionnaire approach and a matched control group of normal adolescents, found that the mothers of the delinquents showed excessive control but little awareness of the child's feelings.[35] A study at the Bellevue Psychiatric Hospital of 65 children with head injuries due to accident proneness found the fathers of this group to be domineering and abusive while the mothers were overprotective, hypochondriacal, and masochistic.[61]

The familiar trait categories turn up again in the study of psychosomatic conditions. A study of 25 Jewish children with various eating difficulties found the families to be characterized by discord, the mothers being immature, domineering, punitive, and devaluating of the father. For their part, the fathers played ineffectual, undependable roles, some being submissive and others erratic and self-indulgent.[127] The parents of children specifically suffering from obesity also showed overprotection and domineering in the mothers and subordination in the fathers.[29] In a study of 63 children with allergic manifestation of all kinds, compared with 37 nonallergic children, 98 per cent of the allergic children had experienced maternal rejection, while only 57 per cent of the nonallergic children had had this experience. Similarly, 57 per cent of the allergic children but only 10 per cent of the nonallergic children had encountered maternal overprotection.[143] A new trait category appears in a well-controlled study of goal-setting (in a very specific context) in asthmatic children, which showed that these children set higher goals for themselves than do nonasthmatics, and that the mothers of asthmatic children set higher goals for themselves and for their children than do mothers of nonasthmatics.[124]

The investigations in which the trait behavior of the parents is treated as the independent variable are much less frequent than the sort just reported, and it is one of the weaknesses of the literature that such studies have not been more vigorously pursued. Some of the studies of parent groups appear to disprove the whole thesis of the significance of pathogenic parental attitudes. For example, an investigation of the social adjustment of the children of 19 neurotic mothers showed that these 58 children differed in no significant way from other groups of children. The author suggests that one reason for this unexpected finding may be that the fathers showed constructive attitudes toward the children.[129] In another study of children born in a mental hospital to psychotic mothers, Gardner found no neurotic or psychotic outcomes in the later adjustment of these children.[76] On the other hand, some studies, focusing intensively on a particular parental trait, have succeeded in demonstrating, within limits, a certain outcome. The best of these is Levy's[119] study of maternal overprotection. This study is a methodological classic. The author distinguished

Downloaded from www.pbookshop.com

five types of overprotection: (1) "pure," that is, unmixed with rejection; (2) guilt overprotection, in which the behavior is compensatory to a desire to reject; (3) mixed cases; (4) mild overprotection, frequently indistinguishable from culturally conditioned attitudes; and (5) nonmaternal overprotection. For methodological reasons he discarded from his research sample all except the first type. Criteria for inclusion in the "pure" group were (1) a "wanted" child, and (2) directly observable and reportable acts of the mother indicative of overprotection. The sample of 20 cases remaining was then found to fall into two types —the dominating overprotective and the indulgent overprotective. In general, the overprotective attitude was found to be correlated with severe deprivation of parental love in the mother's own childhood, the child being used to satisfy the "affect hunger" which the mother had developed as a result of her own deprivation. The indulged overprotected children were disobedient and tyrannical at home, showing temper tantrums and uncontrollable behavior, but on the whole were well behaved in school and did well in classwork. They showed some sexual precocity but no severe problems in the sexual area. The dominated overprotected were submissive at home but had difficulty making friends, needing either to dominate or withdraw. Over half of the group had eating difficulties, but none had problems with sleeping or toilet training. The author reported in great detail the nature of the treatment problem with the child and mother, and concluded with a follow-up study of the subsequent adjustment of each child.

What Levy's study shows is that, when the criteria for the presumably pathogenic trait within the parent can be made sufficiently narrow and specific, and when it can be linked to factually observable behavior (in contrast to inferences about the parent's behavior and personality), a correlation with a specific type of pathological outcome in the child can be established. Even so, the outcome which can be predicted is not a strict one but constitutes, rather, a range of possible behaviors. On the whole, the review of the trait studies produces the impression that none of the parental traits held up for investigation can be correlated with a distinct and predictable pathological outcome, and that, while they may constitute a necessary condition, they certainly do not constitute a sufficient condition for the appearance of a specific form of psychological disorder in the child.

As a corollary to this statement, there emerges the distinct need for studies which inquire into the pattern of relations within the family over a period of time. In Levy's study, for example, the husbands of the overprotective mothers, both dominant and indulgent, were passive and unable or unwilling to intervene in the mother-child relations. This would seem to indicate that more activity on the part of the father—a less condoning attitude, for example—would protect the child from the pathogenic effect of the mother's behavior. But since Levy was interested primarily in the mother's behavior, this possibility was not subjected to investigation.

Interestingly enough, it seems quite likely that the process studies have been motivated by just this point of view on the part of the investigator. The aims of such investigations have been directed at elucidating the nature of the reciprocal responses of the various family members to each other in order to discover what patterns established over a length of time may be correlated with what pathological outcomes for the child. Through intensive study of a few cases, each investigator has attempted to discern such a pattern in the background of a particular child's emotional problems. Most of these studies are based on the psychoanalytic model of personality development and make considerable use of the interaction between conscious and unconscious mechanisms and their communication through implicit behavior. As a result, the possible number of patterns of behavior is very great, and the intricacy of each pattern described is so highly involved as to make comparison between patterns exceedingly difficult. In our review, we have found it impossible to codify the various constellations which have been described and to correlate them with particular symptomatic outcomes. Furthermore, as is evident from Table 3, the process studies make

Downloaded from www.doabinaya.com

practically no use of control groups, so that it is impossible to know whether a particular pattern may occur in some families without being correlated with pathology in a child.

Space considerations preclude our giving examples of the various patterned processes which have been presumed to correlate with the different symptomatic groups. However, we would like to discuss a phenomenon which appears in the process studies and which parallels a similar characteristic noted in the trait studies. Just as with the latter, where the same parental trait, such as maternal rejection, is described for a variety of different symptomatic states in the child, so in the process studies, the same process appears in a variety of contexts. One which is repeatedly emphasized is separation anxiety. It has been described as constituting the core of the pathological interpersonal process in cases of school phobia,[103] stuttering,[70] psychosis,[211] psychopathy,[205] and asthma.[43] Although there is great variation in the network of processes established around this core, the anxiety of the mother with respect to her incomplete separation from and dependence on her own mother is held to be reactivated in her relations with her child. As a result, normal emotional development and maturation of the child are inhibited, overdependence and reactive hostility are stimulated, and reality testing is severely limited. In the context of this general process, the details of the mother's unconscious wishes are then related to the specific symptom developed in the child.

This brief comment cannot do justice to the extensive number and variety of hypotheses concerning the etiology of the pathological development of the child which were raised by the process studies. The cumulative evidence fails to correlate, in a convincing manner, any clear-cut, patterned process with a particular symptomatic outcome in the child. Nevertheless, the weight of the evidence, in spite of the lack of control groups, points to *some* relationship between the unconscious motivation and overt behavior of the parents and the emotional difficulties of the child.

One may well ask what needs to be done in order to clear up the vagueness and confusion about the precise nature of this relationship which presently characterizes the literature. At the very least, it would seem apparent that the confusion will persist as long as investigators attend only to partial relationships within the family. Lacking a stable perception of the family as a structural and functional unit, investigators vary greatly in what aspect of intrafamily relations they choose to study. Some will select the mother-child relation, others the father-child, a third, the husband-wife, and still others the mother's relation with her own mother. Since the family is actually an enduring system of interdependent relationships, none of these partial interrelations can tell the whole story. Because of the usually arbitrary way in which the partial relations selected for study have been chosen, there is no way of knowing whether the most significant set of relations within the family have been included or accidentally excluded from the investigation. This methodological problem is acute, and little hope of greater clarity and consistency of empirical findings can be expected until a large number of investigators become oriented to the family as a unit of inquiry and adopt a more orderly approach to the collection and interpretation of data. We shall comment further on these aspects of the methodological problem after discussing the studies devoted to structural, situational, and constitutional factors within the family.

## *Structural Aspects of the Family as Genetic Factors*

A large body of literature, both psychiatric and sociological, deals with the incidence of various structural or situational characteristics in the families of patients. In general, these are statistical studies which seek to establish whether or not a particular structural or situational feature is correlated with a certain type of disease. With a few exceptions these studies attempt merely to establish a correlation between selected variables. Causal significance is then imputed to the independent variable. The causal nexus is left unexplored, in contrast to the process studies discussed above, in which the causal links are the main object of study.

Downloaded from www.libtool.com.cn

There are other differences set by the strategy of correlation. Correlational studies more often are made on large populations. If pathology is being studied, some identifiable patient population, such as all patients in a given hospital, all first admissions to a given facility, or all known cases in a given area, must be available. Since hospital populations are the easiest on which to secure standardized data, studies on the relationship of structural or situational factors and psychoses are most numerous.

The family characteristics that have received the most attention are those that can be readily determined. Primary among these have been birth rank, age, intactness of home, marital status, sex, and family size. It is difficult not to believe that such characteristics are important. There are deeply imbedded popular notions about their significance. The concrete findings, however, are not always encouraging, for contradictions abound, and, when consistency exists, it is found that the characteristic in question is related to many types of disease and thus has no differentiating power.

### PSYCHOSIS

The correlations of family characteristics and psychoses have been widely studied for almost three decades. Hospitalized populations are usually considered. Sometimes no distinction is made between different kinds of psychoses. Other studies find differences in the correlations of family characteristics and schizophrenia (and even for different types of schizophrenia) and manic-depressive psychoses. In general, however, both types are related to the same structural features.

It is clear that married persons are less frequently psychotic than single persons, divorced persons, or widowed persons.[10, 50, 63, 77, 135, 156, 157, 182] This advantage for the married may, however, be explained in several different ways; it may be, as Durkheim[55] suggested, that, in general, the state of marriage exerts a controlling force on the married persons. Alternatively, it may be that psychotics or psychotic-prone persons are less likely to marry at all.[185] The selection hypothesis is strongly advocated at the present time.[156, 157, 162] It is difficult, however, to account for the great disadvantage to the divorced and widowed, who were once married, within the terms of the selection hypothesis.

This pattern of advantage for the married over those in other marital statuses is not constant. It varies with sex, age, and diagnostic category. Males generally have less advantage than females; they are more likely to be single if psychotic[135] and more likely to be schizophrenic if single.[63] At the same time, sex is related to type of psychosis, women being more prone than men to manic-depressive psychoses.[41, 89] Nor is the influence of marital status independent of age. Rates of hospitalization generally increase with age, and the pattern of relative advantage for different marital statuses shifts. Females evidently lose some of their advantage in connection with proneness to schizophrenia.[133] Thus the picture is complicated. Age and sex and marital status are to some extent related, so that part of the relationship that is found between marital status and disease proneness may be due to age and sex differences.

Many studies have tested the relationship of birth order and psychosis. There is no definitive evidence that birth order is related to psychosis.[50, 51, 84, 232] At the same time, there is evidence that sibling position is an important factor,[191, 195] though Patterson and Zeigler[160] contradict this. Since birth rank and sibling position are related (for instance, one cannot be the eldest of three children without also being the first-born), these findings are not readily reconciled. Roberts and Myers[179] have recently suggested that the effects of ordinal position vary by social class. A similarly contradictory picture is found regarding family size and psychosis. Wahl[232] found the families of schizophrenics consistently larger, but Dayton[51] found that family size of patients' mothers was smaller than normal.

By far the most effort seems to have gone into the investigation of the relationship of the broken home to psychosis. Oltman, McGarry, and Friedman,[158] who had a control group of sorts, were unable to find the differences that others claim, and conclude ". . . the incidence of dementia praecox is unrelated to known external stresses or deprivations"

Downloaded from www.dbraulibrary.org.in

(p. 693). On the contrary side there is a great deal of evidence, which Wahl[232] has reviewed. Wahl's study is exceptional in that he attempts to develop a consistent theory of the dynamics of identification in the face of the loss of love-objects at various stages of maturity. Such a theory might predict the effects of loss of one parent or the other by different means (death, divorce, insanity) at different ages. He notes, however, that many other disease types are related to broken homes, so that the broken home is not a very discriminating variable.

There is, finally, a study of the influence of spatial mobility of families and mental disorders. Tietze, Lemkau, and Cooper[222] found that mobile populations had a disproportionately high incidence of psychosis, but they are unable to say whether the mobility is due to the disorder or the disorder is due to the mobility. Similar arguments rage in sociology about the effect of isolation (compare broken homes) in the development of schizophrenia. It has long been noted that the incidence of schizophrenia is highest in the areas of large cities in which the highest proportion of familyless persons live, and a "social" isolation theory of schizophrenia was developed.[92] This theory, though many studies have supported it, has been challenged by Kohn and Clausen.[114]

### Neurosis

Though the most studies have been made of psychoses in relation to family structure, neurosis has come in for its share of consideration. In studies of neurosis the populations investigated are more usually children. We shall consider in this section not only studies in which a psychiatric diagnosis of neurosis has been made but also those which judge neurosis on the basis of various psychological tests and those which deal with clinic populations without specifying the disorders further than saying that they are "problem behavior" or "behavior disorders."

Since adult populations are less frequently studied, there are few reports on the relationship between marital status and neurosis. The only study dealing specifically with this relationship was that of Downes and Simon,[53] who found a high proportion of single persons among a group of neurotics.

The evidence regarding birth order is mixed. Some have found the oldest child less neurotic.[1, 120, 184] Norton,[153] however, found that higher birth orders are more neurotic, and Sewall[193] and Wile and Jones[236] concluded that birth order is not important. The effects of birth order may well be related to family size, another aspect of sibling position. Fisher and Hayes[66] found that if there are three children or more the oldest and the youngest are most maladjusted, and Hayes[88] reported that the more siblings a child had, as long as she had one, the more neurotic she was. Levy,[120] on the other hand, found that the distribution of problems is independent of family size.

Data on birth order may also (usually) be ordered in terms of sibling position, and many studies talk not about the effects of being first, second, etc., but about the effects of being youngest or oldest. Adler's "spoiled, only child" turns out to be no more neurotic than other children.[1,100] Holman[98] concluded that only children are neurotic, but mainly because of the higher incidence of broken homes. The conclusions about children with siblings range widely. Fisher and Hayes[66] and Wile and Jones[238] found that the oldest and youngest in the family of three or more children are more neurotic. Rosenow and Whyte,[184] however, found the second child in the three-child family more often treated in clinics than the third, and Sewall[193] found that this middle child is more often jealous and that the age difference between siblings makes a difference in jealousy and rivalry.

A similarly confused picture exists concerning the effects of broken homes. Friedlander[75] has maintained that broken homes are infrequent for neurotics. Oltman *et al.*[158] found that neurotics have more often suffered broken homes and parental deprivation than have those with other disorders, and Holman[98] has suggested that broken homes are important. Madow and Hardy[131] reviewed the literature and concur, but Norton[153] disagrees. Tietze *et al.*[222] concluded that frequent moving is related to neurosis.

It is consistently found that boys appear

Downloaded from www.brainvolition.com

more often in guidance clinics than girls,[120] but Wile and Jones[236] did not find differences between the sexes in the incidence of maladjustment.

### Delinquency and Acting-Out Disorders

The acting-out disorders that have been studied and correlated with family characteristics are principally delinquency, in the case of children, and alcoholism, in the case of adults. Since delinquency, as officially recognized, is largely a lower-class phenomenon,[84, 126] the findings may be generalized only with caution. Alcoholism, too, may be subject to similar types of bias in reporting. Birth and sibling position have been investigated much more than other factors. Higher birth ranks have been found to characterize alcoholics more often than would be expected by chance.[14] Mowrer[151] found that alcoholism clusters in the oldest and "socially" next-to-youngest (that is, though in fact the youngest, another sibling is treated as the youngest) sibling positions.

As with other disorders, alcoholism is correlated with marital status. Married males have a consistently lower rate.[13, 167] Amongst those ever married, those still married have a lower rate than the divorced, separated, or widowed.[12] Women have a much lower rate of alcoholism than men.[12] One early study[167] found, however, that married women were overrepresented relative to the total population. Marital status, then, has different effects upon alcoholism rates, depending on sex.

Being an only child disposes one to delinquency according to Levy[120] and Ward.[234] Sletto[201] reviewed the considerable body of literature that existed even in 1934 and showed that the findings were very mixed. His own research revealed no overrepresentation of only children in a group of delinquents. The Gluecks[80] found that fewer delinquents were only children. They also found that delinquents were less often first-born or youngest children than would be expected. According to Sletto,[202] the effects of sibling structure are complex. He has identified 30 different combinations of sex and birth rank and found that different constellations had different effects on delinquency. For instance, delinquency is high when the individual has younger siblings of both sexes, but low when there are older siblings of both sexes. It is higher if the older sibling is of the same sex and the younger sibling is of the opposite sex than if the reverse is true.

There is, according to several studies,[80, 126] a relationship between family size and delinquency, with delinquents coming from larger-than-normal families. Since there have been class differences in family size, and delinquency rates vary by social classes, the relationship may be due to class rather than family size.

The idea that broken homes cause delinquency is strong in the lay mind. There is much evidence to support this view, dating from 1912[26] to the present.[146] The findings, however, are highly variable, owing at least in part to methodological problems of selection. Shulman[197] reviewed the literature and concluded that the broken-home hypothesis may be a good one but that it is so broadly conceived as to be of little use. Toby[224] has recently examined Shaw and McKay's[194] data, often interpreted as disproving the broken-home hypothesis, to show that the data actually support the hypothesis in the case of adolescents but do not hold for preadolescent males or females. Toby has adduced further current data to show that there is thus a differentiated impact of broken homes on males and females and on different age groups.

### Psychosomatic Illness

We have located only two studies of psychosomatic disorders, as related to the structural characteristics of the family, that have large enough samples to be considered. Kingsley and Reynolds[110] found that patterns of illness, some of which might be considered psychosomatic, differ by ordinal position. Only children have many gastrointestinal upsets, skin disorders, feeding disturbances, constipation, asthma, and allergies. First children are high on constipation and feeding disorders.

Second children are high on respiratory and ear infections, tonsillitis, diarrhea, accidents, and enuresis. These authors were not specifically investigating psychosomatic disorders, but there is suggestive evidence that ordinal position is important.

Downloaded from www.unz.org

Vincent[230] has studied the loss of parents in a population with diagnosed psychosomatic disorders. He found that 68.5 per cent had lost one or both parents. No control population was used, but undoubtedly this is a higher incidence than could be expected by chance.

### General Appraisal

When presented with such diverse, sometimes contradictory findings, it is easy to dismiss this approach as unhelpful. The study of situational and structural factors as they relate to mental disorders is, in essence, a trait approach. As in the study of traits of the parents or their personalities, correlational studies do not lead to conclusions in which we can have much confidence and which have much power to discriminate between various disorders.

Still, on several grounds it is difficult completely to reject the approach. Correlations do appear, and some with a moderate degree of consistency. The possibility exists that, with more rigorous methodological techniques, some more stable conclusions could be arrived at. It is difficult, on the grounds of personality theory, too, to conclude that loss of a parent or other love-object, age, sex, sibling position, marital status, and such characteristics would have no effect upon an individual's development, pathological as well as healthy. Psychoanalytic personality theory, however, premises its conclusions not on the basis of some objective characteristics in itself but rather upon the subjective feelings that are associated with the characteristic. It may be that not the formal but the affectional structure is the significant area which requires investigation. It would be expected that these two types of structure would be related, but perhaps they are not closely enough related that the formal structure can be used as a reliable index of the affectional structure. In clinical case studies, any disparity can be recognized and taken into account. In the larger scale correlational studies, the same sort of corrections cannot be made. The investigation of affectional structures is, of course, a more complex and difficult procedure than the identification of formal characteristics, but some progress in this area has been made.[90]

In the present state of affairs, it can only be said that such formal characteristics *may* be conducive to a particular disorder of some sort. The crucial question of how and under what conditions such characteristics do or do not have specific effects cannot yet be answered, but must await more comprehensive studies of greater methodological and theoretical sophistication.

### Methodological Comments

It might seem that correlational studies, measuring the incidence of two identified characteristics, should be straightforward and produce clear-cut results. However, as we have seen, there is a distressingly wide variance among different studies. Much of this variance can be accounted for in terms of the methodological characteristics of the studies. Since space limitations did not allow detailed comments on the methods of each study, some general remarks on methodological issues are appended here.

**Measures.** Different studies of the same phenomenon may use different types of measures, with the result that the studies are not strictly comparable. One study of the incidence of a given disease may measure the proportion of a total hospital population with a given disorder; other studies may use the proportion of first admissions with that disorder, or the rate relative to the total population, say of a city, or the rate relative to the part of the population with given characteristics, or the distribution of cases over time, by age, or by sex. Each such measure is legitimate and proper for specific purposes, but if different studies are to be comparable and our knowledge is to be additive, there must be greater standardization of measures employed.

**Populations and Samples.** Some studies deal with total populations, for instance of a hospital, but without indicating what, other than availability, characterizes the population; others deal with some section or sample of a population without indicating what relation this sample has to what larger population. Any conclusions made should be stated only in terms of the group studied and should be extended only if that group is shown to be representative of some broader population. We find, however, that the restrictions in

Downloaded from www.dbraun.org.ar

applicability of conclusions are almost never stated. Findings on some group of patients tell us nothing about all patients, unless we know that the group studied is a representative sample of all the patients. Similarly, the study of a group of patients does not allow us to make any conclusions about nonpatients, unless, again, the patients are shown to be representative of nonpatients in some ways. Sampling and the size of group needed to allow reliable results are technical matters on which a statistician's advice is desirable.

**Control Groups.** By using control groups it can be demonstrated that the variable studied makes a crucial difference in outcome. Many studies use no control groups at all; others select control groups on unknown or irrelevant grounds. Frequently, there is no conception of what is being controlled when a control group is used. A finding that 20 per cent of a group of disturbed children come from broken homes helps little if 20 per cent of all normal children with the same age, sex, class, and ethnic background also come from broken homes. Similarly, we prove nothing if some factor is found to characterize a group of psychotic patients and is not characteristic of hospital employees, unless it is shown that the two groups differ in no other way which could explain the finding. Again, the selection of control group and of variables to be controlled is a technical matter.

**Interrelatedness of Variables.** Most studies deal with one variable at a time, disregarding the context of the variable. This failure to hold constant other significant variables can lead to spurious findings. Haldane and Smith[85] have shown, for instance, that some things explained by birth rank are really accounted for by maternal age, which, of course, increases as birth rank increases. Similarly, most of the findings about birth rank or sibling position are cast in doubt because age and sex were not held constant. Sletto[202] distinguishes 30 different sibling positions and arrives at quite different conclusions about delinquency for different positions. It may not be the fact of being first born or the oldest of three that is important, but the pattern of being a male oldest child in a family with three girls. The consideration of several variables simultaneously greatly complicates an investigation, but it is necessary if conclusions are to be valid and precise.

**Theories and Hypotheses.** It is clear that it is easier to establish correlations than to interpret them. Generally speaking, it is scientifically more efficient to have theories from which testable hypotheses can be deduced. If, on some logical grounds, it is predicted that some relationship should be found and it is found, then we have grounds for concluding that the relationship is real. If the explaining theory is sought after the finding is made, the likelihood that some explanation can be found is high. When theories of personality and pathogenesis are as well developed as they are, it is surprising that correlational studies so often seek findings and so infrequently test hypotheses. The theory that Wahl[232] attempts to specify about the relation of broken homes and pathology approaches the model of adequate science.

Some of these methodological comments, it will be noted, coincide with the comments made about trait and process studies of parent behavior. Many of us are not sufficiently aware of the relationship of conclusions to such technical issues. The cost in terms of vagueness and uncertainty is great.

## *The Family and Constitutional Endowment*

Among the several functions of the family, one of the most important is the transmission of a particular genetic heritage. In an earlier era, genetic inheritance was seen as the decisive factor in mental illness, and the family, as the carrier of "bad genes," was the *bête noire*; famous studies of infamous families[54, 81] were made to support the theories of genetic determinism. Currently, such studies are regarded as dubious, but the old, false dichotomy of genetic versus environmental factors lingers on. The sort of evidence that leads some investigators to genetic conclusions[99, 105, 106] leads others[97, 168] to opposite conclusions.

A more fruitful, and theoretically more sound, approach would seem to be to regard

Downloaded from www.pbookshop.com

constitutional and environmental factors as interdependent[128] and to pose the problem as one of tracing this interdependence. Every individual has constitutional qualities which are reacted to by significant persons in the environment. Several recent studies[61, 71, 82, 221, 285] do, indeed, take this approach and demonstrate the value of a genuinely integrated theory. They suggest, too, the complexity and subtlety of the interaction, concerning which much conceptual, theoretical, and research work remains to be done.

## ¶ The Impact of Mental Illness upon the Family

Most investigations of the interrelation between the psychiatric patient and his family have focused on the events antecedent to and associated with the development of the illness in the patient. Following the onset of the psychiatric disorder, and the casting of the disturbed person in the role of the patient, the family has tended to recede into the background. From this point on, clinical practice has been prone to consider the family only in so far as its cooperation is necessary in carrying on treatment procedures with the patient or in executing therapeutic recommendations. Frequently, the family is viewed by the psychiatrist in practice principally as an irritating obstacle to success in these areas. In a sporadic fashion, clinical investigations have, at times, treated the responses of family members to the patient's illness as topics for research in the technique and methods of therapy. It is only recently, however, that the responses reverberating throughout the family, as a result of the patient's falling ill, have been studied in their own right.

It is not unexpected that sociology should have taken the lead in this type of investigation. As we have stated, sociologists have for many years been interested in the effects on the family of various types of crises. In general, studies in this area have focused on crises whose origin was originally external to the family, such as the effects of war and economic depression. A few studies have, however, been devoted to the investigation of crises emanating from within the family, and, of these, some have dealt with mental illness in a family member as the specific point of origin.

### *The Impact of the Development of Illness and of Hospitalization*

This area is just beginning to be opened up for investigation, but enough work has been done to indicate the complexities of the process through which the family members become aware that one of them has developed a psychiatric illness and how they deal with this event. The process can be studied in many different ways and from many points of view. Its complexities can best be ordered in terms of the time scale governing the sequence of events, and we have, accordingly, summarized current knowledge with reference to the following stages:

#### Prerecognition Stage

When behavior occurs which deviates from the normal or the expected, it is not automatically recognized as pathological. Instead, attempts are made to see the behavior within the framework of normality. This may involve considerable effort and struggle for the marriage partner and other family members,[39] and may produce feelings of threat and insecurity in them which require compensatory changes.[102]

#### Recognition of Pathology

At some point the deviant person can no longer be seen as normal, and a "break" occurs in the perception of and behavior toward the deviant.[19] At this point a whole range of feelings, attitudes, and interactions must, to some extent, be reordered, with consequent strain.[39] The family now contains a "sick" member whom it is difficult to treat normally and who may be unable to fulfill his normal duties. Such a failure in normal living may lead to a demoralized state, and nearly all family routines may suffer.[226] Attempts to reorganize the family with different roles for the sick member, a new authority structure, and new alliances, may take place.[102] When one mem-

Downloaded from www.dbraulibrary.org.in

ber becomes identified as sick, the emotional problems of others may be repressed.[163]

### Rupture

If the sick member's behavior or its secondary effects are serious enough, some rupture in the family relationships may be required. The sick member then becomes a patient, hospitalized or not. This act is usually felt by patient and family to be a rejection, which produces in the family guilt and consequent defenses of various forms.[39]

The fact of rupture may itself accentuate official and public recognition of illness. The family may then feel disgraced and withdraw from social contacts. At the same time, the strength of the rejection of the patient, at least in the case of children, treated as outpatients, may increase.[48] Problems may be created too—problems of economic support and living arrangements for the family.[102]

### Reorganization of Part of the Family

Once the patient is rejected, whether he is physically absent or not, there is some tendency for the remaining family members to reorganize themselves and establish new patterns of relationships. Clausen, Yarrow, *et al.*[39] have investigated this phase extensively and show that the amount and content of communication within the family, with relatives, and with others, alters considerably, the extent and nature of alteration depending upon the many factors which characterize a specific family.

The organization established during this period may be so "efficient" that the family's ability to cope with problems is quite high. The efficiency may be so great that subsequent problems will arise when the patient tries to re-enter these closed ranks. It might be stated that the more the reorganization is built upon the rejection of the patient, the greater will be the likelihood that the self-sufficient organization will develop. A tendency to justify the rejection and displace responsibility to others outside the family is strong.[39] The fact that action has been taken, even if it is not ultimately beneficial, can be a source of comfort and give the family members a sense of worth.[102] In so far as this feeling is shared, it may give strength to the new patterns that emerge.

### Discharge

Decisions about discharge and the disposition of patients after discharge can involve family members in conflicts and present further problems. Just as perceptions of the wife and the psychiatrist differ in accordance with their roles and their involvement with the patient in the precommitment and immediate postcommitment periods, they differ too in their evaluations of the patient's improvement.[192] Presumably, this can lead to conflict about readiness for discharge and to problems of adjusting attitudes and perceptions in family members. Considerable disagreement regarding release has been found in a group of cases studied intensively at time of release.[199] The conflict among doctor, patient, and patient's family frequently results in coalitions of pairs against the remaining member.

Even after discharge has been settled, there are problems about where the patient should go. Simmons, Davis, and Spencer[199] found a significant tendency for patients to go, on release, to a setting different from the one from which they came. It has been established for some cases, and may be true for many, that if the patient re-enters the family, he and the family are faced with a difficult situation; the ranks that have been closed do not open easily.[102]

### Postdischarge

The postdischarge period, perhaps crucial in the life of both the patient and his family, has been largely neglected. The one study which considers this period[102] suggests that the postreunion period may be beset with problems—such as when the previously alcoholic husband becomes so active in Alcoholics Anonymous that his wife feels neglected.

Even this condensed review of the impact on the family of the development of illness and of hospitalization reveals that the accent is upon the negative, disorganizing effects. A few studies suggest that the complete picture is more complex. Fisher and Mendell[65] suggest that the sick member is in some sense an

Downloaded from www.pdfbooksfree.pk

emissary sent out by the family to get help, manifestly for his own problems but implicitly for the whole family's problems. Perry, Silber, and Bloch[163] found that once a sick role was taken by someone in the family, there was not the "dynamic space" for anyone else in that role. It could be inferred that such a situation controls the deviant tendencies of other members of the family, at least in the short run. Closer examination may reveal that, at all phases in the development and recognition of illness, there are gratifications as well as deprivations.

## *The Impact of Other Crises*

There is a large group of studies, mainly sociological, which do not deal with the impact of mental illness on the family but do deal with impact of other crises or problems. These generically related studies generally confirm the course of effects sketched above. Eliot[58] has described the process of reaction to bereavement. He shows that, just as with the family experiencing mental illness in one member, the bereaved person undergoes a reaction process which includes adjustment or readjustment of cognitive and emotional structures, changing patterns of interaction, communication, etc. Koos[116] and Hill[86] find a similar but more simplified process of reaction to stressful events. Bakke[15] early gave a systematic account of the stages of disorganization and reorganization following unemployment.

Many of the specific responses found in reaction to mental illness have been observed in families faced with other problems. Hill,[86] studying wartime separations and reunions, observed the phenomenon of the closed ranks which reopen only with great difficulty to admit the homecomer. Several studies of families in the depression show that unemployment can be demoralizing to fathers, and this has ramifying effects on many areas of the functioning of the fathers and their roles in the family.[35, 36, 115]

Some of these studies supply elaborations of particular points that might well hold for mental illness. For instance, Geiger[78] found that if the disturbing force was perceived as coming from inside the family, the solidarity of the family decreased, but if the "fault" lay outside, the family solidarity was increased. Similarly, Koos[116] found that when lower-class families experienced "troubles"—delinquency, illegitimate pregnancy, job loss, etc.—if the father was perceived to be responsible, his authority position was weakened. The mother's authority was less likely to be weakened, and a child's position was affected relatively little. Duvall[56] studied the problems of the serviceman's wife and found that adjustment to separation was best when the wife had a high rate of social participation. When a child is hospitalized and subsequently returns home, it has been found[171] that the parents' anxieties could affect their handling of the siblings. In turn, the changed handling of children can enhance sibling rivalry and other problems.

## *The Impact of Treatment*

Many other studies deal not with the impact of mental illness on the family but with the impact of the treatment upon the mental illness. A few psychoanalysts have been interested in the effects of treatment,[27, 154, 155] but mainly as technical problems in the therapy. That treatment can have side effects which are not always beneficial has been recognized for some time, mainly by social workers. They have noted how treatment can shift the balance of family forces so that conflict increases, some other member of the family shows greater disturbance, or the child's therapy is hindered.[20, 33, 213, 233] Psychiatrists have recently begun to explore this area in some detail.[24, 144, 183, 187] Chance, a psychologist, has reported a major research project on the topic.[37, 38] At least two unpublished studies[18, 48] also deal with the effects on the family of the treatment of a child.

The involvement of relatives in treatment, through group therapy, hospital work, discussion groups, and joint treatment, has been attempted in the last decade. Rather impressionistic and usually brief accounts have been given of the amelioration of attitudes toward the hospital, the staff, and the patient by such means.[46, 142, 185, 186, 214] Detailed studies of the further effects, if any, are needed.

In summary, it can be asserted that mental

Downloaded from www.dbraulibrary.org.in

illness and its treatment influence not only the patient but the groups of which he is a member. In the case of the family, these effects may be far-reaching and of great magnitude. The authors feel that such influences cannot afford to be neglected from either a practical or a scientific point of view.

## ¶ The Family and Treatment Procedures

Practice may or may not follow theory faithfully. The dynamic theories of psychopathology and the findings derived through their use have been largely individual-centered. Moreover, these theories have been constructed in such a way that the individual is conceived as a self-contained system, becoming relatively "closed" early in life. Even the social and cultural variants of these theories share this assumption. We do not find evidence that treatment procedures vary significantly from what one would expect on the basis of theory. In the context of the habitual lip service paid to the family-as-a-whole, isolated groups or individuals have attempted to maintain a focus on the family unit in diagnostic formulations and treatment procedures, but attempts to bring the family to the forefront have not become established.

### *Diagnosis*

Since theory has not sensitized research workers or therapists to group variables, and no appropriate interdisciplinary language has been made available, it is not surprising that diagnoses are phrased in terms of the individual. Even those who are strongly convinced of the significance of the family and the necessity of dealing with the family as a unit (for example, Towle[225]) have had to formulate diagnoses in terms of the interaction and interdependency of individual psychodynamic characteristics and processes. This has remained true through the various phases of thinking about pathogenesis and treatment. It is not until the 1940's that we find a departure from this tradition and an attempt to formulate diagnoses in terms of group characteristics.[177]

As might be expected, there has been more innovation in the child-guidance field than elsewhere. As attention has turned to the mother-child interaction, diagnostic formulations have included aspects of the mother-child relationship. Nevertheless, a disturbed "mother-child relationship" has frequently turned out to be a disturbance in the mother with consequent implications for the child. In recent work on atypical children,[132] the focus has been shifted somewhat to the relationship itself. A fundamental feature of this disorder is that the mother-child relationship is undifferentiated, a characteristic of the relationship itself rather than of either party to the relationship. However, such formulations have not been extended to family-group characteristics, and ultimately the structure of the relationship has been reduced again to individual pathology.

Several authors have attempted to solve this difficulty through conceptual reformulation. Sullivan,[217] in his interpersonal theory of psychiatry, attempted to develop a language descriptive of the relations between persons, but actually he seemed to deal more with the interpersonal mechanisms within individuals than with the interpersonal relationships of pairs or groups of individuals. Bateson,[17] with his concept of the "double bind," and Wynne,[238] with the concept of "pseudo-mutuality," deal more specifically with properties of relationships.

Social scientists have long had an interest in disorganized social relationships. It is rather surprising that they have not brought their thinking to bear more directly on developing a conceptual framework for the diagnosis of pathological group relations on the small-group level. Many writers have diagnosed the "ills of society" on a very general and diffuse level. Kardiner[107, 108] has attempted to formulate the connections between broad cultural conditions and modal personality types, but detailed specification of the structures and processes through which this very general relationship operates is still lacking. In recent years, social scientists have applied themselves with spirit to the problem of diagnostic formulations in the child-guidance field.[165, 166] Pollak has been able to recast some concepts and introduce others, so that he has developed a language which is

Downloaded from www.psychiatryonline.org

more consonant with the processes of interaction within the family. Nevertheless, there has been little shift of focus away from the individual and, in spite of the improved vocabulary, diagnostic formulations are still made largely in terms of the "fit" of the unconscious needs and defenses of different individuals. A more recent article departs from this feature, to talk in terms of the properties of relationships.[164]

Another aspect of diagnosis, the strategy of arriving at a diagnostic formulation, is pertinent to the implication of the family in the patient's problem. Most diagnosis is done by interacting verbally with the patient and by observing his responses to the therapist and to test materials, or, in the case of children, through the use of play materials, symbolic situations, etc. Observation of the patient in a natural group has seldom been used. Redl[174] has used groups in diagnosing children, Van Amerongen[228] has interviewed family groups, and Herriott[93] has used psychodrama in diagnosing mental patients. Sigel *et al.*[198] have observed families indirectly in their attempts to diagnose "influence techniques." In our opinion, observation of the patient within his family and in other natural settings should be investigated for its diagnostic utility.

## *Individual Treatment*

The theories on which most psychotherapeutic efforts are based also prescribe many features of treatment technique. Psychotherapeutic treatment by its nature implies a close personal relationship. It is widely assumed that the optimal therapeutic situation is a one-to-one relationship of therapist and patient. Even within the framework of this traditional model of treatment, different things may be focused upon, the form itself not necessarily determining the content. It is the opinion of the authors, however, that in the one-to-one relationship the individual tends to be seen sharply, the family obscured. It can be said with some justice that there is a strong bias against including families in psychotherapeutic procedures. Grieg[83] takes Anna Freud to task for her antagonism to parents as evidenced in her procedures.

The principal ground for the rejection of treatment of more than one person at a time by one therapist has been the reputed difficulty in handling the transference.[117] This view has been advanced strongly, despite the fact that some analysts have successfully treated siblings,[155] spouses,[145, 154] and even families.[144] Recently, the dangers of collaborative or simultaneous treatment of family members has been viewed less seriously. The advantages of such techniques are now being stressed.[21, 137, 144, 212, 219] Ventures into joint treatment have also been reported and are probably not so rare as the published literature would suggest. Pechcy[161] has reported a technique of observation of mother-child interaction prior to each interview with the mother. The joint treatment of parents has been carried out for some time in Buffalo.[87]

Collaborative and joint treatment have far to go before their techniques are adapted to the treatment of the family as a unit, but, out of such attempts to widen the therapeutic range, there may someday emerge a method of therapy more suited than any current one to deal with the family's involvement in the illness of one of its members.

## *Group Therapy*

Group therapy is a method of treating individuals in an artificially created group, that is, treating a number of individuals *as individuals*, at the same time and in the same place. Some leading exponents of group therapy deny that the group can be considered as an entity in therapy and treated as a focus in itself.[200] Most group therapists do not use natural groups in the therapy, particularly natural groups that sustain intimate extratherapeutic relationships, such as the family. Again, the problems of managing the transference when several family members are treated in the same group are stated to be great.

It is rather striking that, at the same time that group therapists have concluded that groups cannot be made the focus of treatment and family members cannot be treated in groups, individual therapists—especially in the child-guidance field—are coming to believe that the family must be treated as a group,[118] and

Downloaded from www.dbraulibrary.org.in

in practice more joint or collaborative treatment is found (see above).

Group therapy has another source—one not so much in the main stream of psychoanalytic theory. This is the psychodrama movement of Moreno.[147] When orthodox therapists were denying the possibility of joint treatment, Moreno was experimenting with the joint treatment of marital problems by means of his role-playing techniques.[148, 149] Others see these techniques as capable of application to and in the family.[44, 128, 227] Still, despite many promising leads, the psychodrama movement has not attracted a wide following and has failed to produce a body of systematic research findings.

There is no dearth of titles suggesting the treatment of families in groups. Corsini and Putzey[45] list 52 items concerning families in group therapy. The great majority of these, as Abrahams and Varon[2] point out in their review of the literature, do not deal with families at all but with groups of unrelated mothers, fathers, or children. There are some exceptions. Abrahams and Varon[2] did treat mother-daughter pairs in a group setting. Parents have been treated as couples in groups,[196] and recently whole families have been studied and treated on an inpatient basis.[24, 238] In each case where such innovations in treatment procedures have been made, success has been reported. Not only does it seem possible to carry out the treatment of families as groups, but the method has advantages. Some of the patterns of interaction that produce and maintain pathology in the affected person are subtle and not easily comprehended except by direct observation of the interaction.

## *Marriage and Family Counseling*

Giving counsel on marriage and family problems is a service that is ancient but a profession that is very young. As a separate profession with some unity and identity, marriage counseling began around 1930.[27] The separating out as a professional activity of what had before been handled by educators, ministers, physicians, etc. was the culmination of an interest in the woman's place in society and concern about the sexual adjustment of women.[152] The several large-scale studies of sex life—many under the auspices of The Association for Social Hygiene—of the late 1920's gave the immediate stimulus to provide advice on marriage and the family.

From the beginning, marriage counseling drew from a variety of sources for theory and operating knowledge. Psychologists, sociologists, and biologists, as well as physicians and social workers were involved in early clinics. To a greater extent than with other therapeutic services related to the family, marriage counseling has maintained contact with this variety of disciplines. At the same time, however, marriage counseling has assimilated a great deal of the social case-work approach and technique,[52] which, in turn, derives in large part from psychoanalytic theory. At the present time, it is difficult to see just what technical method is unique to marriage counseling. Social workers, and even psychiatrists dealing with marital problems, are assumed to be doing "marriage counseling." It would seem that marriage counseling has developed no stable core of functions, techniques, or theories it can call its own.

Eclecticism is characteristic of the aims and methods as well as the sources of influence. Enlightenment through education is a strong element in marriage-counseling practice. For example, marriage counselors teach numerous so-called "functional" college courses, given in preparation for marriage and family life, as part of their effort.[52]

The authors have only a superficial acquaintance with the field of marriage counseling and its literature, but it is our impression that it has not made any radical departure from the other types of therapy in the direction of awareness of the family as a unit, or in attempts to deal with the group rather than with a collection of individuals. Marriage counselors are naturally oriented to the marital relationship, but published case illustrations reveal little attempt to formulate observations systematically in terms of the relationship. Although simultaneous treatment and even joint interviewing may take place, the model of treatment employed is that of individual ther-

Downloaded from www.dbraulibrary.org.in

apy (for example, Mudd[58]). The method of counseling, in particular of Rogerian nondirective counseling,[180] is based on theoretical notions which emphasize the inner desires and capacities of the individual to the exclusion of any external influences. It is characteristic of this field that such a school of counseling should have produced an extensive literature of careful research[181] without adding to our understanding of familial or sociocultural influences upon the individual.

### *The Relations of Families to Treatment Facilities*

The topic of family care is germane to this section on the family and treatment procedures. It is, however, dealt with extensively elsewhere in this volume and need not be taken up here. One comment may be in order, since we feel that there is one aspect of family care that is very revealing of the prevailing attitudes toward the family of the psychiatric patient. "Family care is a program providing paid foster care in a home other than the patient's own. . . ."[16] (p. 643). The term thus seems to be a misnomer. We raise for speculation the question of the sources of this misnaming. Is it felt that the patient within his own family is not cared for? Do only paid, unrelated families care?

There is evidence to show, just as Towle stated nearly thirty years ago, that treatment affects and involves every member of the family, not just the individual patient. The practice, particularly of inpatient treatment, strongly suggests, nevertheless, that patients do not have families. Recently, there has been a great deal of interest in the effects of the total social organization, or milieu, within which treatment takes place.[104, 210] The planning and manipulation of the hospital environment are coming to be considered an important aspect of therapy, but there are few examples of the systematic consideration of the family as part of the environment which is affected by and affects treatment. Some Meyerian therapists are interested in families, but this interest is still without any extensive framework.[130] Brodey and Hayden[28] have noted that the relationships of the members of the therapeutic team may resound to family conflicts. Midelfort[142] has written of his original but limited work in involving families at all phases of the treatment of even seriously disturbed persons. Still, as Fleck *et al.*[87] point out, there have been few systematic studies of the relations of families and hospitals, and the interaction of hospital personnel and families is largely neglected. Interest in this area does seem to be growing, and it may be anticipated that more substantial knowledge will become available about the family's role in rehabilitation.

## ¶ New Approaches to the Family and Its Pathology

### *Family-Centered Approaches*

During the past ten years there has been emerging, in some quarters, a new approach to the relationship of the individual and the family in the genesis, diagnosis, and treatment of mental illness. These changes have taken place largely within the framework of psychoanalytic theory, but they attempt to avoid those aspects of the theory and practice which have proved to be unsatisfactory and inhibiting. In these approaches the attempt is made to avoid the rigid polarity between organism and environment, to find a broader focus including both the individual and his family. Changes in this direction are relatively young, and since they involve departures—sometimes great—from conventional modes of thought, accepted terminology, and well-established ways of proceeding, it is to be expected that many of these approaches are still in the stage of being worked and tested. Many are still in the stages of refinement and have been reported only in fragmentary form.[23, 40, 70, 91, 92, 101, 121, 238]

Ackerman[3, 4, 5, 6, 7, 8, 9] is a leading exponent of these new approaches and may be considered briefly in order to illustrate family-centered approaches. Ackerman, like others, feels that the conventional orientation sees the individual isolated from the continuously operating network of interpersonal forces and

Downloaded from www.uoradiology.org.in

reduces the environment to a vague background of human behavior. As Ackerman himself says:

But it is essential to view these dominant modes of behavior in the growing child as shaped by the total psycho-social configuration of the family, rather than by the parent-child relationship in isolation[6] (p. 177). In psychoanalytically oriented formulations, certain patterns of interaction are suggested between the child's unconscious needs and particular elements of parental behavior, or between the overt actions of the child and the unconscious wishes of the parent. Clearly, such correlations are partial in nature; they hypothesize a relation between a piece of the child and a piece of the parent. This piece of the parent—usually a set of conflicting unconscious needs—is not defined in its proper relation to the whole child, nor is the whole child seen in an accurate perspective with regard to the whole parent, or the full breadth of the relationship between the parents, or to the psychosocial configuration of the family as a whole[6] (p. 182).*

If we are to move toward this goal of handling the psychosocial configuration of the family as a whole, Ackerman maintains[5] that psychoanalytic concepts appropriate to the personality development of the child cannot simply be extended to the family and community. Freudian concepts and formulations are not rejected, but their limitations must be recognized. They must be supplemented by and articulated with conceptions of the structure of the environment and of interpersonal relations.[3] The primary bridging concept Ackerman advocates is that of "social role," or the operation of the integrational aspect of the total personality (the social self). This social self, which may or may not reinforce the "inner self," is what is expressed in social action and is responsive to group organization, thus giving a dynamic link between society and the individual. Goals and values, which have a dual orientation, toward the self and toward others, give the configuration to the social role a person may take.

In his more concrete formulations, Ackerman[7] develops a typology of types of marital interaction based upon what role is dominant, and a typology of family groups in terms of their internal and external integration. The diagnosis of pathology, then, involves the assessment of the internal organization of the family, the external adaptation of the family, parental roles and child-rearing practices, and how they are integrated at each stage of the child's development (Ref. 6, pp. 194–196). The child's pathology, stated in the conventional terms of his psychic processes, is only a part of the broad field that must be viewed.

Such conceptual reformulations radically alter the nature of diagnostic and treatment procedures. No longer is it adequate to study a part of the family and phrase the diagnosis in terms of the child's inner processes, or the mother-child relationship. No longer is it adequate to treat the individual as if he existed independent of the family, as if the therapy were the only force operating on him, and as if therapy altered only the one or two individuals seen. Failure to do so can only result in a partial and artificial view of problems and often in failures in treatment.[8]

Ackerman and other family-oriented investigators have taken a long step away from the approach which has prevailed for more than a generation. The shift in focus is a basic one, greatly complicating both the theoretical formulations and the procedures of observation. Because of the many problems raised by this approach, and also because of the recency of the endeavor, most of its aims are not yet fully attained. Neither a wholly coherent theory nor a consistent, adequate set of observations has yet been advanced, nor has much progress been made toward the long-hoped-for and elusive goal of developing categories of pathogenic family patterns.[10] Even so, however sympathetic one may be with respect to the difficulties and present failures of a youthful and

* In the discussion of this paper, Bender nicely states the traditional point of view that internal processes are of greater significance than environmental forces. "I am repeatedly impressed with how much all children are alike, and how overwhelming is the tendency of the inborn developmental pattern to assert itself in all human young. . . . Race, mixtures of race, language, family patterns, complete abandonment by parents—all these are finally less significant than what the child himself can demonstrate and what the physician, educator, and parental figures have to offer the child in terms of his specific problems"[6] (p. 202).

Downloaded from www.CommunityPsychiatry.in

novel approach, one may question whether its concepts and procedures are adequate for its purposes. If it is artificial to isolate the individual from the family network, is it not equally artificial to isolate the family from its cultural and community (including extended-family) setting? Ackerman recognizes the significance of cultural values, but he has no classification of them and gives them a minor place in his framework. Similarly, the external environment is a collapsed and nebulous factor for Ackerman, and extended-family systems seem to have no part whatsoever.

Such gaps are not easy to fill, but they need not be neglected. Erikson,[60] though not working specifically in the area of family research, has raised the question and pioneered in breaking a path leading from the individual to his family and on to the cultural network. Lindemann[122] has been another pioneer in stating and investigating the reciprocal relationships of individual family and community. Fisher and Mendell[65] have recently demonstrated the curiously enmeshed continuity of cultural and pathological themes extending through the family from generation to generation. The point brought out, though rather indirectly, by such studies is that the base adopted by Ackerman, broad as it may be, is yet too narrow to encompass the forces associated with the pathogenic process in the family. The constriction is both theoretical and procedural. From the point of view of theory, insufficient effort has been made to bring psychoanalytic formulations into line with sociological and anthropological theory. Procedurally, the observations are much too confined to the nuclear family, neglecting the horizontally extended network of relatives and the heritage of generations, as well as the impact of the community and its value system.

## *The Transactional Approach*

A more comprehensive and systematic approach, currently being employed in the study of the relations between the family and mental health or illness, is perhaps not so open to these objections. This is the "transactional" approach first proposed, at a general philosophical level, by Dewey and Bentley,[52] and used by Spiegel,[205, 206] and Spiegel and Kluckhohn[208] in family research. Essentially a field approach, the transactional point of view postulates that the events involving the sick individual with his family occur within a total system of interdependent subsystems, any one of which—for example the individual, the family, the community, the value system—may become, temporarily, a focus of observation. The "world" being observed must include the observer and his act of observing.[188, 189] Within the field encompassing the interconnected subsystems, a component system, such as the individual, can be isolated and studied as an entity, but this is a heuristic device which always involves some distortion and sacrifice of precision or predictive ability.

If this philosophical position is accepted, then the individual and the family are seen as subsystems which are intimately and complexly interrelated. Neither has any greater "reality" than the other,* and no characteristic of one or both has any necessary priority. A somewhat similar philosophical stance has been adopted by others under the name of "general system theory."[231] No matter what it is called, this point of view alters the concept of causality. Viewing one entity or process as causing another, or as dependent upon another is possible only if their interrelations can be isolated from total contexts. Putting variables within a total context shifts the question from "What in the family 'causes' pathology in the individual?" to "What processes occurring between the individual and the family are associated with the behaviors which are called 'pathology'?" As used by Spiegel and Kluckhohn,[113, 204, 207, 208] the transactional approach attempts to articulate the structure and process of events in the individual with the structure and process of events in the family and culture. This involves developing and articulating theories

* The same argument applies, of course, to the relationship between family and community, society, culture, and soma,[205] but it is difficult to keep all subsystems under observation for the purposes of a particular study. For example, the individual and the family may be studied without including the community, society, culture, etc. in the field of observation. Some distortion will inevitably occur under these circumstances, but to a lesser extent than if the two subsystems are treated as separate entities while the remaining subsystems are treated as if nonexistent.

Downloaded from www.dbraulibrary.org.in

of group and cultural behavior comparable to the relatively well-worked-out theory of individual behavior provided by psychoanalysis.[208]

The method currently being used in the Spiegel-Kluckhohn approach to transactional analysis is the attempt to specify the chief sources of strain in the culture, the family, and the individual, and to relate each of these kinds of strain to each other, conceptually and procedurally. The procedure consists of comparing families along two dimensions. The first dimension is cultural and involves the comparison of Irish-American, Italian-American, and "old" American families, all at the working-class level. The second dimension is psychodynamic, and involves the comparison of families from these subcultural groups who have an emotionally disturbed child with a similar group of families matched on sociocultural background factors, differing in that no family member is clinically disturbed. The first group, the so-called "sick" families, are studied through the weekly psychotherapy of the mother, father, child, and other family members, and through participant observation of the family interaction in the home, at work, and at play—such as family celebrations. The second group, called "well" families, are observed only through weekly participant observation in a variety of contexts. Contact with all families is maintained for a 1- to 3-year period and is carried on by a multidisciplinary team consisting of psychiatrists, anthropologists, sociologists, clinical psychologists, and psychiatric social workers.

The method of locating the strain in the family employs three levels of systematic concept formation, for each of the three levels of observation. At the cultural level the theory of variation in cultural-value orientations[111, 112, 113] is used. For locating the strain in the interpersonal relations in the family, the concept of social role and role-conflict resolution[204, 207] is employed. At the intrapsychic level of individual process, the theory of psychodynamics derived from psychoanalysis is used. These theoretical concepts interlock with each other. It is considered that the cultural-value orientations influence the way each family member takes his social role as mother, father, or child, and thus in the way he perceives and responds to "reality." Conflicts in cultural values, either conscious or unconscious, are therefore associated with interpersonal conflicts in the way roles are to be adopted in the family. The overt and covert interpersonal role conflicts can then be correlated, for psychodynamic purposes, with the motivations, both conscious and unconscious, within each family member. This is because a social role always serves the purposes of either gratification or defense, whether manifested in action or in fantasy. At the same time, the social role is the basis upon which action within the family group—or any persistent group—is integrated. Thus the degree and kind of social role conflict at any one time indicates the amount and type of strain in cultural-value orientations, interpersonal relations, and intrapsychic processes.

Using this method of analysis, the investigators have found that there are two sources of strain in the cultural-value orientations. The first arises from lack of fit within the values of the original culture—Irish, Italian, or native American. The second grows out of the incongruity between the values of the original Irish or Italian culture and the dominant American values toward which these two groups are in transition. The amount of cultural "distance" which has to be traversed by these groups—and therefore the degree of shift in values—is quite extensive. Thus, the second source of strain is more significant for interpersonal conflict than the first, though both are important.

In comparing the differences between the "sick" and the "well" families with respect to these strains, the investigators have found several interesting but still tentative correlations. All families studied, both "sick" and "well," are characterized by quite definite role and value conflicts. However, the two sets of families can be distinguished from each other along several parameters. The "sick" families have attempted to change a broader spectrum of values and at a more rapid pace than have the "well" families. The result is that the parents experience intense intrapsychic conflict and potential or outright confusion in their mutual role relations. This produces a disequilibrium in their relations with each other, with their children, with relatives, and others.

For the most part, however, the actual value

Downloaded from www.uratmay.org.in

conflict is unrecognized or denied. The associated role conflicts are accordingly projected to either the marital partner or the children—occasionally to the grandparents. In their projected form they are both distorted and inaccessible to conflict resolution. For this reason, the children are socialized in terms of the role conflicts existing within and between the parents. The children are thus in a position where no role they take can solve the parents' role problem—they are "damned if they do and damned if they don't." Usually, one child is selected, for reasons connected with the residues of the parents' own sibling relationships, to bear the brunt of this pathological stabilization of the parents' role conflicts. The selection of a child for this purpose transforms the disequilibrium between the parents into a pathological equilibrium which is extremely difficult to break up. If the affected (disturbed) child improves under psychotherapy at a rate faster than the parents, another child is often selected as the stabilizer of the pathological equilibrium, and this child tends to develop symptoms.

In the "well" families, although value conflicts do exist, they are not so extensive as in the "sick" families. Only a few value orientations are subject to change, and the transition process occurs very slowly. Associated with this more orderly transition, the parental roles, which are the actual sites of value conflicts, are accessible to consciousness and thus to conflict resolution. There is little need to deal with them in projected form or through distorted symbolic communication. Therefore the socialization of the children takes place in a more consistent fashion. Value conflicts between the children and the parents are less the product of projection by the parents, more a matter of the children's having absorbed new values from their friends, in school, and in the community.

There is, however, no sharp dichotomy between the "sick" and "well" families. "Sick" families have some areas of adequate conflict resolution, and "well" families have some areas of pathological equilibrium. To put this in more ordinary language, all families are involved to some extent in neurotic interaction, and all family members in both groups show mixtures of neurotic and healthy personality mechanisms. Thus the population of families under investigation form a series in which the sickest families, showing the most extensive pathological equilibria, are at one end of a continuum, the healthiest, with the fewest irreconciled role conflicts, at the other.

Two practical considerations arise from this transactional approach. The technique of therapy, as well as the method of inquiry, is directed not toward the isolated individual but toward the disturbed person embedded in a pathological family and cultural setting. Both treatment and investigation require attention to extensiveness of the disturbance. The understanding of mental illness becomes a question not of locating an isolated factor, nor even an overdetermined causality, but of an interplay of homeostatic mechanisms which have gone astray. Treatment involves the restoration of homeostatic controls across cultural, social, psychological, and somatic boundaries. Treatment methods must therefore be rationally adapted not only to the individual and his somatic and psychological strains but to the strain within the family in its cultural setting. To accomplish this, the training of the therapist must be extended so that a broader range of significant transactions can be brought within his range of skills, to understand and alter.

## *The Outlook for the Future*

These new approaches inevitably bring forth questions concerning what new developments can be expected in the future. Judging by the past, movement is bound to be slow. Up to the present time, the area of the psychiatric patient and his family has shown more promise and less achievement than almost any other segment of psychiatric work. For more than thirty years the profession has been aware that family forces are both genetically and currently involved in the pathological state of the individual. This insight, however, has not led to effective formulations of the *nature* of the involvement, nor has it produced any but the most minor contributions to diagnosis, prognosis, and therapy. It is generally apparent, and poignantly so in this area, that theory exer-

Downloaded from www.dbraulibrary.org.in

cises a strong, though sometimes unavowed, influence over what is observed and how it is stated. Accordingly, effective progress must wait upon further advance in theory construction of the kind we have just been considering. Only when such theories have been well worked out in fine detail will students from the many disciplines concerned with this area be in a position to form and develop a scientific tradition.

CHAPTER 6

# THE COMMUNITY OF THE PSYCHIATRIC PATIENT

Edward Stainbrook

Downloaded from www.dbraulibrary.org.in

EVERY BEHAVIORAL EVENT occurs in a specifiable physical and social space. For an understanding of any specific human behavior, this basic observation dictates a comprehensive theory of human action which interrelates the process and dynamics of the structure-function systems conceptualizing the physical and natural world, the body, the personality, and society and culture. In medicine, particularly, the epidemiological analysis, the etiologic determination, and the therapeutic alteration of disease must be based upon an adequate evaluation for each diseased individual of this total context of disease determinants.

In an informal way, at least, medicine has always been aware of the necessity for a general theory of human behavior in a comprehensive conception of health and disease. Nevertheless, the formal medical science of the nineteenth century considered diseases almost entirely as occurrences within the physiological system. The major etiologic statements either asserted a constitutional diathesis predisposing to dysfunction or considered dysfunction to be initiated solely by changes in tissue or cellular structure and function. The long-retained idea of the "functional" psychoses is but one inheritance of the insistence that either structural or functional alterations in the body were the prime causes of disease.

We are all familiar, nonetheless, with at least the aphoristic acknowledgment by the medicine of the last century of the etiologic importance of individual and social behavior. Since the prevailing theories of personality and of society and culture were not aptly related to disease theory, however, very little scientific evidence accumulated about the interrelations of human action, social organization, culture, and biological processes.

## ¶ A General Theory of Behavior

The twentieth century, in its early decades, was characterized in medical science by the introduction of theories of personality struc-

ture and function and by increasing research in psychophysiology. More recently, the acceptance within medicine of the sciences of sociology and anthropology has provided the conceptual methods for making correlative statements in the theoretical languages of biology, personality, and society about events in the life process. It is true that these more recently emerging behavioral sciences are struggling separately with their own theoretical models and with the task of facilitating the translations of description and explanation from one theoretical system to the others. Moreover, these system-constructs, used to conceptualize the body, the person, and the human group, must be represented as open systems constantly transacting with each other. In this respect Talcott Parsons' statement about a general theory of action is applicable also to an open-system conception of physiology, personality, society, and culture. In his *The Social System*[20] Parsons writes, ". . . the concept of system as a guiding conceptual scheme is of the first importance as an organizing principle and guide to research. It may thus be said that the concept of a theory of systems is the most strategic tool for working toward the attainment of a system of theory."

The theoretical stance which currently enables us to make meaningful statements about the ecology of behavioral disorders is, then, the conception of reciprocally adjusting, transacting open systems conceptualized in structure-function and process terms. Depending upon the characteristics of their organization, upon their interrelating communication and other transactions, and upon their separate histories, these systems of the human group, the person, and the body are, at any behavioral moment, transmitting or absorbing excitation in relation to each other, affording or denying action for excitatory discharge and goal seeking, and, in general, facilitating or impeding mutually healthful adaptation. Hence, the adequate specification of any etiologic matrix of behavioral disease requires the description of any antecedent or consequent structure-function deficit in the body, its effect upon or its being affected by the organization, history, and functioning of the personality even as the personality, itself, affects and is affected by the human groups constituting its here-and-now relatedness.

The therapeutic plan of alteration then follows as the rational assessment of how and when to evoke ameliorative change in the body, in the person, and in the organization and culture of the significant human groups in which the person may activate a role. Obviously, different modalities of treatment are necessary for alteration of the different systems, although changes in one system—for example, changing the perceptual and conceptual assumptions of a person about the reality of another—may also alter the pathogenic stress arising from another system. Moreover, since every system has a history which has modified it, and this is particularly true of the personality, it is necessary to be quite clear about the extent to which any structure-function alteration of a system, either directly, or indirectly by modification of another system, can change the history of the system. Perhaps we shall someday be convinced, especially in relation to personality and character, whose differentiation and integration are based so largely on learning and experience, that the only rational way to alter the effect of history on the person is by means of more history, that is, of more learning and experience.

From the standpoint of epidemiology, our task is to specify the total field of disease determination. The processes by which the biological past is enregistered in genetic biochemical patterns which transmit communicative guidance to the structure-function development of the contemporary organism are, of course, of basic importance in relation to the subsequent vulnerability of the person to pathologic strain. Also crucial for our explanations are the history and dynamics of the internal reality with which the person encounters the constantly oncoming present. Indeed, from some points of view, this has been almost the total explanation of behavioral illness. Our concerns here, however, in epidemiology as well as in etiology and treatment, will be restricted largely to the influence of the person's social and cultural space upon psychiatric disease.

## The Sick Role

Any man may define himself as ill, any time, anywhere. Indeed, his dreams may dramatize him as sick without his conscious concurrence or even in spite of his open denial. But only an existing social process, organized for the recognition, acceptance, and treatment of illness and activated by one or more other role-specified individuals, can socialize the individual definition of illness and create a patient role and so keep the individual, even though ill, meaningfully related to society.

The self-perception of "not feeling well" is oftentimes a very vague and undifferentiated subjective experience. The individual who is feeling ill may not, on his part, know very clearly how to define his distress either physiologically or psychologically. He may, under certain circumstances, take a covert sick role in which he alone is involved. This may happen when the individual is actually physically alone but also may be the use of the self-given sick role as a psychological adaptation to his stress. Many such patients, before occupying an overt sick role, privately accept themselves as sick and use their self-validated sick role as a way of rationalizing inadequacies of self-realization, achievement, and participation.

Formerly, the petition to be ill was legitimized largely within the family, and the individual strain of illness was met, with or without formal medical help, by a temporary or even permanent reorganization within the family to support an effective sick role for one or more of the members. Today the modern hospital has become increasingly the social system in which the sick role as a meaningful mode of participation in society is lived out.

The transition of sick-role participation from family to hospital is, of course, very significant in all the chronic diseases, and any epidemiological assessment through historical times or across cultures of the prevalence of schizophrenia, for example, must take into account the historical social changes or the cultural differences in the familial relation to the sick role.

With particular reference to schizophrenia, one may see a whole family organized around the illness of one of its members, sometimes seeming to participate collectively in the covertly maintained sick role of the schizophrenic member. Conversely, as Benjamin Paul[21] has demonstrated in a Guatemalan family, the granting of the sick role by the family may result for the sick one in a restitution of existing psychological deprivation or a resolution of conflict. Somewhat similarly, in an extended family system or in families maintaining self-sufficient economic functions, the stabilizing absorption of the chronically sick member within the microsociety of the family may be achieved. Obviously, too, social pressures from the surrounding environment, either with direct reference to the sick person's behavior or related to other familial interactions, may overwhelmingly stress the family organization and so operate to change a covert sick role into an overt one.

As Hollingshead and Redlich[13] have shown, the social-class membership of the patient may also determine many of the medical transactions related to his illness and so influence the destiny of his sick role and, hence, of his disease.

There are "shameful" as well as "respectable" sick roles in our society. Severe psychiatric illness is the taking of a shameful sick role. In such a case, if the patient accepts his illness, he defeats his self-esteem. Hence, the admission of sickness may be avoided not because the patient does not want to be helped but because he does not want to be demeaned.

Because of the internalized culture of each individual, many of these determinants of sick-role recognition, acceptance, and outcome are operative for the prospective patient in that crucial period of time during which he may perceive himself as ill but in which he has not yet been socially defined as overtly sick. This is complicated further, in general medicine as well as in psychiatry, by considerations as to whether entrance into a hospital is to be part of the sick-role action. The psychiatric hospital has special cultural meanings, again at different positions of social-class perception.

Downloaded from www.dbraulibrary.org.in

In this latter respect it is highly desirable to have specific knowledge about how the incoming patient is already perceiving the hospital as a social world and what expectancies he brings concerning his own role in the hospital. As a first admission, he has probably never had a formal or informal training in how to be a psychiatric patient. Moreover, the assault of his uneasiness on his ego-functioning may prohibit or distort the realistic learning about what his role in the hospital society should be. In such a setting the distorted or fantasy-directed conception of himself, which he may play out actually as the most secure way of being in the hospital, may lead him, as Gregory Bateson has observed, into a game of madness which he may not be able to abandon.

For the psychiatric patient the hospital is the life space, the social group, and the institutional system in and through which he is going to act and interact, frequently for an indefinite time, as someone who is perceived as ill and as someone who may or who may not conceive himself as sick. In most instances the patient will have undergone some experience with others in his induction into the sick role before entering the hospital. He will always have had a history of his own intrapsychic dialectic about the perception and acceptance or rejection of his illness before any sharing with others. The patient, therefore, has already had a frequently complicated experience with the sick role before he is admitted to the hospital. Indeed, the hospital is a special institutionalization of the sick role which may enter into the destiny of the ill person at different phases and with different meanings in the course of his illness. Caudill,[2] particularly, and Stanton and Schwartz[26] have described the human behavior in the small society of the psychiatric hospital.

Schwartz[24] has succinctly conceptualized a simple framework for thinking about the patient's mode of role participation in the hospital society. He suggests that, for each patient, answers be derived from the following questions:

1. What mode of participation with others characterizes the patient's illness?
2. What is the hospital staff's response to the patient's pattern of participation?
3. What configuration of patient-staff interaction gets stabilized?
4. Does this configuration of transaction reinforce illness? If so, how can it be changed?
5. If altering intervention is attempted, how is it represented to the staff and how instituted?
6. What effects follow intervention?

In recapitulation, therefore, the sick role can be considered as a sociological construct and discussed as an abstraction from a specific human-action process. It is a patterning of potential individual behavior through time in relation to a social system of medical practices and a cultural system of medical theory and is essentially a set of special expectancies about the behavior of the role occupant and about the behavior of others toward him. As indicated elsewhere, Parsons[20] has described some essential aspects of the institutionalized expectation system relative to the sick role. Exemption from normal social role responsibilities, exemption from responsibility for being helpless, assumption of the undesirability of being sick and acceptance of the obligation to want to be well, and the obligation to seek and to cooperate with technically competent help are the aspects of the sick role underlined by Parsons.

In addition to these positive and negative sanctions relating to the social conditions of being sick, there are other important aspects of the sick role. Of primary importance for the problem of conflict over the acceptance of the sick role is the perception of the social meaning of such a role. This varies cross-culturally as well as across social classes and relatively to different diseases or manifestations of illness. Since social sanction of the sick role in the formal sense depends upon the recognition by the medical institutions in the society that he who is stating his illness in terms of his symptoms has, in fact, a disease which merits a sick role, the nosology of the medical culture and the associated sentiments and values will be one of the fundamental influences in the decision to allow or to deny a legitimate sick role to the suppliant.

Downloaded from www.dbraulibrary.org.in

Hence, the ideological aspects of the medical culture itself may determine the social perception of the meaning of illness. If, for example, a statement made by a prospective patient about his unhappiness is refused by a physician as a legitimate expression of a recognizable illness, the person who comes to a physician with this symptom will be denied a sick role and an entrance into the medical helping process. Such a person may be urged to become a religious penitent, or he may be told categorically that he is not ill. Whether the encountered physician allows or denies the petitioning patient a sick role depends partly upon the personality characteristics and educational sophistication and experience of the physician and partly upon the prevailing theory of disease in his medical culture. In contemporary American medicine it is becoming more usual for the physician to accept some motivational unrest as the explanation for the patient's coming for help, even when the patient's statement of symptoms does not seem to point to primary disease in the physiological system. The increased scientific knowledge of human behavior also now available to the physician enforces the acceptance of both disease and uneasiness as legitimate concerns of medical-practice processes and institutions.

Nevertheless, it is common knowledge that the sick-role legitimation of an individual's expression of his uneasiness may depend upon what his statement of his symptoms is, to whom he makes his symptom presentation, and in what social context he asserts his illness. As an example, the medical culture of a military society may deny a recognition of sickness for many evidences of behavioral and physiological adaptations to psychological stress. In World War II the Germans and Russians apparently made the sick role much less easily available for battle-stress reactions than did the American and British armies. Hence, if the incidence of "war neurosis" is comparatively assessed among these various armies, it must be remembered that the formal measure of disease incidence is not the counting of how many men were uneasy, anxious, depressed, and physiologically strained, but of how many were accepted as sick by the medical culture in which they found themselves.

In this sense, in World War II the American and British medical military culture, by broadening the perception of what statements of uneasiness were acceptable petitions for the sick role, effectively used action in the social system itself to absorb individual stress and to support individual strength.

So, too, not only in the military culture but elsewhere, there may be confusion about how to control individual behavior when the illness-legitimizing system is not clear about the meaning of any deviant behavior. As Parsons suggests, we seem more and more, in our American society, to be using the sick role as a method of control for criminal and delinquent behavior. We cannot discuss the significance of this trend for the social system of the psychiatric hospital. Here, we want only to point out the conflict that obtains within the hospital in deciding whether certain individual behavior should be perceived as an illness or as behavior which ought to be punished or, at least, condemned. Illustrative of this confusion in the medical culture is a recent letter of inquiry in the *British Medical Journal* asking how to distinguish an anxiety neurosis from "lack of moral fibre."

These illustrations are sufficient to indicate that the perception of an illness by the members of the medical system of a society is based, like most perception, upon a set of assumptions about what an illness should be, and that these assumptions have considerable individual, social, and cultural variability. Nevertheless, it is largely the doctors of a society who mediate the use of the sick role as a pattern of action in the social system.

The assessment of the sociology of the sick role is important also in relation to any epidemiological studies of behavioral disease. For example, Halliday,[11] leaning heavily on the writings of Donnison[5] on civilization and disease, states that in the period from 1900 to 1939 in Great Britain there occurred a progressive increase in psychoneurotic and psychosomatic disease. This may be an accurate observation, but it is also an acceptable hy-

Downloaded from www.libtool.com.cn

pothesis to postulate that such an increase may have been conditioned to an undetermined extent by changes in the medical culture relative to the decisions about what symptoms merit a sick role and under what diagnostic title.

Socially and culturally related changes in medical theory and practice therefore condition the frequency and characteristics of sick-role use, and hence of disease incidence. The sick-role values and action patterns are discoverable and describable aspects of the social system. By giving our attention to the sick-role practices of a society as well as to the manifestations of disease in the physiological and personality systems, we may avoid some of the ambiguities and nebulosity now involved in discussions about the cultural relativity of the abnormality or deviance of human behavior.

## ¶ Social Class and Psychiatric Illness

In so far as the past is a partial determinant of the present, an individual is his internalized and integrated past functioning in the here and now. Social institutions and culture, or, better, their behaviorally enregistered effects, are part of the person's internalized reality as well as a large part of the significant current external reality of the individual. By means of the integrating, remembering, "impressed" individual, the childhood and later society encounters the society of the present adulthood.

Social and cultural stress may arise, consequently, in several different ways. The life styles, values, and positively and negatively sanctioned action patterns learned in childhood may, as individuals mature, come into conflict with the desirable, rewarded, or necessary behavior of the adult society. This can occur either because the childhood society was not sufficiently adequate preparation for adulthood, because an adequate developmental experience of transition from childhood to adult society was not provided, or because, as in our American middle- and upper-class society of the last few decades, we innovated different child-rearing techniques and values into the society of childhood without effecting a corresponding change in the goals, values, and socially rewarded behavior of the adult society. This past-present culture conflict can also occur because rapid change in the adult society outruns the change in childhood preparation. So, too, because of social and also geographical mobility, culturally induced stress arises as a result of the cross-class, cross-regional, or cross-national acculturation process.

Moreover, with more particular reference to specific psychopathology, the social class and cultural determination of the developmental experiences of childhood presumptively differentially influence the encounter with the life tasks of growth and development by conditioning or limiting the ability of the human group of the family to do its mothering, fathering, and other child-raising transactions. Indeed, from at least birth onward, the influence of society and culture, particularized for each child's social life space, is impressed both dynamically and topically upon almost every learned action of the individual. Even the "unlearned" functions of physiology and biochemistry learn through symbolic and other associative conditioning to participate in interpersonal and psychosocial processes.

Hollingshead and Redlich[13] have made some provocative comments with special relevance to the possible influence of social class upon the basic socialization experience of the first five or six years of life in becoming a more or less well-delineated individual in the family group, with an awareness and a healthy acceptance of self-images, familial roles, personal interrelations, and functions. They suggest that schizophrenia seems to be more prevalent in low-class (Class IV and V) families. One part of the etiologic matrix of schizophrenia is probably a "loveless infancy," which for any child, whether or not he is also considered to be genetically vulnerable to schizophrenia, provides an immediate postnatal environment inimical to learning how to master progressively an adaptive and satisfactory state of being in the world. Such an experience in infancy is seen by them as more likely to occur

Download from www.pdfbooksfree.pk

in a Class V family than in an upper-class, or Class II, family.

Hollingshead and Redlich also state that defective super-ego structure and dynamics are more prominent in the low classes and point out that 95 per cent of persons in state prisons are from Classes IV and V. In psychotherapy the lower-class patient is more apt to act out. So, also, the lower-class adolescents miss the extended adolescence of the middle and upper classes, with their sublimational and long transitional "rites of passage," and so remain more sexual, aggressive, and dependent.

These authors also remark on the greater ego-weakness of Class V persons relative to the upper-class individuals. On the other hand, obsessive-compulsive characters are more frequent in the higher classes, and oedipal conflicts appear to be particularly intense in Class III.

Other important social and cultural factors in the assessment of a complete etiology of behaviorally manifest illness reside in the interrelations between organizational and institutional structure and function, values, and the capacity of the individual to react adequately to stress. Anxiety, resentment, lowered self-esteem and personal meaning, thwarted cognitive and emotional development, enforced passivity, and the threat of helplessness may be induced in persons partly because of the ways in which our current industrialized mass society and our rapid and somewhat chaotic urbanization function. Fragmentation of the productive task, the decrease of meaningful participation in organizational work, the failure to provide some autonomy in work experience, and the inadequacy of communicative involvement for relatively undistorted reality testing of what is being done, thought, and felt within the total organization, the dependency on secondary, remote controls for the moderation of community behavior, the anonymous and therefore casual and uncommitted relationship to neighborhood and community—these are some of the factors in the community and organizational context of individual behavior that induce needs which then may demand satisfaction or relief within the family group. The family may strain overmuch in meeting these demands and so disorganize, leaving the individual members without the stress-reducing and stress-absorbing support of the familial group.

The "tempo of life," so often referred to as a journalistic description of social and cultural stress, probably does not play too significant a role in the creation of uneasy tension. A more telling evaluation of social stress is to consider the need-induction activities and processes of a society relative to the accessibility and the availability of action patterns and objects for the satisfaction of the induced needs. In this respect, for example, our middle-class-oriented educational system may be inducing needs and goals in low-class children for which the community, during adolescence particularly, is not sufficiently differentiated to provide for the low-class child accessible and meaningfully significant action and goals for adequate need satisfaction.

## ¶ Culture and Psychopathology

The logical extension from a social class and social and institutional organizational analysis of possible contributions to behavioral illness is, of course, to a consideration of the relation of different cultures to the problems of psychological disorders. Today, we are just at the beginning of a comparative cultural psychiatry. The assessment of the cultural variability of psychiatric illness as to etiology, incidence, detection, ideational content, action dynamics, and treatment is a formidably complicated problem.

At a purely descriptive level certain culturally determined differences seem reasonably clear. Suicide, depressive reactions, sexual deviation, hysterical dissociative states and sensory and motor dysfunction, and obsessive and compulsive character and its decompensated obsessive-compulsive neurosis are distributed differentially across cultures. There is considerable evidence to indicate that psychophysiological and psychosomatic illness are related to the social and cultural context—particularly to various life styles and their associated values about goals and actions. Ruesch,[23] among

Downloaded from www.dbraulibrary.org.in

others, has also suggested the possible relations between social class and psychophysiological adaptive failure.

The schizophrenic reactions, while observable in every society and culture, nevertheless are demonstrably influenced, topically and dynamically, by the culture and the organization of their particular society. A contemporary summation of the available knowledge about society, culture, and psychopathology is made by Linton[17] and Opler.[18]

A change of residence and social participation for an individual as he moves from one country to another, after having learned more or less adequately how to behave as a member of an original society of cultural orientation, may induce conflict, deprivation, and general cognitive and evaluative error and uncertainty in his perceptual assumptions about his new social and cultural world. "Acculturation stress" may thus be considered in terms of conflicting goals, values, and action. The determinants of psychopathology arising from acculturation, or related to it, however, are many.

The motivation for migration may itself have arisen as an attempted adaptation to painful stress, uneasiness, and inadequacy. Some of those who migrate on their own initiative may already be psychiatrically ill or highly vulnerable to social and other stress. In an assessment of the history of those individuals who suffer an "acute alien paranoid reaction" during usually their first year in a new culture, an interestingly significant percentage of this group are found to have had a previous psychotic experience in their native countries.

Recent studies have pointed to the higher incidence, relative to native populations, of first state hospital admissions of recent migrants, even of those who have moved from one state to another within this country. It also seems likely that the rate is highest among the most recent migrants, thus giving support to the proposition that for some people who get into the psychiatric hospital, the migratory moving itself is intimately associated with the illness.

Since a basic requisite for successful interaction with others is an adequate communicative evaluation of reality, the presence of linguistic difficulty in communication is a significant factor in the development of psychopathology. Hence, the "alien paranoid reaction," which is an acute schizophrenic reaction related to acculturation experience, seems to be associated positively, in terms of frequency beyond expectation, with both isolation from people as well as with diminution and distortion of informational and transactional responses from others because of an inability to understand and to use the proper linguistic and symbolic interaction. Since an individual's social and cultural articulation depends so much on role knowledge and confident expectation about role reciprocity and complementarity, inadequacy in language behavior inevitably means deviant general behavior. Hence, part of a program of preventive psychiatry would be an insistence on providing, for cross-cultural migrants, an urgent and intensive learning experience with the language of their new cultural group.

The linking of the character and personality of individuals to a national character attributed to their whole culturally visible society has a long history in formal writing as well as in folk talk. The concept of national character has, however, rather limited sociological value. From the standpoint of culture and its relation to individual behavior, we would be more concerned about how the various culturally specified life styles for different occupational, sexual, and age-referred roles rewarded or punished various character traits and, most particularly, in what ways the mothering and fathering behavior and the associated child-rearing values and lore influenced the learning of early character formations.

Certain individual adaptive responses, such as repression, reaction-formation, or denial, to internal and internalized need demands and to social and physical reality stimuli may be culturally reinforced. The "hysterical character" of the nineteenth century related to Western European and American sanctions against sexual fantasy, feeling, and action may be one illustration of this. How much has been learned of the formal logic of a society and

Downloaded from www.dbraulibrary.org.in

how much cognitive development has occurred in an individual may also determine the ease with which repression can be supported and the readiness with which magic or alogical thinking is used, particularly in the failure to distinguish between "having a thought" and the anxiety-supported feeling of having the thought actually happen.

Some aspects of Japanese character which Westerners, at least, perceive as overpoliteness masking an underlying hostility are undoubtedly developed by general social values and action patterns transmitted as taught and learned culture in child-raising and general education. Similarly, cultural influences on character formation are determined by the extent to which a culture emphasizes fantasy as gratifying behavior for need satisfaction rather than as it permits direct, expressive action or, indeed, even creates negative sanctions about fantasy tension reduction as well. ("As a man thinketh in his heart, so is he.") According to Opler, for example, Irish-American psychiatric patients are very apt to elaborate their needs in fantasy, whereas the Italian-American patient may more directly and expressively act out his tensions. In Brazilian society the behavioral observer is impressed by the common social reinforcement of the individual denial of the emotional meaning of accidents and other external physical violence and threat.

Perverted sexual behavior and sexual deviance in general are differentially distributed across social classes within the same society and within cultures. Some of these differences also depend upon the variability in different societies about what behavior is sex-typed and associated with the general social roles of masculinity and femininity. In our own society it is frequently assumed that deviation from the sexual-role behavior of an earlier historical period means a demasculinization, and hence feminization, of the contemporary male. Whatever the present and presumably psychodynamically motivated value judgment of these changes may be, it must be held in mind that social changes in the acts of behavior to be learned as part of the general masculine and feminine role behavior of the society make much of human maleness and femaleness a culturally relative matter.

The incidence of the various addictions to food and to more specific pharmacodynamic substances such as alcohol and drugs is significantly conditioned by social and cultural variables. This is so not only in relation to the factors determining preferred modes of tension reduction or contributing to conflict or deprivation but also with reference to the availability and distribution of the social action patterns of drinking and drug using and to the cultural values associated with such behavior.

In a very definite sense, the addictions, in general, may be considered to be metabolic diseases. In diseases of metabolism, the etiologic precipitants may occur in one, or some pattern, of the four functions of intake, anabolism, catabolism, and excretion. Obesity, alcoholism, and drug addiction are initiated by deviant intake behavior of ultimately biochemical substances which overstress physiological mastery and lead to sometimes reversible and sometimes irreversible structure-function bodily changes.

Facile typological concepts do not offer any more than first approximations to an understanding of the subtle interrelations between pharmacodynamic effects, individual needs, psychodynamic gratification aims and goals, and cultural values about addicting substances. The psychiatry of the late nineteenth century began to point to personality differences between the morphine user and the alcoholic, an observation preceding the current folk statement that an alcoholic gets drunk, goes home, and beats up his wife, whereas a "dopey" takes a "shot," goes home, and is beaten up by his wife. The question was then debated as to how much this was a self-selection of drug effects based on individual psychodynamic operations, either autoplastic or alloplastic, and how much cultural preferences were involved. At the present time many Oriental and Middle East countries have negative sanctions against alcohol and permit social usage of the *Cannabis* derivatives and of other drugs. It is thinkable, of course, that the cultural sanctions arose as projections of the individual

Downloaded from www.uratrai.org.in

dynamics, which are, in turn of course, related to internalized cultural values and perceptions.

The intake behavior initiating and sustaining addictions of various degrees and kinds is highly dependent on socially induced needs such as, for example, the peer-group demands in adolescence. Narcotic addiction has, within the last decade, become somewhat of an endemic among adolescents in urban regions in this country. This has occurred largely because drug using became a part of the approved peer-group culture. The intensity of the pleasure-giving experience is also dependent not only on group induction but also on the group-supported expectations of what the drug effect will be. Hence, whether or not the first intake of an addicting substance will give enough of a pleasurable effect to lead to subsequent repetition and so to a developing addiction depends on the total context of the intake act.

As has been suggested, the schizophrenic reactions are universally occurring behavioral illnesses. This fact does not necessarily support an endogenous or genetic-disease concept of their character. It is also true that because of psychological regression, or of neurophysiological de-differentiation, or of both, schizophrenic patients, seen cross-culturally, look more alike in their basic behavior than do the nonregressed, adequately socialized individuals of various cultures, just as the world's children seem more commonly akin and less specifically culturally differentiated from each other.

No adequate studies give us any evidence of high truth value that the subtypes of schizophrenia are referable to specifiable social space. It is more likely that we shall find that the catatonic and, particularly, the hebephrenic reactions are more related to the vicissitudes of the helping process and to the sick-role experience than to an essentially separate etiology of the schizophrenic reaction forms.

It is not yet clear how valuable the nineteenth-century conception of primary and secondary symptoms may be in an assessment of cultural variation in schizophrenic symptom expression. Cross-culturally, one of the problems of disease detection and acceptance of an ego psychosis such as schizophrenia resides in the extent to which each culture has developed secondary process thinking, in Freud's sense, and so has created in its general enculturation of thinking behavior and cognitive differentiation a generally obvious and commonly detectable difference between alogical and logical thought; that is, the closer the ordinary logic of a culture is to magical thinking, the less is there a tendency to consider any person to be schizophrenic on the basis of thinking disturbances alone. In Brazilian rural society, for example, it was normally considered possible to talk with the spirits or with God, even though, probably, only schizophrenic patients did so in a hallucinatory way. A significant and presumably culturally determined aspect of schizophrenic behavior in Brazilian low-class society, which has also been documented by others as occurring in other somewhat similar societies, is the relative absence of severe avoidance-withdrawal behavior from human beings. As a hypothesis, this may be related to the characteristics of the extended family and to the giving and acceptance of dependency transactions with minimal guilt and anxiety. It also seemed obvious that the "secularization" of the paranoid distortions of the external reality paralleled an increasing social status and social-class position. Hence, feelings of helplessness and inadequacy, particularly in males, seemed in the low class to be comprised dynamically either by projecting the accusation, "You keep me helpless and passive," to the spiritual universe with the resultant hostility and persecution, or by the megalomanic restitution of identifying with the omnipotent deities. The middle- and upper-class males seemed to homosexualize more openly their passive and dependent needs in a disclaiming projection to other men, and their delusional restitutions of personal power and esteem used powerful contemporary human figures.

It is obvious that this condensed review of some of the facets of what is only a beginning social psychiatry points to the urgent need for increasing research in the development of new knowledge about the etiological matrices of

Downloaded from www.dbraulibrary.org.in

behavioral disease and for continuing validation of the impressive body of hypotheses and tentative information we now have. It seems obvious also that the formulation of a comprehensive theory of human behavior, with separate but inwardly consistent scientific models of body, personality, society, and culture, must be the basic and continuing task of psychiatry. Whatever diagnostic and therapeutic hope the contemporary exciting new developments in molecular biology alone may bring, psychiatry will always have to deal with man as individual and social man.

CHAPTER 7

# IMPORTANT STATISTICAL DATA ABOUT MENTAL ILLNESS*

Benjamin Malzberg

Downloaded from www.dbraulibrary.org.in

THE FIRST SERIOUS ATTEMPT at a census of the mentally ill in the United States was made in 1850. This was in connection with the general census of the population. Mental patients were counted not only in mental hospitals but also in their homes. Similar counts were made in 1860 and 1870. According to these censuses, there were 15,610 patients with mental disease in 1850, 24,042 in 1860, and 37,432 in 1870. The number per 100,000 population increased from 67.3 in 1850 to 97.1 in 1870. All of these totals were considered to be seriously defective, however. The first census to which reliability was attached was that of 1880, according to which there were 40,942 patients with mental disease in hospitals. In addition, through the cooperation of physicians, a total of 51,017 patients were found outside of hospitals. This made a total of 91,959, representing 183.3 per 100,000 population. In 1890 those enumerated in institutions increased to 74,028. Owing to the fact that physicians had not been asked to cooperate, as in the previous census, the total of those counted outside the hospitals fell to 32,457, giving a grand total of 106,485. Whereas the patients in hospitals showed an increased ratio to population, those outside of hospitals showed a marked decrease. Because of these serious errors in counting mental patients outside of hospitals, the Bureau of the Census finally abandoned the effort. Beginning with 1904, the census of such patients has been limited to those in hospitals for the treatment of mental disorders.

According to the census of 1904, there were

* This investigation was supported by a research grant from the National Institute of Mental Health, of the National Institutes of Health, United States Public Health Service.

150,151 patients in hospitals, more than twice the corresponding total in 1890. In fact, there were more patients in hospitals in 1904 than were counted both within and without hospitals in either of the preceding censuses. The hospital population provided a rate of 183.6 per 100,000 population in 1904, compared with *total* rates of 170.0 in 1890 and 183.3 in 1880. The next census, taken in 1910, showed a total of 187,791 in hospitals, an increase of 37,640 in 6 years. The rate per 100,000 population increased to 204.2 In 1923, 13 years later, the census showed a population of 267,617 in mental hospitals, or a rate of 245.0 per 100,000 population. Thus, between the first census in 1850, which included patients both within and without hospitals, and the census of 1923, which included only patients in hospitals, the rate per 100,000 population increased almost fourfold. (These data are summarized in *Patients in Hospitals for Mental Disease, 1923*.[13, p. 11])

In 1926 the Bureau of the Census began to issue annual statistics. Since 1947 they have been prepared by the National Institute of Mental Health. These reports indicate a steady upward trend. The total of such patients on the books of state hospitals reached 574,881 in 1950, or a rate of 381.4 per 100,000 population. (Computed from data in *Patients in Mental Institutions, 1950 and 1951*.[14, p. 36])

Before examining the significance of this trend, we may consider the distribution of mental disease throughout the United States, as shown in 1950.[14, pp. 36-38] Data for this large group are available by census divisions and states. For the country as a whole, the state hospital population represented a rate of 381.4 per 100,000 population. These rates varied from a minimum of 253.1 in the East South Central States to a maximum of 513.4 in New England. The former division includes Kentucky, Tennessee, Alabama, and Mississippi. New England includes Maine, New Hampshire, Vermont, Massachusetts, Rhode Island, and Connecticut. Almost as high as New England was the rate of 471.1 for the Middle Atlantic States, which include New York, New Jersey, and Pennsylvania. Next in order was the Pacific division with a rate of 371.0. This region includes Washington, Oregon, and California.[14, pp. 36-38]

Among the individual states, the rates varied from a minimum of 200.1 in New Mexico to a maximum of 649.7 in New York. New Hampshire, Massachusetts, Connecticut, Illinois, and Delaware had rates well above the average for the country. Most of the low rates occurred in the South.[14, pp. 36-38]

Before concluding from these data that there is less mental disease in the South than in the Northeast and the Pacific regions, we must consider the following: In the first place, the South, as a result of its higher birth rate, has a greater part of its population at the younger age levels. Since the incidence of mental disease is lowest among the young, the rate for the general population is correspondingly low. In the next place, it is known that hospital facilities are not as prevalent in the South as in the North; hence, the admission rate tends to be lower. This is especially true with respect to Negroes, who constitute so large a proportion of the population of these states. Therefore, the total over-all rate is unduly low. On the other hand, rates of mental disease are highest in industrialized, urban areas, such as predominate in the North. The Pacific Coast has problems peculiar to itself, largely because of the phenomenon of migration. We may conclude then, that the rates are lowest in the South, but that they are spuriously low.

We may return, now, to the significance of the data with respect to the increase over the years in the number of mental patients. The interpretation of almost all those inclined toward the eugenic point of view is that there has been a great relative increase in the prevalence of mental disease in the United States. Opponents of this view maintain that the increase is due primarily to an increase of hospital facilities, which made it possible to admit more patients. For the country as a whole, there is undoubtedly much truth in this statement. Broadly speaking, however, both groups overlook the very simple fact that the population of the hospitals must increase, even if the rate of mental disease were constant. Until recently, admissions always exceeded discharges and deaths during a year. In 1950, for example,

Downloaded from www.dbraulibrary.org.in

there were 141,493 admissions (excluding transfers) to the state hospitals in the United States, but only 125,798 separations (exclusive of transfers). Thus the admissions exceeded the separations by 15,695, increasing the hospital population by that amount. Obviously, therefore, we cannot conclude, from the statistics of resident patients alone, whether or not there has been an increase in mental disease.

What is desired is a count of new cases of mental disease in a stated period, usually a year. However, it is impossible to submit an entire population to psychiatric scrutiny. As a practical matter, it is necessary to count new patients in those places where they can be readily identified, and we must therefore return to a consideration of patients admitted to mental hospitals. We may consider the annual number of new admissions to hospitals for mental disease, or, as they are usually called, "first admissions."

Such data were first reported for the United States for 1922. In that year there were 71,676 first admissions to all hospitals for mental disease, or a rate of 68.2 per 100,000 population. Since 1926, these statistics have been presented annually. We may select certain of these years to show the increase in first admissions. In 1935 there were 101,462 first admissions, or a rate of 79.7 per 100,000 population. In 1941 there were 107,861 first admissions, or a rate of 82.0. In 1950 there were 151,074 first admissions, or a rate of 100.6. Thus, between 1922 and 1950, the rate advanced from 68.2 to 100.6 per 100,000 population, an increase of 48 per cent.[14, p. 22]

Can we infer from the increase in annual rates of first admissions that there has been a corresponding growth in the incidence of mental disease? Were the conditions which determine admission to a mental hospital, especially to a state hospital, constant, we should have to conclude that there has been a relative increase in the incidence of mental disease, but we cannot do this, for the reason that the conditions surrounding admissions have not remained constant throughout the country. New hospitals have been constructed, and new standards of treatment have been introduced throughout the United States. Part of the increase in first admissions is, therefore, a response to the improvement in hospitals. Consequently, to an unknown degree, the rates of first admissions to all mental hospitals in the United States indicate, in part, a possible increase in the incidence of mental disease but also an increase in hospital facilities.

We may overcome this difficulty by considering the history of admissions to the New York civil state hospitals. Let us bear in mind that what we desire is a body of data with respect to new cases of mental disease, but, since such information is not available, we use as an approximation the number of first admissions to all hospitals for mental disease. This number is less than the true total of new cases, because an unknown number of mental cases never receive medical attention and are therefore not discovered, and another unknown total is treated by private practitioners, who are not even necessarily psychiatrists. We must therefore assume that the ratio of first admissions to the unknown total of new cases arising in the state during the same period is sufficiently constant for practical purposes. If this is not the case, if the ratio has changed from year to year, with an approach to unity in more recent years, then any upward trend in rates of first admissions may have resulted from a more accurate count rather than from an increase in the number of patients with mental disease. Beginning in 1843, and coming to fruition in 1890, New York State adopted a system of state care, as a result of which the total of new cases gradually adjusted itself to the parent population of such cases, and justified the assumption that there has been a stabilization in their ratio.[5]

Data with respect to first admissions to the New York civil state hospitals are available since 1910. They are summarized in Table 1, where average annual rates per 100,000 population are shown from 1910 to 1950. Except for decreased rates during the two World Wars, there has been a steady upward trend in the rate of first admissions.

When a trend such as the preceding could not be explained by extraneous social factors, the ground of argument was shifted. Now the upward trend was declared spurious, on the

| 1930 | 78.9 | 64.9 | 71.9 |
| 1932 | 90.8 | 74.2 | 82.4 |
| 1934 | 99.0 | 82.9 | 91.0 |
| 1936 | 102.9 | 88.3 | 95.6 |
| 1938 | 107.8 | 92.3 | 100.0 |
| 1940 | 108.2 | 95.5 | 101.8 |
| 1942 | 110.9 | 97.2 | 103.8 |
| 1944 | 102.8 | 102.7 | 102.7 |
| 1946 | 100.7 | 103.4 | 102.1 |
| 1948 | 104.4 | 101.4 | 102.9 |
| 1950 | 109.9 | 102.4 | 106.0 |

* The rates are based upon the average number of first admissions during 3 years; that is, the rate for 1910 is the average for 1909–1911, inclusive.

basis that the general population has been aging for several decades, and, as a larger proportion of the population reached old age, the rate of first admissions with mental disease increased. It is, of course, true that the general population has aged, though not to the extent that is often implied. It is also true that there has been a remarkable increase among first admissions of those aged 60 or over. But it does not follow that the rate of increase of the aged has been the same among the mental patients as in the general population. To test this, we may compare the average annual rates of first admissions to all hospitals for mental disease in New York State during four periods —namely 1919–1921, 1929–1931, 1939–1941, and 1949–1951. In making these comparisons, we may ask the following question: What would have been annual rates of first admissions in 1930, 1940, and 1950 if, in these years, the general population had had the same sex and age proportions as in 1920. In the latter year the rate of first admissions was 109.1 per 100,000 population. In 1930 the corresponding rate would have been 118.2, in 1940 it would have been 136.7, and in 1950, 150.0.[10]* Thus in 30 years, the rate of first admissions, constant for age and sex, increased by 37 per cent. The evidence appears conclusive, therefore, that there has geen a genuine increase in the rate of first admissions, and it may be inferred further that there has been a corresponding increase in the incidence of mental disease.

Thus far we have considered mental diseases in their most general aspects—the number of such patients, their rates of admission, and the question of their relative increase. We shall consider next certain important characteristics such as the distribution according to types of mental disorder, the age distribution of new admissions, and certain comparisons with respect to environment and race.

We may start with the distribution of mental disorders. In 1950 the data were available for 100,223 first admissions to state hospitals for mental disease in the United States. Of this total 71.7 per cent were included in eight groups of psychoses, as follows: dementia praecox, 23,637, or 23.6 per cent of the total; psychoses with cerebral arteriosclerosis, 15,187, or 15.2 per cent; senile psychoses, 10,822, or 10.8 per cent; manic-depressive psychoses, 5,240, or 5.2 per cent; general paresis, 3,000, or 3.0 per cent; psychoneuroses, 4,653, or 4.6 per cent; involutional psychoses, 4,863, or 4.9 per cent; and alcoholic psychoses, 4,485, or 4.4 per cent. A group even larger than many of these consisted of 14,691, or 14.7 per cent, who were admitted without a psychosis, but who were diagnosed as cases of epilepsy, mental deficiency, alcoholism, etc.[14, pp. 77–89]

Diagnosis, even in the purely physical disorders, and with the aid of laboratory procedures, is not yet an exact science. Therefore we cannot expect a higher degree of accuracy in connection with mental diseases. Standards of diagnosis may differ from state to state, and therefore the data for the country as a whole

* This study includes an extended analysis of the question of an increase in mental disease.

Downloaded from www.libraryofpsychiatry.org.in

are probably subject in some degree to the error of mixed categories.

For this reason we shall consider New York State, where statistical data have been gathered in a standardized manner for many years. Diagnoses are more uniform from hospital to hospital, owing to the teaching influences of the New York State Psychiatric Institute. Furthermore, the data are influenced only slightly by the inclusion of a group without psychosis. In New York this group represents about 1 per cent of the admissions to the state hospitals, as compared with 14.7 per cent for the whole country.

During 1950, there were 16,012 first admissions to the New York civil state hospitals. Of this total, 13,440, or 83.9 per cent, were included in 7 groups. The largest was dementia praecox, which included 4,658, or 29.1 per cent. The others were as follows: cerebral arteriosclerosis, 3,379, or 21.1 per cent; senile psychoses, 2,439, or 15.2 per cent; involutional disorders, 1,093, or 6.8 per cent; alcoholic psychoses, 1,078, or 6.7 per cent; general paresis, 420, or 2.6 per cent; and manic-depressive psychoses, 373, or 2.3 per cent.

Compared with the country as a whole, we find higher percentages of first admissions with dementia praecox, psychoses with cerebral arteriosclerosis, and senile psychoses. Involutional disorders also appeared to be more prevalent in New York. On the other hand, manic-depressive psychoses represented only 2.3 per cent of the first admissions in New York State as against 5.2 for the country as a whole.

## ¶ Psychoses with Cerebral Arteriosclerosis

The most interesting annual series of first admissions, from a statistical viewpoint, is that presented by the group of psychoses with cerebral arteriosclerosis. The records in New York State began in 1912. During that year there were 166 such first admissions. They represented 2.9 per cent of all first admissions. They increased year by year, and passed 1,000 in 1928. They passed 2,000 in 1935. In 1940 the total was 2,581, and in 1950 it reached 3,379. With respect to all first admissions, this group increased from 2.9 per cent in 1912 to over 20 per cent in 1950. Finally, the rate of first admissions increased year by year from an average annual rate of 2.4 per 100,000 population in 1913 to 22.9 in 1950.

TABLE 2. **First Admissions with Psychoses with Cerebral Arteriosclerosis to New York Civil State Hospitals, 1913–1950, per 100,000 Population***

| FISCAL YEAR | MALES | FEMALES | TOTAL |
|---|---|---|---|
| *1913* | *2.4* | *1.9* | *2.2* |
| *1914* | *2.8* | *2.0* | *2.4* |
| *1916* | *4.4* | *2.3* | *3.4* |
| *1918* | *4.6* | *3.3* | *3.9* |
| *1920* | *5.5* | *3.8* | *4.7* |
| *1922* | *6.6* | *4.3* | *5.4* |
| *1924* | *7.1* | *5.1* | *6.1* |
| *1926* | *8.7* | *6.4* | *7.6* |
| *1928* | *10.1* | *7.4* | *8.7* |
| *1930* | *11.5* | *8.7* | *10.1* |
| *1932* | *15.1* | *11.2* | *13.1* |
| *1934* | *17.8* | *14.2* | *16.0* |
| *1936* | *19.3* | *16.1* | *17.7* |
| *1938* | *20.1* | *16.9* | *18.5* |
| *1940* | *21.8* | *18.0* | *19.9* |
| *1942* | *25.2* | *21.0* | *23.1* |
| *1944* | *25.1* | *22.8* | *23.9* |
| *1946* | *22.7* | *21.3* | *22.0* |
| *1948* | *22.7* | *19.3* | *21.0* |
| *1950* | *24.6* | *20.4* | *22.4* |

* The rates are based upon the average annual number of first admissions during 3 years; that is, the rate for 1913 is the average for 1912–1914, inclusive.

There is no doubt, therefore, that there has been an increase in these disorders, as measured by rates of first admissions up to 1950. However, there have been objections that the upward trend is merely a result of the aging of the population. The force of this argument may be determined by studying the average annual rates of first admissions with these psychoses in 1920, 1930, 1940, and 1950. As psychoses with cerebral arteriosclerosis are more prevalent among males than females, it is necessary to consider changes not only in age but in sex proportions. Therefore the question

Downloaded from www.sibraulibrary.org.in

was asked: What would have been the rates of first admissions with psychoses with cerebral arteriosclerosis in 1930, 1940, and 1950 if the general population of New York State had had the same age and sex proportions as in 1920?

In 1920 the rate of first admissions was 21.3 per 100,000 population aged 45 and over. In 1930 the standardized rate was 44.4. In 1940 it was 66.7. In 1950 the rate fell to 62.2, but this was still in excess of the rate for 1920 by almost 200 per cent. The corresponding increase for all mental disorders was only 37 per cent.[10, p. 176]

## ¶ Senile Psychoses

We may next consider the senile psychoses. These, too, have shown an upward trend for several decades, though the rate of increase is less than that for psychoses with cerebral arteriosclerosis. In 1909 there were 606 first admissions with senile psychoses to the New York civil state hospitals. These represented 11.6 per cent of total first admissions. There was very little fluctuation in these disorders for several decades, but from 1935 to date there has been a steady upward trend. Whereas these disorders represented 8 to 10 per cent of all first admissions prior to 1935, they have since grown to 15 per cent. Between 1930 and 1950, the average annual rates increased from 6.3 to 16.5 per 100,000 population. Unlike psychoses with cerebral arteriosclerosis, senile psychoses are more prevalent among females.

TABLE 3. First Admissions with Senile Psychoses to New York Civil State Hospitals, 1910–1950, per 100,000 Population*

| FISCAL YEAR | MALES | FEMALES | TOTAL |
|---|---|---|---|
| 1910 | 6.1 | 7.1 | 6.6 |
| 1912 | 5.8 | 6.9 | 6.3 |
| 1914 | 5.3 | 6.6 | 6.0 |
| 1916 | 5.1 | 7.2 | 6.1 |
| 1918 | 5.6 | 7.3 | 6.4 |
| 1920 | 5.1 | 7.6 | 6.4 |
| 1922 | 4.9 | 8.0 | 6.4 |
| 1924 | 5.2 | 8.0 | 6.6 |
| 1926 | 5.8 | 7.7 | 6.7 |
| 1928 | 6.1 | 8.0 | 7.0 |
| 1930 | 5.3 | 7.4 | 6.4 |
| 1932 | 5.6 | 7.9 | 6.8 |
| 1934 | 6.0 | 9.3 | 7.6 |
| 1936 | 6.6 | 10.2 | 8.4 |
| 1938 | 8.1 | 11.4 | 9.7 |
| 1940 | 9.4 | 12.8 | 11.1 |
| 1942 | 10.7 | 14.9 | 12.9 |
| 1944 | 13.4 | 18.2 | 15.9 |
| 1946 | 13.3 | 18.8 | 16.1 |
| 1948 | 12.5 | 19.6 | 16.2 |
| 1950 | 12.9 | 19.4 | 16.3 |

* The rates are based upon the average annual number of first admissions during 3 years; that is, the rate for 1910 is the average for 1909–1911, inclusive.

To rule out possible changes in the annual rates that might have resulted from sex and age variations over the years, it was necessary to standardize the rates. It then appeared that there was no change between 1920 and 1930. The average standardized rate of first admissions with senile psychoses per 100,000 population aged 45 and over rose to 37.2 in 1940, and increased still further to 41.3 in 1950. In 30 years the rate increased by 30 per cent.[10, p. 176]

Since the upward trend in senile and arteriosclerotic disorders cannot be ascribed to the factor of age, we must look for another explanation. I set forth the following hypothesis:

> The human organism must break down at some time. In younger persons, the organism is subject to one set of diseases, for example, tuberculosis. The control of such diseases has extended the expectation of life, and consequently more people are reaching that period of life at which circulatory and other degenerative diseases become manifest. A generation ago, those surviving to middle age probably constituted a better physical selection on the whole, than those reaching the same age periods today. Consequently, in corresponding age periods, we now find greater morbidity and mortality from degenerative diseases. With these are associated the physical conditions that produce senility and cerebral arteriosclerosis. In brief, then, we find increasing rates of both senile and arteriosclerotic mental disorders, because the individuals constituting the susceptible age groups today are probably not selected as rigorously as were the corresponding age groups of an earlier generation."[5, p. 497]

## ¶ General Paresis

Whereas psychoses with cerebral arteriosclerosis were important statistically because of their great increase, general paresis is interesting for the opposite reason. For almost three decades there has been a steady decline in the relative incidence of this disease, as measured by rates of first admissions. In the years 1929 to 1931, for example, there were 2,719 first admissions with general paresis to the New York civil state hospitals. Ten years later, despite a large increase of the general population, there were only 2,681 such first admissions. Ten years later, there were even fewer first admissions, only 1,145, despite a further increase in the general population. Prior to 1915 first admissions with general paresis represented 12 to 13 per cent of all first admissions. Today, they represent less than 4 per cent. The rate of first admissions has decreased steadily from 8 per 100,000 population to an average of 2.8 in 1950.

TABLE 4. First Admissions with General Paresis to New York Civil State Hospitals, 1912–1950, per 100,000 Population*

| FISCAL YEAR | MALES | FEMALES | TOTAL |
|---|---|---|---|
| 1912 | 12.0 | 4.0 | 8.0 |
| 1914 | 13.2 | 3.2 | 8.2 |
| 1916 | 13.8 | 3.4 | 8.6 |
| 1918 | 14.0 | 3.6 | 8.8 |
| 1920 | 13.2 | 3.0 | 8.1 |
| 1922 | 12.6 | 2.9 | 7.7 |
| 1924 | 12.1 | 2.8 | 7.8 |
| 1926 | 11.5 | 2.9 | 7.2 |
| 1928 | 11.6 | 3.0 | 7.3 |
| 1930 | 11.4 | 3.1 | 7.3 |
| 1932 | 12.1 | 3.4 | 7.8 |
| 1934 | 12.3 | 3.4 | 7.8 |
| 1936 | 12.1 | 3.5 | 7.8 |
| 1938 | 11.1 | 3.4 | 7.3 |
| 1940 | 10.3 | 3.4 | 6.9 |
| 1942 | 9.5 | 3.1 | 6.2 |
| 1944 | 8.4 | 2.8 | 5.5 |
| 1946 | 7.1 | 2.3 | 4.6 |
| 1948 | 5.2 | 1.8 | 3.4 |
| 1950 | 3.8 | 1.4 | 2.6 |

*The rates are based upon the average annual number of first admissions during 3 years; that is, the rate for 1912 is the average for 1911–1913, inclusive.

There are marked sex differences with respect to general paresis. This disorder is much more prevalent among males. Rates of first admission are from three to four times higher among males. Both sexes, however, have participated in the decrease in the prevalence of general paresis.

The use of standardized rates shows the decline more clearly. In 1920 the rate of first admissions was 12.9 per 100,000 population aged 15 years or over. In 1930, on the basis of the same sex and age proportions of the general population of New York State as in 1920, the rate fell to 10.9. In 1940 the corresponding rate was 8.4, and in 1950 it fell still further to 3.0.[10, p. 176] There was a decline of 77 per cent in the annual rate of first admissions with general paresis between 1920 and 1950.

One can only speculate as to whether this downward trend will continue. It is known that syphilis began to increase in frequency during World War II. Whether this will ultimately result in more cases of general paresis and other forms of neurosyphilis depends upon the accuracy of case finding and the thoroughness of early treatment of syphilitics.

## ¶ Alcoholic Psychoses

Relative to all first admissions, those with alcoholic psychoses have been decreasing steadily since 1910 in New York State. In that year they represented 10.5 per cent of all first admissions to the civil state hospitals. Today they represent about 7 per cent. This is an artifact, however, due to the relatively large increases of other groups of psychoses. A better picture of the trend of the alcoholic psychoses is therefore obtained from the rates of first admissions. These began to decrease in 1918 and reached a low point in 1921, probably as a consequence of the successful application of wartime prohibition. After 1921, the annual rates grew until by 1941 they were higher than at any time since 1910. After 1941, however, there was a decline, the average annual rate

Downloaded from www.dbraulibrary.org.in

falling to 5.4 per 100,000 population in 1946. The rate rose after 1946, and increased to 7.3 in 1950. These recent shifts in annual rates

TABLE 5. First Admissions with Alcoholic Psychoses to New York Civil State Hospitals, 1910–1950, per 100,000 Population*

| FISCAL YEAR | MALES | FEMALES | TOTAL |
|---|---|---|---|
| 1910 | 9.7 | 3.0 | 6.4 |
| 1912 | 9.4 | 3.0 | 6.2 |
| 1914 | 7.2 | 2.4 | 4.8 |
| 1916 | 6.7 | 2.4 | 4.6 |
| 1918 | 5.9 | 2.1 | 4.0 |
| 1920 | 3.0 | 0.8 | 1.9 |
| 1922 | 3.6 | 0.7 | 2.2 |
| 1924 | 5.3 | 1.3 | 3.3 |
| 1926 | 6.6 | 1.7 | 4.1 |
| 1928 | 7.4 | 1.5 | 4.4 |
| 1930 | 7.4 | 1.4 | 4.4 |
| 1932 | 8.1 | 2.0 | 5.1 |
| 1934 | 9.9 | 2.4 | 6.2 |
| 1936 | 10.2 | 2.7 | 6.4 |
| 1938 | 10.9 | 2.3 | 6.6 |
| 1940 | 11.3 | 2.4 | 6.8 |
| 1942 | 11.4 | 2.7 | 6.9 |
| 1944 | 8.0 | 2.4 | 5.1 |
| 1946 | 8.3 | 2.4 | 5.3 |
| 1948 | 10.0 | 3.1 | 6.4 |
| 1950 | 11.0 | 3.2 | 7.0 |

* The rates are based upon the average annual number of first admissions during 3 years; that is, the rate for 1910 is the average for 1909–1911, inclusive.

seem to indicate that the alcoholic psychoses decrease during war. Because of fluctuations in the size and composition of the general population during World War II, we cannot be certain of this. Some investigations of the age composition of such admissions, however, lead to the belief that the wartime changes probably were significant, and they suggest some relation between mental disorders and war, similar to that which is known to exist between suicide and war.

At any rate, we know that the rates of first admissions with alcoholic psychoses increased between 1920 and 1940. Ruling out possible changes due to the age and sex proportions of the general population by standardizing the rates, we obtain the following results: the rates rose from 3.6 per 100,000 population aged 20 years or over in 1920 to 8.0 in 1930, to 10.6 in 1940, an increase of 294 per cent in 20 years. The standardized rate decreased to 9.9 in 1950.[10, p. 176]

## Manic-Depressive Psychoses

Relative to all first admissions, the manic-depressive psychoses increased from 1909 to about 1920 in New York State. The rate of first admissions also increased during this period, reaching a maximum of about 9 per 100,000 population. Since 1933 the rate has decreased steadily, reaching a minimum of 2.5 per 100,000 population in 1950. Males and females showed similar trends. But as the dis-

Downloaded from www.ohiolink.edu

order is much more prevalent among females, we may consider their rates in more detail. First admissions with manic-depressive psychoses increased among females up to 1922. In that year they represented 20.8 per cent of all first admissions, with an average annual rate of 12.6 per 100,000 female population. Since 1922 there has been a marked decrease, culminating in a minimum in 1950. In that year, female first admissions with manic-depressive psychoses included only 3 per cent of all first admissions. This was due to an actual decrease in the number of admissions, for, despite a large increase in the female population of the state, the female first admissions with manic-depressive psychoses decreased from 862 in 1933 to 229 in 1950. The annual rate of first admissions among females decreased from a maximum of 12 per 100,000 female population to a minimum of 3.0 in 1950.

We may obtain another measure of the trend in manic-depressive psychoses by considering the standardized rates of first admissions for 1930, 1940, and 1950. Again using the age and sex proportions of the population of New York State as in 1920, we find the following rates: 17.7 in 1920, 17.4 in 1930, 11.1 in 1940, and 7.1 in 1950. There was a minor decrease between 1920 and 1930, but between 1930 and 1950 the rate decreased by 60 per cent. In the case of the females, the standardized rates decreased from 23.3 per 100,000 aged 15 and over in 1920 to 21.2 in 1930, to 15.3 in 1940, to 9.4 in 1950. The decrease between 1920 and 1950 amounted to 60 per cent.[10, p. 176]

## ¶ Dementia Praecox (Schizophrenia)

Finally, we may consider the trend with respect to dementia praecox, which represents the largest group of admissions to the state hospitals. Dementia praecox includes close to 30 per cent of all first admissions. Data with respect to such first admissions are available since 1909. Except for some minor fluctuations, the trend has been upward. The average annual rate rose from approximately 10 per 100,000 population in 1910 to 31 in 1950. During this period, males and females showed similar trends, but the annual rates were, until recently, higher among males.

Referring again to standardized rates, in order to make the proper comparison with respect to age and sex, we find the following rates per 100,000 population aged 15 and over, for 1920, 1930, 1940, and 1950: 31.7, 31.6, 37.6, and 54.6. Thus, the prevalence of dementia praecox, as measured by first admissions, was almost constant between 1920 and 1930, but there was an appreciable increase between 1930 and 1940, and an even greater increase between 1940 and 1950.[10, p. 176]

There has been a notable change during the past decade in the sex distribution of dementia praecox. Thus, prior to World War II, male first admissions with dementia praecox always exceeded females, both in absolute numbers and in rate per 100,000 corresponding population. Since 1944, however, this has been reversed, females now being in excess. This may be due in part to the admission of male veterans to federal hospitals instead of state hospitals. It will be necessary, therefore, to study rates closely in succeeding years to be sure that we are experiencing a fundamental change in the sex ratios with respect to dementia praecox.

## ¶ Age

From a consideration of trends in the more important numerical groups of mental disorders, we may now pass to an analysis of certain of their characteristics. The most important would appear to be the age distribution. We may begin with first admissions to all hospitals for mental disease in the United States in 1950. There were 142,353 first admissions, of whom only 1,171, or 0.8 per cent were under 15 years of age. Those aged 15 to 19 included 5,145, or 3.6 per cent. There were 48,602 between ages 20 and 39, or 34.1 per cent; 45,233, or 31.8 per cent, were aged 40 to 59; and 40,682, or 28.6 per cent, were aged 60 or over. The median age was 45.8 years.[14, pp. 36-38]

This distribution differs in a fundamental respect from that for New York State. In 1950, 22.5 per cent of the total first admissions in New York State were aged 70 or over, as

Downloaded from www.dbraun.org.uk

TABLE 7. First Admissions with Dementia Praecox to New York Civil State Hospitals, 1910–1950, per 100,000 Population*

| FISCAL YEAR | MALES | FEMALES | TOTAL |
|---|---|---|---|
| 1910 | 10.8 | 10.0 | 10.4 |
| 1912 | 10.6 | 9.8 | 10.2 |
| 1914 | 12.6 | 11.6 | 12.1 |
| 1916 | 14.6 | 12.7 | 13.7 |
| 1918 | 18.4 | 16.2 | 17.3 |
| 1920 | 19.9 | 17.6 | 18.8 |
| 1922 | 19.2 | 16.3 | 17.8 |
| 1924 | 18.4 | 16.7 | 17.6 |
| 1926 | 19.4 | 16.7 | 18.1 |
| 1928 | 20.3 | 16.8 | 18.6 |
| 1930 | 20.0 | 17.0 | 18.5 |
| 1932 | 22.9 | 20.3 | 21.6 |
| 1934 | 24.4 | 22.4 | 23.4 |
| 1936 | 25.3 | 22.6 | 24.0 |
| 1938 | 26.0 | 23.2 | 24.6 |
| 1940 | 26.0 | 25.1 | 25.5 |
| 1942 | 26.1 | 24.4 | 25.2 |
| 1944 | 23.3 | 25.9 | 24.7 |
| 1946 | 23.7 | 29.1 | 26.4 |
| 1948 | 27.8 | 30.4 | 29.1 |
| 1950 | 31.5 | 31.0 | 31.2 |

* The rates are based upon the average number of first admissions during 3 years; that is, the rate for 1910 is the average for 1909–1911, inclusive.

against 16.9 per cent for the country as a whole. If we draw the line at age 60, we find that 35.4 per cent of the first admissions in New York were aged 60 or over, compared with 28.6 per cent for the whole country.

Whatever the true percentage, both distributions agree in showing that there is a real problem with respect to the aged. Thus, in 1930, there were 6,642 first admissions to all mental hospitals in New York State aged 60 or over, or 23.2 per cent of the total. In 1940 such admissions had reached 13,869, or 29.7 per cent. This increased still further to 20,670 in 1950, or 35.4 per cent.

This reflects more than a mere increase in the proportion of the aged. If we consider rates of first admissions per 100,000 of corresponding age, instead of absolute numbers, we find the following: among males the rate increased at ages 60 to 64 from 139.7 per 100,000 in 1920 to 198.0 in 1950. At ages 65 to 69, the rate increased from 178.6 to 264.0. At ages 70 to 74, the rates were 190.1 and 395.4, respectively. Similarly among females, the rates at ages 60 to 64 increased from 134.0 to 169.2; at ages 65 to 69 they increased from 149.0 to 219.2; and at ages 70 to 74 they increased from 208.4 to 372.0. Hence, we find that not only are more elderly people entering hospitals for mental disease, but they are doing so at an increasing rate.[2, p. 206]

Rates of first admissions are at a maximum in the older age groups. They are at a minimum at the youngest ages. In between, the rates increase steadily from age to age. For example, among males in New York in 1950, the rate of all first admissions to all hospitals advanced from 22.8 per 100,000 at ages 10 to 14, to 123.5 at ages 30 to 34, to 136.6 at ages 50 to 54, to 198.0 at ages 60 to 64, etc. Among females, the rates increased from 18.6 at ages 10 to 14, to 129.2 at ages 30 to 34, to 137.0 at ages 50 to 54, to 169.2 at ages 60 to 64, etc.[2, p. 205]

This steady increase is characteristic, however, only of mental disease as a whole. If we consider individual groups of mental disorders we find some important differences. In the case of general paresis, for example, the rates rise from a minimum of less than 1 per 100,000 at ages 10 to 14 to a maximum of about 7 per 100,000 at ages 50 to 59.[2, p. 207] They drop off to less than 5 per 100,000 at the advanced ages. In the case of the alcoholic psychoses, the rates rise to a maximum in the fifth decade, and then taper off to a minimum of less than 4 per 100,000 in old age.[2, p. 209] In the manic-depressive psychoses, the rates rise to a maximum in the fourth decade, and decline rapidly thereafter.[2, p. 217] Similarly with respect to dementia praecox, there is a rapid rise to a maximum in the late twenties and early thirties, and a steady decline thereafter.[2, p. 219] On the other hand, the senile psychoses and psychoses with cerebral arteriosclerosis begin in the fifth decade and rise steadily to maxima in old age.[2, p. 211, 213]

Reviewing such data, I wrote as follows:

The probability of a mental disorder is a direct function of age. The probability is low in child-

Downloaded from www.dbraulibrary.org.in

hood, rises rapidly in youth and maturity, grows at a more moderate rate during the involution period and then advances rapidly to a maximum in old age. In this growth the aging process is implicated both directly and indirectly. It is evident in the specificity of such a disease as epidemic encephalitis. Constitutional factors seem related to the relatively early periods of life at which dementia praecox and the manic-depressive psychoses manifest themselves. We observe limitations with respect to general paresis and the alcoholic psychoses, which are clearly due to a combination of physiological, constitutional, and social factors operating during the prime of life. But the effect of age is seen most clearly in the direct consequences of physical and mental deterioration, resulting from senility and from arteriosclerotic changes.

Each period of life is therefore susceptible in large degree to certain characteristic types of mental diseases.[9]

## ¶ Environment

We may next ask whether there are any gross environmental differences in the relative distribution of mental disorders. By this is meant, are the rates of first admissions higher in urban areas than in rural areas? Are there any differences corresponding to differences in the size of urban populations? Based upon data for New York State from 1949 to 1951, it may be said that mental disease is more frequent among urban populations than among rural populations.[4] The rates are in the ratio of almost 2 to 1. This is true of all the major groups of mental disorders, including the old-age psychoses. On the whole, the rates grow uniformly larger as we progress from the rural areas to cities. There is great fluctuation in the rates of first admissions in the larger cities —New York, Buffalo, Rochester, Syracuse—but these rates, nevertheless, are well above those for the rural populations. The greatest relative differences are in connection with general paresis and alcoholic psychoses.

There is a further differentiation of the rural population into those living on farms and the nonfarm population. It is significant that the rates of first admissions among the former are now higher than for the nonfarm population, especially with respect to dementia praecox.

The non-farm population has grown significantly in recent years, a fact which is associated with a population movement from cities back to suburban and rural areas. . . . It has been shown that migration over long distances is associated with increased rates of first admissions. . . . This trend is reversed, however, when migration occurs over short distances, as represented by the nonfarm population. This is, in large part, a selection of higher economic groups. As such groups tend to have rates of first admissions below the average, they are probably responsible for the contrast in rates between the farm and non-farm populations.[4, p. 237]

## ¶ Racial and Ethnic Groups

Racial and ethnic differences have not, on the whole, received the consideration they merit. This is due primarily to the absence of a detailed racial classification of the people of the United States. The most obvious comparisons, and the only ones which can be carried out on a large scale, are those between Negroes and whites. If one were to accept statistics of first admissions in southern states at face value, it would appear that Negroes have lower rates of mental disease than whites. This is a clear reversal of the truth. On the contrary, rates of first admissions are far higher among Negroes than among whites. The fallacy in the statistics for the South resides in the fact that admissions are low for Negroes, owing to inadequate provision for their care and treatment. In New York, on the contrary, where no racial discrimination of any kind is practiced in admissions to the state hospitals, we find clear evidence of the excessive rates for Negroes.[6, p. 450-476] Detailed analyses of the average annual rates from 1939 to 1941 showed that the total rate of first admissions was twice as high among Negroes as among whites. The Negro excess was especially noticeable in connection with general paresis and the alcoholic psychoses. The problem resolves itself into whether the excessive rates among Negroes are

Downloaded from www.dbraulibrary.org.in

due to racial factors or to social factors. The latter are clearly associated with high rates of general paresis and of alcoholic psychoses. Migration is also a very important factor among Negroes.[7, p. 350-364]

A group of ethnic interest is the Jew. Most writers have attributed an excessive amount of mental disease to Jews. It was shown in a series of studies that this conclusion was based upon inadequate data and upon wrong methods of analysis. The question was therefore studied in detail for New York State and for New York City, and it was shown that, far from being in excess, Jews actually had lower rates of first admissions than the remainder of the population. It has been customary to emphasize the prevalence of functional mental disorders among Jews, such as dementia praecox, but in this major group, the rate for Jews was not in significant excess. Therefore, whatever may be said about "nervousness" in general, or about the prevalence of the psychoneuroses, the evidence shows that Jews have less than the general average with respect to the psychoses. Attention should be directed to the exceptionally low rate of alcoholic psychoses among Jews. Even though their habits of drinking have changed during the past generation in the United States, their rate of alcoholic psychoses is still near the zero mark.[8]

On the other hand, the Irish, whether native-born or foreign-born, have higher rates of alcoholic psychoses than any other population group, including Negroes. This same excess was shown in connection with senile psychoses, psychoses with cerebral arteriosclerosis, and manic-depressive psychoses. The rate of dementia praecox was also among the highest. On the other hand, the Irish had the lowest rate with general paresis.[11]

There is a very complex combination of racial and environmental factors in relation to mental disease, not easily susceptible of differentiation. My impression is that biological factors in mental disease are more closely associated with family lines than with race. To determine the racial and ethnic factor, it will therefore be necessary to transfer our interest to family data within these populations. We are only opening the door at present to this type of investigation.

## ¶ Conclusion

It remains to ask what happens to the patients with mental disease who are being hospitalized at increasing rates. The general impression has long been that the prognosis is unfavorable, the rate of discharge being low and the death rate high. These conclusions were drawn from incorrect premises, however, despite the fact that Pinel had pointed out the correct methods of analysis more than a century ago.[11] Only recently has the correct procedure been adopted. This consists in tracing the histories of cohorts of first admissions to mental hospitals over uniform periods of time, beginning with the date of hospitalization. Such studies are now available for Ohio,[12] Pennsylvania,[1] and New York State.[3] They are all in good agreement, showing that the probability of discharge within a short period is high, and that rates of recovery or other degree of improvement are encouraging. Because of the greater number of first admissions, reference may be made to the results for New York State.

Cohorts of first admissions during five successive fiscal years, beginning April 1, 1943, were submitted to analysis. The closing date of observation in each case was March 31, 1949. The members of a cohort had equal periods of exposure, and this varied from a minimum of 1 year for the cohort of 1947–1948 to a maximum of 5 years for the cohort of 1943–1944.

Of the male cohorts, an average of 42 per cent were discharged within 5 years after admission, and 36 per cent were discharged from the books within 2 years. Those leaving the hospitals either by direct discharge or by placement in convalescent care (parole) within the first year amounted to approximately 30 per cent. Rates of discharge were low among first admissions with psychoses with cerebral arteriosclerosis, amounting to only 16 per cent at the end of 5 years. First admissions with senile psychoses had an even lower rate of

Downloaded from www.ajph.org

discharge, namely 6 per cent. However, of manic-depressives, three fourths were discharged within 2 years, and two thirds left the hospitals within 1 year, either by discharge or by parole. By the end of the fifth year, 83 per cent had been discharged. Of first admissions with involutional psychoses, 50 to 55 per cent left the hospital within 1 year, and 68 per cent were discharged within 5 years. Of dementia praecox, 45 per cent left within 1 year, and 53 per cent were discharged within 2 years. These three groups of disorders had higher rates of discharge than corresponding cohorts of circa 1910. An equally favorable result occurred among general paretics. Of this group, only a fourth were discharged within 2 years, but this was well in excess of corresponding results for earlier cohorts.

Females showed similar results. The average per cent of discharge over 5 years was 44. The percentages were low for psychoses with cerebral arteriosclerosis (17), and senile psychoses (6), but high for manic-depressive psychoses (87), involutional psychoses (70), and dementia praecox (63). As with males, the three latter groups have higher rates of discharge than existed 3 decades ago. General paretics shared in this improvement, a third being discharged within 2 years.

Of the male cohorts, 39 per cent died within 5 years, most deaths occurring during the first year of hospitalization. As might be expected, mortality was high among first admissions with psychoses with cerebral arteriosclerosis, and with senile psychoses. Of the former, 72 per cent died within 5 years; of the latter, 84 per cent died within 5 years. On the other hand, mortality was low during the period of 5 years for dementia praecox (5 per cent) and manic-depressive psychoses (10 per cent). Sixteen per cent of first admissions with involutional psychoses died within 5 years. Mortality rates for these three groups were lower than corresponding rates for earlier cohorts. Half of the general paretics died within 5 years; nevertheless, this was lower than the rate for early cohorts of general paretics.

Females had lower death rates than males. In general, however, the trends were similar. Mortality was high among the arteriosclerotics and seniles, but low for dementia praecox, manic-depressive psychoses, and involutional psychoses. Except for the psychoses associated with advanced age, rates of mortality for females were less than corresponding rates for early female cohorts. General parctics showed a similar decline in mortality.

Because of high death rates, only 10 per cent of the males with cerebral arteriosclerosis remained in continuous residence at the end of 5 years. This was even lower for the seniles (6 per cent). On the other hand, because of a high rate of discharge, only 6 per cent of the manic-depressives remained at the end of 5 years. Because of their lower discharge rates, 30 per cent of the cohort with dementia praecox was still in residence after 5 years.

Among females, high mortality left only 12 per cent of the arteriosclerotics and 11 per cent of the seniles in residence after 5 years. Of the manic-depressives, only 4 per cent were still in residence. Thirty-five per cent of first admissions with dementia praecox were still in residence at the end of 5 years.

Except for the psychoses of old age, it appears that the results of therapy in mental hospitals are not only favorable, on the whole, but that there has been a significant improvement in outcome in recent years. Since the close of these follow-up studies, new types of treatment have been introduced, most notably the tranquilizing drugs. One may therefore look forward to a further improvement in rates of discharge and, in general, to an encouraging prospect for the treatment of mental disease.

CHAPTER 8

# THE GENETICS OF MENTAL ILLNESS*

Franz J. Kallmann

Downloaded from www.dbraulibrary.org.in

IF THERE IS A GRAIN OF TRUTH in the idea that the unique behavioral norms of man during his stay on this planet have a gene-specific basis, then it is clear that, in order to understand the genetics of mental illness, we have to explore the genetics of mental health. The very fact that a specific type of psychopathology may result from an obscure deficit, traceable to either the action or inaction of a mutant gene, assures the reasonableness of this premise.

In line with an elementary genetic principle, the occurrence of a mutational change is sufficient evidence for the existence of a normal allele (the corresponding member of a pair of genes located at a definable point of a chromosome). The normal gene, even if its biochemical equivalents have yet to be identified,[72] can be assumed to make a vital contribution toward maintaining adequate health and normal behavior.

One of the corollaries of modern genetic theory, therefore, is that such phenomena as personality integration, emotional balance, and mental health are more than the result of chance circumstance reflecting only mild cultural pressures, or a fortuitous absence of disturbing experiences in childhood. More appropriately, the given phenomena are viewed as end products of a multitude of genetically potentialized properties and functions that are continuously molded by "ethnoplastic" forces —"the myriad elements constituting the life cycle of a human organism."[80]

## The Place of Psychogenetics in the Science of Man

The very gaps in our knowledge of this self-perpetuating interaction between the genetic and nongenetic components of man's existence kept a door, or at least a porthole, open to the

* From the Department of Medical Genetics of the New York State Psychiatric Institute, Columbia University, New York.

influx of speculative conceptual schemes regarding the roots of human behavior. Moreover, much of the background for inquiries into the genetics of normal and abnormal behavior patterns was formed by "a cleavage between natural and social science . . . which really was a cleavage between substance and action, body and soul, the objective and the subjective."[48] Under these circumstances it was rather inevitable that psychogenetic theories, covering the field of physiological, psychological, and psychiatric genetics, should have become the subject of much hypothetical argumentation.

Now and then, this ill-founded debate, widely referred to as the "nature-nurture" controversy, would boil over so vehemently that Muller[109] called it "an excellent example of wishful thinking by two sets of fanatical opponents, both of whom ought to know better." More to the point and certainly somewhat humbler was Braceland's[14] description of modern dynamic psychiatry as a slowly emerging medical discipline having the difficult task of coordinating two disparate ways of appraising mental disorder: the humanistic approach (insight into the meaning of human existence) and the scientific approach (knowledge of human nature derived from being "a part of the science of man").

Be that as it may, the current trend is toward increasing recognition of genetic principles in the medical and behavioral sciences —psychiatry and clinical psychology not excluded. This development, reflected in the gradual convergence of psychodynamic and physiodynamic theories of health and behavior, was given added impetus by two provocative events in the biological sciences. The first was the discovery of a causal relation between a high degree of specificity in many hematologic and metabolic functions, and the properties and actions of genic elements.[56, 111, 115] The second was the focusing of world-wide attention on the health hazards of nuclear radiation.[21, 36, 51]

Cautioned by the stark tenor of these authoritative reports, medical men everywhere have begun to consider possible prophylactic measures against the cumulativeness of genetic irradiation damage. The prevailing view is that exposure to mutagenic energy sources calls for the lowest safety levels consistent with medical necessity. Current estimates of the maximum dosage of medical radiation per individual allowable for safety during the first thirty years of life vary from 4.6 to 10 roentgens.

At the same time, there is greater realization of the imperative need for "the collection of more detailed information . . . about all kinds and all levels of genetics . . . to counteract dysgenic effects on the structure of human populations."[78, 95] With man's prospects of "meeting the evolutionary tests of survival and extension" hinging primarily on his ability "to avoid the missteps of blind nature,"[101] it is apparent that we must learn to put to optimum use our knowledge about basic genetic phenomena.

## ¶ General Genetic Principles

### *Chromosomes and Genes*

The modern theory of genetics evolved from a rough picture of heredity as a kind of shuffling of the cards at the time of fertilization, to the all-encompassing concept of the molecular origin of life. The groundwork for this intricate scheme was laid in 1900 upon confirmation of Gregor Mendel's experimental garden-pea data, presented before the Brünn Natural Science Society in 1865.[35, 75]

Convinced of the statistical meaningfulness of the observed distribution of certain plant characteristics (shape and color), the Austrian biologist set forth his hypothesis of the "unblended" separation and subsequent recombination of stable genetic units. The gist of it was that single characters behaved as if determined by paired particles (later called genes) in the germ plasm.

Another implication was that of the two members of a pair joining to form the zygote (one-celled stage of the new individual), one being derived from the father (male germ cell) and the other from the mother (female germ cell). When new germ cells are formed by the matured individual, the paired mem-

Digitized from www.dbraulibrary.org.in

bers separate again, without having had a chance to influence each other or enter the same germ cell (law of segregation). It also follows from Mendel's hypothesis that two corresponding or allelic genes occupy the same linear position on two homologous chromosomes (coiled filamentous structures in the nucleus of a cell).

Parenthetically, it may be mentioned here that a plant or animal is called a homozygote for a particular gene and is expected, under ordinary environmental conditions, to show its characteristics, if that gene is received from both parents. A heterozygote (hybrid) originates when the given gene is received from only one parent and, at the corresponding locus, a different one from the other parent.

In some cases the Mendelian trait displayed by the heterozygous individual will be intermediate between the traits represented by homozygotes; in others the possession of only one member of a gene pair will suffice to produce the trait (dominant), while its partner remains unexpressed (recessive). Homozygousness is necessary for the expression of a recessive trait in the individual's appearance (phenotype), as heterozygousness merely allows the gene to remain part of the individual's genic formula (genotype) to be transmitted to the offspring.[78]

It was not just by chance that discovery of the chromosomes[150] took place in the thirty-four-year interval during which Mendel's findings remained unnoticed. The nuclear filaments, observed under the microscope as threadlike bodies with a peculiar staining reaction, were seen to divide in the process of ordinary cell division and to be redistributed as duplicates, with each germ cell receiving half the parental chromosome structure. This pattern was consistent with Mendel's experimental observations and made it possible to combine the knowledge derived from breeding experiments with that provided by cytogenetic, biochemical, and evolutionary studies. When advances in experimental, clinical, and population genetics merged with the *avant-garde* units deployed by other biological disciplines, more precise formulations of the chromosome theory became feasible.

Although chromosomes were visible microscopically and known to consist largely of nucleo-proteins (substances of high molecular weight made up of proteins and nucleic acids), the original concept of a gene was of a minute, invisible protein particle, or large molecule, situated in a certain segment of a chromosome and distinguished from the molecular structures of adjacent segments by a high degree of specificity of its biochemical action. This old construct of a gene has been elaborated into that of a clearly differentiated functional region (locus) which preserves its identity, produces a specific effect, and is capable of duplicating itself. Its self-duplication is executed by attracting from the cellular surroundings (nuclear fluid) the raw materials for reconstructing the same type of directional center, rearranging and binding them into a pattern identical with its own.[100] Because of this unique faculty of genes to construct exact duplicates of themselves and thus serve as the synthesized product of chemical reactions that they themselves have directed, genic activity is basic to all growth and reproduction.

Chemically, genes have been described as DNA segments (desoxyribose nucleic acid) of perhaps several hundred nucleotides which apparently carry the ingredients for the synthesis of a specific macromolecule.[10, 92] The genetic specificity of these primary functional (informational) units is assumed to depend on proportions and sequences of base pairs in a particular DNA segment. Replication is probably accomplished by separation of complementary nucleotide chains, followed by synthesis of complementary daughter chains. An essential part of this hypothesis is the assumption that the functional process of gene action involves a transfer of DNA specificity to RNA units (ribonucleic acid), which, in turn, may serve as templates in protein synthesis.

With the present balance of evidence pointing to proteins as primary gene products, it is easy to conceive of a mutant gene's effect as the possible cause of either a quantitative deficiency or a qualitative alteration of the given protein. Obviously, one or the other can result in pathological changes.[30]

Downloaded from www.pbookshop.com

From the standpoint of physical and mental health, the potentialities for maintaining it on a satisfactory level apparently depend on the ability of all genic elements to work together by means of meticulously coordinated reactions, thereby establishing what is called "the balance of the genes." By and large, this physiological state is analogous to general conditions of integration described by such terms as homeostasis, adaptiveness, and emotional equilibrium.

By the same token, the species characteristics of human populations rest on rigid specifications as to number, size, shape, and relative positions of the original sets of chromosomes found in every cell of the body. Whether a human cell contains forty-eight chromosomes, as has long been accepted, or only forty-six "essential" ones, as has recently been discovered, the numerical constancy is maintained by reduction to one half the number in the course of fertilization.

Since there is no correspondence of a species' complement of chromosomes with its position on the evolutionary scale, the modern definition for such an intrabreeding Mendelian population rests on the concept of "a reproductive community of individuals who share a common gene pool."[34, pp. 1, 2] Accordingly, subspecies or ethnic groups are "subordinate Mendelian populations differing in relative frequencies of genes or chromosomal structures, and usually also in external appearance and . . . physiological properties."

Because human subpopulations undergo continuous boundary changes in other distinguishing (isolating) factors—geographic, cultural, socioeconomic, and the like—a well-established formula is used to describe a random-mating population in equilibrium (no selective advantage of one allele over the others at any locus, and absence of mutations). Known as the Hardy-Weinberg law,[58, 152] this formula, together with an analysis of adaptational and selective phenomena, is indispensable for an understanding of continuing intrapopulation variations from generation to generation as a corollary of simple Mendelian principles.

## *Mutation and Variable Gene Expression*

As the prototype of genetically produced and genotypically transmitted changes, both evolutional and pathological, mutational processes play a crucial role. Generally speaking, a mutation occurs during gene reproduction, either spontaneously or in response to mutagenic agents, but always as an expression of the failure of two synapsed genes to reproduce in the form of exact replicas of themselves.

The given change may be structural (deletion, duplication, inversion, translocation) or chemical (substitution of one component for another, or a shift in the order of components). Depending on whether the affected chromosomal point or portion is altered to a greater or lesser extent, the mutational effect may be extremely deleterious (lethal), moderately severe, or slight and only detectable statistically in large populations by a change in certain health and survival values. In any case, mutations are apt to be transmitted to the next generation via the germ cells.

Subsidiary genes, which cause quantitative changes in the expression of a major mutant gene, are referred to as modifier genes if they contribute to the variable expressivity of a trait. Although generally difficult to identify, they are called suppressor genes if they are responsible for incomplete penetrance of the main gene. The failure of a major mutant gene to be expressed at all (lack of penetrance) can be determined by studying populations known to be homozygous for the given trait, that is, children of two affected parents or one-egg co-twins of affected persons. The extent to which either group falls short of an expected manifestation rate of 100 per cent represents the degree of incompleteness of the gene's penetrance.

Other variations in the expression of a gene may arise either from the fact that it produces different effects depending upon its location on the chromosome (position effect), or from a tendency to exert different effects upon various organs from one and the same location (pleiotropic effect). Positional changes

Downloaded from www.brainvision.co.in

may subject the gene to different cytoplasmic influences or may make it necessary for the gene to express itself in different linkage groups. The effect of a major mutant gene may also be simulated by a chromosomal aberration (supergene).

Of course, every gene may undergo a number of mutational changes, although only two of these mutants, present in a population, can form a pair occupying a certain position on a particular chromosome in any one individual. A good example of such a series of multiple alleles is represented by the blood groups.

Under conditions of linkage of two or more different sets of genes (proximity of location on a chromosome), a study of the frequency of the given genes' separation in the offspring allows an estimate of the relative chromosomal positions of linked genes. This method has made it possible to construct highly important chromosome maps that may be verified "in a number of ways by direct microscopic observation."[100]

One of the main genetic principles is that the phenotypic expression of simple genes with a distinguishable normal or pathological effect is not an independent entity; rather, it is "a unified action of a field type which results in a hierarchical order of not strictly delimited fields."[55, p. 182] A gene does not directly produce a given trait, nor can it be expected to be "the absolute . . . or simple determiner" of a trait.[100] It merely sets in motion a chain reaction that may be modified by environmental factors, prenatal or postnatal, as well as the action of other genes, before culminating in the production of a particular trait.

Hence, a gene effect may vary from complete expression to no apparent expression, although there is usually only one major conspicuous effect or characteristic symptom whereby the gene's presence is identified under ordinary circumstances.

## *Modes of Inheritance*

Where a single mutant gene is potent enough to express itself distinctly against a vast number of other genetic background factors, its phenotypic effect will tend to be pathological. In this single-factor type of inheritance, the distribution between the sexes of a dominant or recessive gene is usually equal (autosomal). Exceptions are due to the effect of genes transmitted on the sex chromosomes (XX in females, XY in males). In recessive X-borne conditions, males are more frequently affected than females. The sex prevalence is reversed in dominant sex-linked traits, while Y-borne characters occur only in males.

Distinguished by transmission in the direct line of descent and by inheritance from one parent, autosomal dominant traits are apt to be rare (self-eliminating) and incompletely expressed. Their appearance in the phenotype requires only one member of a gene pair (heterozygousness), and unions between two afflicted persons are uncommon.

Simple recessive traits, expressed only by homozygotes, require inheritance from both parents, who are frequently unaffected phenotypically (heterozygotes). No parent, whether heterozygous or homozygous for such a trait, can possibly have an affected child (homozygote) unless he marries another carrier of the given gene. Consanguineous marriages are apt to increase the chances of this type of mating, especially in the case of a relatively rare and severe disorder. Transmission along collateral rather than direct lines of descent is the rule, a principle which militates against the common practice of accepting the verdict of an "inherited" disorder only where the symptoms are clinically traceable to one of the direct ancestors of the patient.

For statistical purposes it may be borne in mind that many mutant genes in man do not conform to simple schemes of single-factor inheritance. Some genes are neither strictly dominant nor strictly recessive but somewhere in between (incomplete dominance or recessiveness). While a dominant trait will not be manifested by every heterozygote, a recessive gene may express itself mildly in a heterozygote whose corresponding factor for health is only incompletely dominant. Such modalities promise to be helpful in devising new techniques for the detection of carriers.

Downloaded from www.PublishingPro.com

Intermediate gradations always characterize the additive effect of polygenes which interact in determining small variations in normal personality characteristics in a given population.[92] In this multifactor type of inheritance, cumulative contributions are made by an assortment of genes which individually produce only minor effects.

In an intermarrying population with random mating, the resultant distribution of polygenic traits can be plotted in a bell-shaped curve showing variations from the lowest to the highest grades. With medium-grade persons expected to be in the majority, and with the two extreme types the least numerous, the total effect will not fall in the pathological range, unless placed there either by clinical definition or by a mutational change in one of the polygenes involved.

In line with these broad principles of quantitative inheritance, it is now generally agreed that the list of polygenically determined traits includes the reaction norms of height, intelligence, longevity, and variable resistance to selective types of infectious disease. As to inadequate intellectual potentials, for instance, undifferentiated high-grade defects (morons with no other clinical symptoms) are assumed to form the lower end of the Gaussian distribution curve of intelligence in the general population, while low-grade defects do not fit into any scheme of continuous variation.

Formulated in this comprehensive fashion, the polygenic theory of familial mental deficiency is consistent with the idea that "a Kallikak family tends to propagate its own culture as well as its own heredity and, by assortative mating, continually accumulates its own kind of both." According to Allen,[3] this concept reflects "a reassuring convergence of genetic and behavioral thought."

Assortative mating trends are genetically identified as interfering with random mating. From the standpoint of population genetics, the effect of this interference may be *positive* (increase of marriages among people with the same traits) or *negative* (resistance to marriage on the part of people with the same traits). The consequences of positive assortative mating may either be desirable (intelligence, musical talent) or undesirable (deafness).

## ¶ Methods of Genetic Investigation

The methods used in genetic studies in man differ according to whether an analysis deals with the health problems of entire populations or certain groups of families. In either case it is essential to note that gene-specific variations follow the theory of probabilities.

Mendelian ratios express no more than the average expectancy of a genically determined trait in a representative population sample. Diversified statistical procedures are needed to test the validity of inferences drawn from individual observations.[90, 107] This principle applies to all genetic mechanisms and attributes —physical or mental, normal or pathological, frequent or rare. Here, however, only those statistical methods will be discussed that are necessary in psychogenetic studies.

### *Family-History Method*

Since statistically representative samples of particular subgroups of people or populations are a principal requirement, genetic data obtained from individual families (pedigrees) or sets of relatives (one pair of concordant or discordant twins) usually prove of limited value. Family histories are seldom published because of familial concentration of exceptionally fine health in one generation after another, or because of the rare occurrence of a severe pathological condition in a particular family. Also, it is obvious that an affected person would have to be fertile in order to have a similarly afflicted child, or his parents would have to have had at least seven children if he is to have six affected siblings.

At best, therefore, the usefulness of the ordinary family-history method is restricted to counseling problems and the study of rare pathological traits which are easily traced genealogically and known to be fairly constant in penetrance and clinical expression. Single pedigrees demonstrate mainly how often sim-

Downloaded from www.dbraum.com

ilar varieties of a familial trait may occur in the members of an affected family. They are not expected to furnish conclusive proof of the operation of heredity as such, or of the usual mode of inheritance observed.

Generally, the various systems of constitutional typology are the equivalent of pedigree studies in the area of population genetics. In the opinion of Rees and Eysenck,[117] the major part of the measurable variation in any human group is accounted for by two factors alone—growth in length and growth in breadth.

## *Census Method*

For purposes of a comprehensive genetic analysis, the applications of total-population surveys (census method) are also limited. Exceptions are surveys concerned with small and sufficiently cooperative populations (isolates) as well as those dealing with relatively uncomplicated traits ascertainable by enumerative procedures (questionnaires, vital statistics, registries of reportable diseases and defects). Even without close personal contact with the members of the communities to be surveyed, pertinent population data may be obtained censuswise on the distribution of freckles, pellagra, or blood groups (if blood samples are available). The situation is different for possible linkage phenomena, the selectivity of dietary deficiencies among the members of certain families, or the genetics of a special form of blood incompatibility between mother and child.

Similarly, a line has to be drawn between the relative frequencies of tasters and nontasters on the one hand, and inquiries into possible psychological deviations of nontasters on the other. Hence, the census method is neither economical nor fruitful when it comes to genetic problems presenting difficulties of diagnosis or ascertainment (reluctance of families to disclose embarrassing private affairs with nonspecialized research personnel) or to questions calling for data on differential fertility rather than general marital fertility rates. The application of ordinary census procedures is equally unsuitable in problems where differential morbidity-risk estimates, rather than actual prevalence statistics, are needed.

## *Morbidity-Risk Data*

When statistically corrected expectancy rates are used in a genetic analysis, the comparative scheme is focused on the probable or empirically observed morbidity risk (expectancy) of members of certain families with respect to particular traits and their phenotypic variations under different circumstances (different periods of time or life, various ethnic or socioeconomic settings, etc.) By definition, the disease expectancy of a person is "the risk of becoming ill during one's lifetime, if one lives long enough to pass the period of risk," that is, the time during which the disease may develop.[141] The two principal methods for obtaining expectancy rates in clinical genetics are Weinberg's system (proband-sibship, abridged, and double proband methods) and certain extensions of the twin-study method (twin-family method). Other procedures include Ilse's and Strömgren's methods, morbidity tables, and Bernstein's a priori method.[73, pp. 135–147]

In *Weinberg's system*[151] the chief objective of a comparative analysis is to determine whether a given trait occurs more frequently in blood relatives of a representative number of probands or index cases (persons disclosing clinical evidence of the trait in question) than in the general population. The observed number of affected persons among the siblings of the probands (full sibs, half-sibs, step-sibs) is analyzed in terms of varying parental matings (affected or unaffected).

In the case of full sibs, both parents may be phenotypically free of the disease, but, for purposes of a genetic analysis, they are distinguished by the fact of having produced at least one affected child, the proband. In other words, parental matings with no affected child cannot be reached by a procedure which begins with a sample of patients of a certain variety within the boundaries of the area covered by the study. This statistical bias in the ascertainment of index sibships is corrected by omitting

Downloaded from www.dbraulibrary.org.in

from the analysis all patients obtained as probands.[127]

In order to adjust inequalities in age distribution, the actually observed (absolute) morbidity figures are related to the total number of persons who have survived the given period of manifestation, increased by half the number of persons who at the time of the study are still within the age limits of this period (abridged method). Persons who never reached the beginning of the manifestation period because of death or who are too young to have reached it are not counted. The resulting morbidity rates are average expectancy figures, valid for persons who are old enough to have developed the usual clinical symptomatology of the disease in question.

The range of the given manifestation period is to be chosen in accordance with clinical experience. Obviously, statistical accuracy in employing the abridged method depends as much on a fairly uniform distribution of the persons observed within the accepted period of manifestation as it does on the representative size and diagnostic uniformity of the total group studied. Several methods are available for testing the assumed homogeneity of clinical subgroups.

The corrective procedures of Weinberg's system are also used in the twin-family method, which combines the principles of the proband-sibship and abridged methods with those of the twin-study method, as well as in the analysis of normal control data for a comparable general population, that is, a group of persons not ascertained through known consanguinity to the given type of proband.[78]

## *Twin Studies*

The twin-study method is a quasi-experimental procedure which has been profitably employed in exploring the genetics of both normal and abnormal behavior patterns. Introduced as a genetic-research tool by Galton,[41] the method is based on the regular occurrence of two genetically different types of twins, one-egg (monozygotic) and two-egg (dizygotic). Whereas one-egg twins are always of the same sex, two-egg twins may be of the same or opposite sex.

In the original version of the twin-study method, the comparison of observable similarities and dissimilarities in the histories of genetically similar and dissimilar members of a family is limited to twin subjects. This procedure requires access to a representative series of one-egg and two-egg twins, of the same or different sex, presenting evidence of a diagnostically well-defined trait to which the principles of the proband method can be applied. The most useful criterion for an unbiased sampling of twin index cases (rather than pairs) is provided by an approximate agreement between a twin sample and the parent population in regard to the proportion either of opposite-sex pairs or, when known, of one-egg pairs.[1]

In the United States the general twin rate is 2.19 per cent of all babies born since 1928. This rate is reduced to about 1.9 per cent by excess twin mortality within the first year of life, while the 2-to-1 ratio of same-sex to opposite-sex pairs observed at birth persists in all age groups. After the first year of life, there is no significant difference between the mortality rates of twins and nontwins, so that the proportion of twin individuals in the population remains nearly the same at all ages.

While morbidity statistics obtained from twin samples are to be related to twin subjects rather than pairs, twin data on normal personality characteristics are expressed in terms of varying degrees of intrapair similarity or dissimilarity, and not in terms of concordance or discordance. An effective statistical technique employed in estimates of genetic components in normal personality variations is Holzinger's $h^2$: the variance of two-egg twins minus the variance of one-egg twins, divided by the variance of two-egg twins.[108] In order to establish the significance of the $h^2$ values, an F test may be used for the ratio of the two-egg over the one-egg variance.

In another version of the twin-study method, called the co-twin-control method,[49] observational or experimental data are obtained from a few selected pairs of one-egg twins whose

Downloaded from www.dmaulibrary.org.in

aptitudes, physiological reactions, or adjustive patterns can be compared under different life conditions, or in response to planned differences in management. In spontaneously discordant pairs (one schizophrenic and one nonschizophrenic, or one deaf and one hearing partner) longitudinal comparisons of chemical and psychometric tests may prove illuminating as to etiology, treatment, or personality assessment, provided the given twins are monozygotic.

For determining the zygosity of same-sex twins, the method of choice is the modern similarity method, with its dermatoglyphic (qualitative and quantitative) and blood-group data.[75, p.63] In particularly important instances, where all other diagnostic criteria are indecisive, reciprocal skin grafts may be performed. Twins cannot be monozygotic if their blood groups differ or full-thickness homografts are rejected. The fetal-membrane method is no longer in use, since it is now known that not all one-egg pairs are born with only one placenta.

In the third version, the twin-family method, the comparative scheme is extended to complete sibships of twin index cases and their parents. The six dissimilar sibship groups to be compared are one-egg twins, two-egg twins of the same sex, two-egg twins of opposite sex, full sibs, half-sibs, and step-sibs. The main advantages of this procedure lie in its effectiveness as a sampling method and its inconspicuousness as a pluridisciplinary approach to total population surveys which require combined cross-sectional and longitudinal investigations in a cooperative family setting. So broad is the scope of this combined procedure that it fulfills nearly all requirements specified by Cattell *et al.*[29] for the use of the multiple-variance method in investigating functionally (not necessarily genetically) unitary traits in the normal range of personality development.

In analyzing twin-family samples in terms of expectancy rates, it is essential, too, to compute all statistics from twin index cases rather than twin pairs. This requirement applies especially when many pairs are represented by a single index case, and morbidity-risk figures are to be compared within the sample. Regardless of the advisability of using the same means of computation for penetrance and concordance estimates, however, the number of index cases from concordant pairs is eventually halved in computing concordance rates, in order to correct for the twofold representation of concordant pairs in the sample.[1] With this stipulation, differences between one-egg and two-egg groups of twins will have the same statistical significance whether they are evaluated in terms of concordance or of morbidity expectancy.

## *Procedural Considerations*

Like any other scientific procedure, twin studies have their limitations, hence it would be a mistake to let the method bear the full burden of proof in zealous attempts to isolate multiple and continuously interactive variables.[72] Yet it would be equally inappropriate to belittle the value of twin studies solely on the grounds of some inherent imperfections in applicability.

Twins, as a research species, fall short of perfection. For one thing, they are prone to prematurity and birth trauma and may carry some genes which are sensitive to asymmetrical cytoplasmic influences in the prenatal period. For another, twins cannot be separated before they are born, nor can they be kept in cages. What is more, they are destined to enter a world in which parents specialize in the practice of rearing their own children, so that similar and dissimilar twin partners can neither benefit from nor be observed in entirely different cultures.

Fortunately, once a twin has survived his first year of life without definite signs of organic damage, he is bound to be undistinguished from single-born individuals, even to the extent of having a complete ego of his own. Just as there is no evidence that premature babies are more likely than full-term infants to develop a psychosis, so are there no statistical indications that infections, emotional disturbances, or other tangible disabilities are more prevalent in twins than in the general

Downloaded from www.cbatman.org.in

population. On the contrary, twins are known to vary as much in their personalities, intellectual performances, and stress-symptom thresholds as do single-born people. Compared with the latter, twins have not been shown by any investigator to be less healthy, less longevous, or less selective in regard to their own formula of adjustment.

The popular notion that the behavior patterns of one-egg twins are alike chiefly because of unusual similarity in their early environments has yet to be substantiated. If confirmed, the argument "would only strengthen rather than weaken" correctly formulated genetic theories.[72] No psychodynamic concept is inconsistent with the general biological premise that "heredity acts, in part, by influencing the selection, and in fact the creation, of the environment of the given individual."[100]

In Muller's opinion, another factor should be considered in this respect. As a rule, the tendency of one fetus to gain an advantage over the other is assumed to be stronger in one-egg than in two-egg twins, as the former are more closely associated and more prone to mirror-imaging than the latter. However, since this factor "acts to decrease the resemblances between identical twins more than those between fraternal twins . . . it leads to an underrating rather than an exaggeration of the influence of heredity."

In any case, although the refinement of twin studies may have been somewhat impeded by the complexities of human nature, this method has made it possible gradually to amass a wealth of empirical data which have to be considered in the formulation of every psychiatric theory of fundamental intent. In particular, for a great number of normal personality characteristics, it has been shown that consistent intrapair similarity is not observed in the absence of genotypic identicalness.

Two-egg twins of the same sex tend to differ as much in their personalities as any siblings reared together or apart. It is only in one-egg twins that even pronounced differences in life experiences are not potent enough to erase basic similarities in appearance and general personality traits.

## ¶ Genic Control of Disordered Metabolism and Behavior

Realization that a well-integrated metabolism is a requisite for normal behavior and balanced neurohormonal functioning has assured the strategic position of biochemical genetics in current psychiatric research programs. An important by-product of this development is that genes are now fairly generally accepted as exerting their effects through control of metabolism, their action taking place in the same fashion as that of "any other agent that influences the course of a biochemical reaction."[149] Through the use of experimental techniques in studying specific products of gene action, investigations into the causal relation between gene-specific metabolic deficiencies and disordered behavior patterns have gained in volume as well as in purpose.

In exploring a chain of reactions between the direct activity of a gene and the observable end product, some difficulty arises from the fact that "valid generalizations about these reactions are more likely to concern the initial links than the terminal ones." What has been clearly established, however, is (1) that many mutational changes in biochemical reaction potentials "are due to changes in quantity, quality, or activity of enzymes, enzyme complexes, or other macromolecular systems that undergo specific kinds of chemical combinations and thus cause non-random orientations of molecules"; and (2) that "enzymes and other macromolecules have their specificities determined by direct gene action in which the genes participate by serving as models or templates."[149, p. 188] The question of whether it is always by direct gene action that a specific protein, nucleic acid, or polysaccharide is formed or destroyed has yet to be supported by experimental evidence.

Generally speaking, it can be said that a deviant metabolic chain reaction is apt to be set in motion by a mutant gene effect which produces either a quantitative or a qualitative alteration in one of the many thousand protein

Downloaded from www.dbraulibrary.org.in

varieties in the body. This concept of a faulty link in protein synthesis follows the pattern of Garrod's classical work on alkaptonuria[45] which led to the tentative hypothesis of a 1-to-1 relation between genes and enzymes. Recent developments in the analysis of these "inborn errors of metabolism" have been so rapid and diversified[30, 92, 123] that it is not possible to present more than a few illustrations here.

## *Gene-Specific Defects in Protein Synthesis*

An almost complete loss of the ability to synthesize gamma globulin antibodies (agammaglobulinemia) is produced by a sex-linked recessive gene.[50] The ensuing lack of resistance to bacterial infections is so precarious that prior to the discovery of antibiotics it seems to have caused the death of many affected infants.

A reverse effect of pharmacological advancement has been observed by Dean and Barnes[31] in South African families with a dominantly inherited disorder in the metabolism of pyrrole pigments (porphyria). In these porphyric Afrikanders, painful abdominal attacks and severe emotional disturbances are almost always precipitated by drugs, especially barbiturates.

The action ascribed to the autosomal recessive gene for sickle-cell anemia has been identified as a qualitative change in the synthesis of hemoglobin. Compared with normal hemoglobin, deoxygenated abnormal hemoglobin has a lower solubility which reveals itself clinically in the sickling of red blood cells and is demonstrable electrophoretically. Chemically, the difference between the molecular structures of normal and sickle-cell hemoglobins seems to lie in but two amino acid residues, with the gene-controlled substitution of two methyl groups in sickle-cell hemoglobin for two carboxyl groups in normal hemoglobin.[68, 112, 114] This change of less than 0.1 per cent of the molecular weight of hemoglobin "is sufficient to result in a fatal disease."[122]

Among the many other pathological conditions known to be associated with inherited deficiencies in protein synthesis are hemophilia, albinism, and alkaptonuria.

## *Metabolic Deficiencies Incompatible with Normal Brain Function*

The biochemical deficiencies identified as recessively transmitted causes of intellectual inadequacy have been divided into the following four groups of metabolic disorders: lipids, amino acids, carbohydrates, and pigments.[70]

The first group consists mainly of the cerebral lipidoses and is typified by amaurotic idiocy (Tay-Sachs disease) and gargoylism. A consistent pathological feature is the tendency of the nerve cells throughout the nervous system to be distended with lipid material.

In the second group, which is associated with disordered amino acid metabolism, phenylpyruvic oligophrenia exemplifies a quantitative deficiency of an enzyme protein rather than a qualitatively altered form of the normal enzyme. According to Knox and Hsia,[82] phenylalanine hydroxylase is the deficient protein that disrupts the metabolism of phenylalanine and leads to excessive urinary excretion of phenylpyruvic acid. The degree of mental defect is usually severe and is thought to be the result of a diminished rate of oxidation.

Another well-documented example is Wilson's disease (hepatolenticular degeneration), distinguished by a genetically determined deficiency of ceruloplasmin.[124] Identified as a plasma copper protein with a molecular weight of 151,000, this blue globulin contains eight atoms of copper per molecule. Through its enzymatic properties as an oxidase, it regulates the absorption of dietary copper from the gastrointestinal tract.[125] Apparently, a ceruloplasmin deficiency is followed by an excessive accumulation of copper and its subsequent diffusion through the blood into almost all tissues of the body.

The third group of special mental-deficiency states is associated with aberrant metabolism of carbohydrates. In galactosemia,[62, 69] galactose is not normally metabolized because of an almost complete deficiency of the protein

downloaded from www.dbraulibrary.org.in

phospho-galactose-uridyl transferase. In healthy persons this enzyme is responsible for the conversion in the liver of galactose-1-phosphate to uridine diphosphate galactose.

Similarly, glycogenosis (von Gierke's disease) represents a failure in the breakdown of glycogen, a polysaccharide with a treelike structure.[24] The accumulation of the carbohydrate in various organs is due to a deficiency of a specific glycolytic enzyme (glucose-6-phosphatase).

The fourth group, characterized by altered metabolism of pigments, is represented by Hallervorden-Spatz disease. A slowly progressive muscular rigidity is the outstanding clinical symptom, with the brain showing a gross accumulation of pigment in the globus pallidus and substantia nigra.

The common denominator for all these varieties of gene-specific mental defects is some biochemical mishap, the variations in phenotypical expression depending on external trigger factors. Just as porphyrics may have no acute distress without barbiturates, so sickle-cell anemia patients may be saved from an infarction unless oxygen tension diminishes. Similarly, agammaglobulinemia is not apparent in the absence of bacterial invasion, while the clinical symptoms of phenylketonuria, galactosemia, and Wilson's disease "can be at least partly prevented or reversed by the dietary exclusion, respectively, of phenylalanine, milk, or copper."[123]

Awareness of such far-reaching therapeutic potentialities ought to be sufficient in itself to stimulate further work in all areas of biochemical genetics. This need extends to pathological conditions where the part played by genetic elements is either still unclear, as in mongolism, chondrodystrophy, and the like, or is known to be indirect, as in blood incompatibility between mother and child or an association between certain blood groups and physical vulnerabilities.

## *Biochemically Obscure Disorders of Genetic Origin*

There is no doubt that many remaining neurological and psychiatric disorders are genically controlled and develop from some biochemical deficiency state. In most of them, however, pathogenetic details have not yet been worked out in biochemical terms. The list is headed by a number of clinically severe conditions with gross anatomical lesions and a more or less dominant mode of inheritance. In this group are Huntington's chorea, retinoblastoma, the hereditary ataxias and craniofacial dysostoses, the familial forms of paralysis agitans and hypercholesterolemia, and the dermodysplasias (neurofibromatosis, tuberous sclerosis, von Hippel-Lindau's syndrome).

In the category of presenile brain atrophies, the action of a dominant gene influenced by other modifying genes is considered more plausible in Pick's than in Alzheimer's disease.[130] Recent advances in the genetic analysis of Recklinghausen's disease have at least made it possible to establish the mutation rate of the syndrome as well as the occurrence of somatic mutations.[26]

The scarcity of basic biochemical data is equally pronounced among those disorders which are *not* usually transmitted as Mendelian dominants (autosomal recessive, sex-linked, multifactorial). Here one finds the progressive muscular dystrophies and atrophies, convulsive disease, dyslexia, Leber's optic-nerve atrophy, Schilder's disease, and most genetically determined forms of early total deafness.[75, 77]

In the group of mental disorders with no circumscribed anatomical lesion, no biochemical substrate is known for manic-depressive psychosis (apparently associated with an irregularly dominant disturbance in affect regulation), although various leads exist toward the eventual identification of a genically controlled biochemical basis for schizophrenia and alcoholism. As to compulsive drinking patterns ("alcoholism-prone" individuals), the underlying metabolic deficiency may be traceable to one or more of the following components (found to be significantly different in alcoholic men): serum sodium, serum potassium, serum calcium, blood glucose, urinary creatinine, urinary hippuric acid, urinary sodium, and urinary chloride.[155]

Regarding the biochemical deficiency that

Downloaded from www.dbraunbrary.org.in

may produce the specific potentials of a schizophrenic reaction pattern, the following theories have been proposed to explain the primary vulnerability factor on a genetic basis:

1. Inability of the liver or certain cellular systems involved in liver function (reticulo-endothelial elements) to transform exogenous toxic substances into endogenous protein-bound chemicals (Block, Georgi, Kallmann, Patzig).
2. Inborn error in the phenyl-tyrosine-adrenaline cycle (Fabing[41]).
3. Synaptic inhibition with secondary stimulation phenomena (Marrazzi).
4. Taraxin toxicosis (Heath).

In connection with the phenyl-tyrosine-adrenaline theory, Fabing has pointed out that most of the hallucinogenic (producing hallucinations), psychotomimetic (producing psychotic symptoms), and psychodelic (stimulating the mind) drugs studied in recent years contain the benzene nucleus, either as indoles or as aromatic amines. The remarkable factor is that "the human body, despite its constant and amazing accomplishments in synthesis, cannot make the benzene or aromatic nucleus, except in rare instances where it is locked tightly within the structure of female sex hormones."

The following major areas of current biochemical research in schizophrenia are listed in Fabing's report: (a) adrenal cortex and medulla (Pincus and Hoagland, Funkenstein *et al.*); (b) imidazoles and glutathione (Young *et al.*, Altschule *et al.*); (c) adrenochrome and adrenoxin (Hoffer *et al.*, Rinkel *et al.*); (d) serotonin, indoles, and 5-hydroxyindoles (Eyspamer, Hoffer *et al.*, Woolley and Shaw); (e) aromatic compounds and tryptophan metabolites (McGeer *et al.*, Sherwood, Riegelhaupt); (f) serum copper (Leach *et al.*, Akerfeldt, Abood); and (g) histamine and catechol amines (Lovett Doust *et al.*, Sulkowitch and Altschule).

Although the primary physiodynamic substrate of a schizophrenic psychosis remains veiled in mystery for the time being, there is no overestimating the potential value of successful progress in the search for definitive biochemical correlates of gene-specific deficiency states. With all available facts pointing to complex modes of causation in most psychiatric disorders, it is clear that the prospects for conquering such illnesses will only be brighter after well-planned exploration on the cellular and metabolic levels. In Fabing's opinion[41] it is likely that "our knowledge about exact etiology will come in parts, and perhaps even in bits and pieces."

## ¶ Psychogenetic Twin Data

For a statistical evaluation of the genetic aspects of behavior disorders, only the comparative morbidity-risk data obtained by serial twin studies will be reviewed here (partly because of space limitations). In regard to psychopathological intrapair variations in one-egg twins, it may be re-emphasized that, from a genetic standpoint, unusual behavior of any kind is looked upon as the outcome of a complex and continuous chain of events in the individual's adaptive history, and not as the fixed expression of an unalterable metabolic defect that is always present at birth. Accordingly, the boundary between a normal state of adjustment and those minor behavior deviations commonly referred to as psychoneurotic is only vaguely defined and never static.

In line with this principle, a spirallike development toward marked behavioral dissimilarity, such as has been reported for chronic alcoholism, delinquency, or suicide, sometimes results from an apparently insignificant difference in the original adjustive patterns of one-egg twins.[72, 131, 134] In other words, even the finest genetic endowment can go awry, either because of an unusual combination of adverse circumstances—intrinsic or extrinsic in origin—or because of prolonged abuse. However, extreme disparities of this type are the exception rather than the rule.

### *Psychoneurotic Behavior Patterns in Twins*

As to psychoneurotic reaction potentials, Eysenck and Prell[40] were among the few who

Downloaded from www.vidyapustak.org.in

availed themselves of the opportunities afforded by the twin-study method. They interpreted their findings as favoring the classification of a "neurotic personality factor" as a biological and largely gene-specific entity. The genetic contribution to this "neurotic unit predisposition" was estimated as high as 80 per cent.

Less specific was Slater's[131, 133, 134] definition of neurotic symptoms as exaggerations of polygenically determined personality variants, less closely related to a given type of stress than to the basic personality. Despite "almost identical personality," seven of his one-egg pairs failed to present concordant psychoneurotic histories. Therefore, critical deviations in a person's history were assumed to be due to relatively chance occurrences, such as the personality of the marital partner. For instance, one twin "might suffer a mischance which would lead to a vicious circle of ill-health, social failure, hardship, discouragement and increased ill-health, while the other totally escaped."

According to this theory, the genetic basis for neurotic symptoms lies in graded constitutional vulnerabilities in more than one dimension, that is, "in a number of distinct qualities, each of them subject to normal variation."[94, p. 97] The majority of persons who break down with a neurotic illness are likely to be handicapped by "minor deficiencies along a number of different lines rather than . . . by an extreme deficiency along one line only."

In another twin study (62 same-sex pairs between the ages of twelve and fifteen years), Shields[128] found evidence for one-egg twins (69 per cent) being twice as likely as two-egg twins (31 per cent) to have the same degree of adjustive difficulty. With each child rated "on a four-point scale of psychiatric maladjustment," twins of either zygosity had no higher incidence of neurotic adjustment problems than did single-born controls, but male twins and nontwins far exceeded their female counterparts in presenting adjustment difficulties. Little more than one half the total group of South London school children were classified as nonneurotic. Nongenetic explanations for the observed differences between one-egg and two-egg twins were rejected, perhaps somewhat summarily, especially in regard to the frequent similarities in type and severity of neurotic behavior patterns.

## *Male Homosexuality*

One of the highest one-egg concordance rates reported has been that for homosexual behavior in the adult male.[75] In Sanders' series of 7 one-egg pairs, 6 were found to have been concordant as to overt homosexual tendencies. In the second series, 44 one-egg pairs yielded a nearly perfect concordance rate, with the index cases standing at least midway on the homosexuality scale applied, and with pronounced similarity in the role taken by twin partners in their individual sex activities. In the two-egg group (51 pairs) nearly 60 per cent of the co-twins of predominantly or exclusively homosexual index cases showed no evidence of overt homosexual behavior at any age, and only 11.5 per cent were given homosexuality ratings of 5 or 6 on Kinsey's scheme. Interestingly, all concordant twin partners in this entire series denied any mutuality in overt sex relations.

The most plausible genetic explanation for these findings would seem to be a gene-controlled disarrangement in the balance between male and female maturation patterns, resulting in a shift toward an alternative minus variant in the integrative process of psychosexual maturation. In the opinion of Mayer-Gross *et al.*,[94, p. 178] "there is some genetical basis for the development of homosexuality and some influence is probably exerted also by the attitude prevalent in society and the circumstances of the patient's upbringing . . . the proportional contribution of heredity and environment probably varying not only in different ages and countries, but also from one individual to the other."

## *Mongolism*

Another condition with a well-established one-egg concordance rate of close to 100 per cent is an entirely different defect of more obvious organicity, namely, mongolism, the history of which "presents a pattern of contradictory observations and false hypotheses

Downloaded from www.psychiatryonline.org

that should make all students wary."[8] While discordance was not observed in a series of 6 one-egg pairs,[4] the concordance rate for 23 two-egg twins was so low that it did not exceed the morbidity risk of their later-born siblings (approximately 4 per cent).

The implication of this finding would seem to be that the search for the etiological factor in mongolism has been narrowed down to a more or less permanent change in the mother's endocrine or reproductive system. Apparently, the noxious influence during a mongoloid pregnancy is not transient but acts on a genetically predisposed embryo, or upon the ovum, or upon the embryo prior to the earliest stage when twinning occurs by division. For this reason, and in view of the fact that the relative importance of high maternal age ("long challenged by countless exceptions") is also regarded as adequately substantiated, Allen's[3] present hypothesis is that mongolism may prove to be the result of some unusual type of blood incompatibility between mother and child.

## *Cerebral Palsy*

Serial twin studies have also aided in investigating the etiology of cerebral palsy, for which twins have been shown by the data of Allen (60 twin cases) and Thums (90 pairs) to be rarely concordant.[75] There is a high rate of stillbirth or neonatal death in the co-twins of cerebral palsy cases, but no evidence for a specific genetic susceptibility to prenatal or natal injury. Apparently, many twins with cerebral palsy are survivors of adverse conditions which proved fatal to their twin partners.

The circumstances most likely to affect both twins of a pair include nonspecific maternal and genetic causes, as well as prematurity per se, but probably not mechanical trauma during birth.

## *Convulsive Disease*

The most extensive series of epileptic twin pairs (30 one-egg, 130 two-egg) is that of Conrad,[22] with concordance rates of 66.6 and 3.1 per cent, respectively. Unless plainly repudiated, the results of this study represent strong evidence for the genetic origin of true convulsive disease.

According to Lennox and Jolly,[87] cerebral dysrhythmia is an electroencephalographic expression of the epileptic genotype, assumed to be the result of a dominant gene by the Boston group, and of polygenic factors by Alström.[5] In epileptic twins, 25 per cent of two-egg and 100 per cent of one-egg pairs have been reported to be equally dysrhythmic, despite marked dissimilarities in clinical symptoms.

## *Criminal Behavior*

In the area of criminal behavior, there is still an emphatic need for well-planned cross-sectional and longitudinal twin data. Based on the findings of Kranz,[83] Lange,[86] Stumpfl,[142] and others, criminality concordance rates vary only from 14 per cent in opposite-sex pairs to 54 and 66 per cent in same-sex two-egg and one-egg pairs, respectively. This distribution indicates that both family milieu and basic personality traits play important parts in shaping the habitual criminal. Therefore, the trend toward similar criminal behavior in two-egg pairs may stem largely from the effect of unfavorable environmental influences.

Measured by the same yardstick, concordance in one-egg pairs can often be expected to extend to specific personality features likely to lead to a life of crime (brutality, ruthlessness, predatoriness, irresponsibility), rather than to the particular kind of crime perpetrated. With criminality itself determined in many cases by constellational factors, discordance may occur even in one-egg pairs, where one partner "manages to keep within the bounds of law, while the other having once taken a criminal step remains outside the law and does not find his way back."[133, 134]

## *Manic-Depressive Psychosis*

One of the behavioral disorders that are not sufficiently explained on a situational or experiential basis, one of the least common and most irregularly expressed conditions for which detailed twin data are now available is manic-depressive psychosis.[75] According to twin-family studies, typically cyclic psychoses, if

Downloaded from www.coraljmanh.org.in

diagnosed on the basis of periodic, self-limited mood swings before the fifth decade of life and only in the absence of progressive or residual personality disintegration before or after such episodes, do not occur interchangeably with schizophrenic syndromes in the same sibships or twin pairs. Therefore, the potentialities for a cyclic psychosis are assumed to be genotypically specific and to be somehow associated with an incompletely dominant disturbance in a neurohormonal control mechanism, which ordinarily protects a person from having harmful extremes of emotional responses.

Compared with the general average frequency of manic-depressive psychosis which does not exceed 0.4 per cent (probably because of a reduced reproductive rate of the carriers), there is a difference from 26.3 to 95.7 per cent between the concordance rates of two-egg and one-egg twins. Corresponding family-risk figures vary from 16.7 per cent for half-sibs to 22.7 per cent for full sibs and 23.4 per cent for the parents of cyclic index cases. The affective-metabolic instability produced by the manic-depressive genotype seems to be correlated with predisposing factors for gout, obesity, diabetes, and cardiovascular disorders.

## *Involutional and Senile Psychoses*

Involutional melancholia and other nonperiodic forms of depressive behavior in the involutional and senile periods have been shown by twin data[76, 77] to be unrelated to the manic-depressive group of disorders. Instead, it is indicated by increases of involutional psychoses in the families of schizophrenics, and of schizophrenic psychoses among the relatives of involutional cases, that there is an indirect link with the schizophrenic genotype through certain forms of emotional instability characteristic of schizoid personality traits. The twin concordance rates differ from 6.0 per cent for two-egg pairs to 60.9 per cent for one-egg pairs.

Other disorders in the senescent period may arise either from gene-specific metabolic dysfunctions peculiar to the *senium*, or from an age-specific intensification of long-existing but minor deficiencies in general emotional adjustment. Concordance for senile psychosis varies from 8.0 per cent for two-egg pairs to 42.8 per cent for one-egg pairs.

## *Schizophrenia*

Regarding the interaction of genetic and nongenetic determinants in the etiology of a schizophrenic psychosis, strong evidence has been accumulated in support of the theory that some gene-specific metabolic deficiency is at the root of the disorganizing personality disorder which often leads to adaptive incompetence. In Allen's opinion[2] the potentials of such a disordered behavior pattern may stem more directly from a change in primary gene action than can be assumed for a correlated anatomic defect.

On the whole, schizophrenia occurs in every segment of the human population, regardless of social, economic, or cultural status. It is observed in slums and in the wealthiest families. Variation in its prevalence from group to group is surprisingly limited, at least in the absence of special conditions of inbreeding.

This limitation is true of urban, rural, and primitive communities, of the Hutterites as well as the Swedes living north of the Arctic Circle, and probably even of very special populations, such as people reared in orphanages or those afflicted with total deafness since early childhood. Except for families with a hospitalized case of schizophrenia or an unusual degree of consanguinity, the general expectancy of the disorder is close to 1 per cent (0.9 per cent). This finding more or less precludes a universal species vulnerability, or explanations based on such general emotional group experiences as may be related to dominant cultural value systems or other social-class variables.

The hypothesis that the recurrence of schizophrenia follows selective patterns of distribution has been substantiated by many independent studies. In families with a clear case of schizophrenia, the morbidity risk of the given kinships is not only much higher than that of random population samples but also varies within the family itself. The observed trend is consistently toward an increased frequency of schizophrenia rather than any other type of disorder, with the magnitude of

Downloaded from www.dbraulibrary.org.in

the increase proportional to the degree of consanguinity to the schizophrenic relative. For instance, full sibs (11.5 to 14.3 per cent) have a higher expectancy than half-sibs (7.1 per cent), and half-sibs a higher risk than step-sibs (1.8 per cent). The highest schizophrenia rates are found in the children of two schizophrenic parents (68.1 per cent) and in the one-egg co-twins of an unselected series of schizophrenics.

The difference in concordance between two-egg (14.7 per cent) and one-egg (85.8 per cent) pairs of twins approximates a ratio of 1 to 6, whether the twins lived together or apart. This difference is so significant that it cannot be explained on nongenetic grounds alone.

Parental schizophrenia rates tend to vary from one population to another, according to an adult person's chances of becoming a parent despite certain signs of emotional instability. Under ordinary circumstances the majority of schizophrenic hospital patients, both early and adult cases, have been found to have nonschizophrenic parents (87.5 to 90.8 per cent). While every region has its quota of schizophrenic mothers whose children are normal, there are very worthy parents with a schizophrenic child. The observed schizophrenia rates for the parents of representative samples of schizophrenics approximate 10 per cent, and there is no significant difference between the morbidity rates of fathers and mothers.

As to the morbidity risk for the offspring of matings between one schizophrenic and one nonschizophrenic parent, it has long been established that the expectancy is close to 16 per cent and depends largely on the biological qualities of the second parent.[73] However, the question of how to designate a mode of transmission that seems distinguished by a specific unit factor for the entire syndrome, plus a number of modifying genes responsible for the variable clinical expressions of the main genotype, is more or less a matter of semantics.

For several reasons it still seems appropriate to interpret the main adaptive defect in a potentially schizophrenic person as the result of a basically recessive unit factor, although it is quite irrelevant with respect to the over-all genetic theory whether the given main gene is classified as primarily dominant or recessive, or fails altogether to show simple segregation ratios. The modern concept of human heredity does not hinge "upon the counting of simple Mendelian ratios,"[2] and it seems that most pathological conditions in man are neither fully dominant nor completely recessive, but only relatively so, depending "upon the facility with which the trait is detectable in the heterozygote."[63]

The really important point is that, regardless of whether or not all heterozygous carriers of such a mutant gene might react abnormally if placed under sufficient biological stress, the genetic potentials of a schizophrenic behavior pattern are highly specific and associated somehow with a basic integrative deficiency. Clinically, it is of particular value that the varying phenotypic expressions of this deficiency apparently depend on the type and degree of constitutional defense reactions that can be mobilized against the gene-specific vulnerability to stressful life experiences.

## General Eugenic Considerations

The deeply rooted reluctance to recognize genically determined elements in the etiology of mental illness will inevitably have harmful consequences. The common denominator for damaging trends of this kind may be seen in the toleration or promotion of general attitudes that are liable to divert attention from important public health issues.

Apparently, the tendency to de-emphasize genetic factors as potential causes of behavior disorders is an occupational hazard of all mental-health professions and is older than psychiatry itself as a social phenomenon. Whether accomplished by fiat or the Promethean power of allegoric expression, this tendency easily grows into a habit. While it may be obscurable by fluid levels of abstraction, it is sufficiently potent to deflect much investigative and therapeutic effort. Hence, neither conceptually nor for purposes of guidance, can the resultant attitude be expected to be of real help.

Aside from harmful omissions in treatment and family guidance, damage may be caused

Do not reproduce www.drahmadmary.ir

by disregard of two general genetic phenomena: (1) the hazards of a gradual increase in the number of poorly adapted carriers with a chance of reproduction, such as may result from assortative mating trends and improved medical techniques; and (2) further increases in the mutation rate of populations due to excessive use of ionizing radiation.

The theory that an increasing load of mutations in future generations will be the penalty for relaxing natural selection by medical advances has been supported by many genetic experts.[7, 25, 30, 51, 99, 102] It is based on the estimate that the average person is heterozygous for at least eight genes of a specified variety. Under the conditions of equilibrium prevailing for present gene frequencies, there would be an effective genetic loss in the population of 20 per cent, resulting from the total of these "more or less familial patterns of weaknesses."[102]

With a large part of this segment apt to be salvaged for reproduction by modern medical procedures, the frequency of mutant genes will inevitably rise to a new level. Accentuated by the accumulation of gene-specific disabilities due to ionizing radiation, the adverse consequences for future generations may reach a point where the population's survival is threatened.

General public health measures for the prevention of such hazards will require the organization of "much more systematic research about all kinds and all levels of genetics"[21] as well as the foresight implicit in a concern with the health of future generations. Beyond doubt, real progress in this direction will also enhance the understanding and management of the genetic aspects of mental illness.

CHAPTER 9

# THE PSYCHIATRIC INTERVIEW

Ian Stevenson

Downloaded from www.dbraulibrary.org.in

THE PSYCHIATRIC INTERVIEW as practiced in most American psychiatric facilities has undergone a marked change during the past fifty years. Formerly, a question-and-answer type of interview satisfied the requirements of psychiatric interviewing, as it did and still does satisfy those of medical history taking with regard to exclusively physical illnesses. But the modern psychiatric interview, although it includes questions, puts much more emphasis on a free-flowing exchange between the psychiatrist and the patient. This alteration in our practice has resulted from changes in the kinds of information we want about patients and in our ideas of how we can best obtain this information. We also have learned the limitations of verbal communications. We now notice not only what the patient says but his manner of saying it as well, for this may show what his words conceal. And we have learned that, when two people talk together, what they say depends not only upon what they want to tell each other but also upon what they think of each other. In what follows we shall discuss first the information a psychiatrist usually wishes to obtain in an initial interview, next how the psychiatrist's relationship with the patient influences what the patient tells him, then the psychiatrist's optimal attitude and some techniques which can increase the yield of an interview.

The theory and technique of psychiatric interviewing both receive attention, although to be sure not as much as they should, from American research psychiatrists. We may hope that from their efforts will emerge changes fully as great as those which the last fifty years have brought. This will require, among other things, that each of us challenge constantly his own habits and remain unwilling to practice, for the rest of his lifetime, only whatever his teachers have taught him.

We shall discuss the psychiatric interview chiefly with regard to the initial evaluation of a patient. Sometimes we can achieve this in one interview, but quite often we need several. Moreover, the initial interview or interviews should blend with the psychiatric examination.

The following chapter discusses the psychiatric examination and the methods of including part of the examination in the psychiatric interview and of making a transition from the interview to the more definitive examination (Chap. 10).

## ¶ What the Psychiatrist Wants to Learn

The psychiatrist should learn first what the patient usually most wants to tell, namely, a description of his symptoms and the story of their onset and progress. After this, the importance of life stresses in precipitating mental illness requires a detailed review of the patient's current environment. The discussion of this can lead easily into talk about the patient's early environment and thence toward his family history. From this may naturally follow an account of the patient's own earlier life—his personal history.

Most psychiatrists understand the importance of eliciting this material in initial interviews, and only two items deserve further emphasis. First, much importance must be attached to a detailed account of the patient's symptoms. We should try to imagine what the patient has experienced and now experiences. We should try to see the world as he sees it, but we can do this only if we let him talk to us in great detail. Moreover, many psychological symptoms require study not only as direct experiences of the patient but also with regard to the purpose they serve the patient in adapting to other people or to other forces within himself. In short, we enter into detail so that we may know both what functions are disturbed and how these functions relate to others. Secondly, the study of the patient's current environment must be emphasized. Although we all recognize the importance of major life stresses in precipitating mental illnesses, we often neglect, to our and the patient's disadvantage, the careful study of how the patient lives. Only by entering into his daily life, as it were, can we come to appreciate the subtle but cumulatively powerful relationships between the patient and others close to him. And usually only such an appreciation will permit us to dissect the respective contributions of the patient and those around him to the strain he experiences.

While listening to the history, the psychiatrist should attend not only to the bare facts of peoples, places, and events as chronicled by the patient; he must study, no less, the meaning of these events for the patient and the attitudes which the patient showed to them then and, if those have changed, the attitudes he now shows toward them. In studying attitudes the psychiatrist must include, additional to the patient's words, observations of the patient's emotions.

There is another important reason for observing the patient's emotions as he talks. The psychiatric interview begins and includes much of the psychiatric examination. The patient's recital of his complaints and his history contributes valuable data about the illness. But that illness is a product (in most instances) of the action of stresses on sensitivities. The psychiatric interview should therefore study the special sensitivities and vulnerabilities of the patient. As the patient talks, the psychiatrist should scan him and his remarks for signs that certain events or topics are of special importance to him. The signals which reveal such events or topics deserve a brief review.

One may ask the patient directly about the events, people, and thoughts which bother him most. More often than is usually done, we should ask for this information directly. At the same time, we should remember the frequent, almost invariable, inability of patients to give a direct and complete answer to direct questions. In studying physical illnesses we can ask patients about the occurrence of nausea, bloody stools, or swollen feet and usually expect reasonable and valuable answers. But we cannot ask a patient to tell us about his marriage, his parents, or his employer and expect that the words he returns us can alone contain all we need to know. Several factors are responsible for this difference. In the first place, our society strongly emphasizes the importance of other persons having a good opinion of us. For psychiatric patients this becomes especially important, since they usually think poorly of themselves and have become doubly dependent upon approval by

Downloaded from www.dhtaihuaravi.in

other people. When a patient finds himself in a psychiatrist's office, he has additional reasons for winning and preserving the favorable opinion of the psychiatrist. Consequently, with his words he attempts to portray himself (unless he is very depressed, or self-effacing) as a person who is in all respects lovable and "normal." Secondly, even the patient with the greatest candor has within himself large and important aspects of mind and behavior which lie quite outside his awareness. With the best will in the world, he cannot tell what he does not know about himself. And finally, even if he knew much more than he does, words would still furnish only a feeble channel for the communication of life's richest experiences, both of suffering and of happiness.

Working against these limitations of verbal communications, the psychiatrist fortunately has other clues to what he wants to learn. These lie in the various signs of emotion shown by the patient as he talks, for our most important experiences become bound to emotions, or, more accurately, they become important because they affect us deeply.

Emotions show themselves in many and sometimes unexpected ways. The patient's arrangement and manner of presenting his verbal statements reveal much. The psychiatrist should note what the patient says first (both at the beginning of an interview and subsequently in response to questions), what he talks about most, what he returns to many times, and what he omits or glides over quickly. Thus the psychiatrist needs to learn what the patient specially wants to talk about and what he specially wants to avoid talking about. Unusual speed of speech, hesitations, blockings, amnesias, and confusions all deserve attention as signs of emotion and, hence, clues to the significance of events or topics. The order of the patient's remarks deserves attention, and especially the connections of thoughts associated in one sentence or adjoining ones. Verbal associations betray affective links.

The psychiatrist should notice changes in the pitch and timbre of the patient's voice as he talks. Such changes express alterations in the tensions of skeletal muscles, of which many other indications can appear in the patient's face and limbs. Accordingly, the psychiatrist should watch for the play of emotion in the patient's face, in the posture of his body, and in the movements and gestures of his limbs.

Changes in the patient's viscera deserve equal attention, for emotions affect the autonomic nervous system as markedly as the central nervous system. The special apparatus of physiology has revealed the occurrence of many important visceral changes during emotional disturbances. Not many of these lie exposed to the unaided eye of the interviewing physician. Nevertheless, he may notice changes in the patient's breathing and in his heart rate, observed, perhaps, in the beat of the carotid artery in the neck. He can notice flushing and pallor of the face and sometimes perspiration. The patient's mouth may dry up, or tears may glisten in his eyes. During an interview, emotional changes may bring (and sometimes remove) the patient's symptoms. Thus palpitations may occur, or a headache may disappear. A patient with a psychophysiologic skin reaction may scratch a tender spot on the skin when the conversation touches something tender in his mind. Each patient has his own special mode of expressing his emotions, almost as characteristic as his gait or his fingerprints. Some patients, for example, rub their eyes, others glance swiftly away from the interviewer, and still others swallow whenever they experience anxiety. The psychiatrist should watch the patient for characteristic traits especially in the early parts of the interview, partly because the patient is then usually most anxious and partly because the psychiatrist can use what he then learns to identify moments of anxiety later in the interview.

The identification of an important emotion only begins its study by the psychiatrist. With techniques described later, he should try to open a further discussion of the topics which have evoked the emotion, although he may often defer this to a more appropriate time. In that discussion he wants to learn in what way this topic is important to the patient and how it became so. Exactly what thoughts does the patient have about the event, person, or topic which cause these strong emotions? The

Downloaded from www.pdfbooksfree.pk

psychiatrist cannot consider that his study of an emotion is complete unless he has elicited from the patient the details of the accompanying thoughts. For this he returns again to the patient's words through which alone (outside art) the patient can communicate his thoughts.

The detection of emotion during the psychiatric interview contributes to the examination of the patient which, as already mentioned, starts at the beginning of the interview and indeed cannot and should not be separated from it. During the interview the psychiatrist has ample opportunities to examine other aspects of the patient's mental functioning, as described in the following chapter.

A final purpose of the psychiatric interview is the evaluation of the patient's readiness for psychiatric treatment and efforts to improve this when necessary. Since this properly belongs to psychiatric treatment, it is mentioned here without further discussion. But the psychiatrist should remember it during his interviews. Although his assigned tasks may resemble those of a juggler keeping five balls in the air, unless the psychiatrist can accommodate in his technique a study and strengthening of the patient's motivation for treatment, he may conduct a superb interview which leads to nothing.

## ¶ The Physician-Patient Relationship

As mentioned earlier, the patient's wish to tell his story is frequently obstructed by his wish to win and preserve the psychiatrist's approval and assistance. This interference is experienced by all patients to some degree. But each patient varies from every other one in the experiences which have led to this shielding of himself and to other behavioral patterns. And each psychiatrist differs from all others in his capacity to stimulate or reduce such patterns in his patients.

When the patient was a child, like everyone else he learned from experiences what to expect that his parents (and other people) would do. He then generalized many of these expectations, learned with certain persons, to guide his behavior with other persons. Sometimes his generalizations guided him correctly, at other times inappropriately. A dog conditioned to respond to a sound with a frequency of 512 cycles per second may respond (unless carefully trained) to a range of sound say between 475 and 550 cycles per second. The more careful and prolonged the conditioning, the more discriminating will be the dog's response to different stimuli. But his discrimination may weaken under stress or without proper reinforcement. In much the same way, humans may discriminate poorly as well as correctly. They may respond to physicians as if these were duplicates of their parents. Such misperceptions on the part of a patient never occur first with regard to the psychiatrist; on the contrary, they have happened often before and have contributed importantly to the patient's difficulties with other people. But the psychiatrist should especially notice how the patient perceives him, first because he can study this directly instead of depending upon observations of other people, and secondly because the patient's perceptions of the psychiatrist furnish important clues to his difficulties with other people.

The more closely the psychiatrist resembles the significant persons of the patient's earlier life, the more he will be likely to evoke the behavior in which they trained the patient. (The frequency of 512 cycles per second stimulates the conditioned dog, mentioned above, to the greatest extent, even though he may respond to a lesser extent to other frequencies.) Suppose that the psychiatrist, after studying in advance a portrait of the patient's father or better still a moving-picture sequence, should carefully disguise himself in appearance and manner to resemble the patient's father. We could hardly blame the patient for responding to the psychiatrist-actor as if somehow his father had wandered to the psychiatrist's office and sat behind his desk. After a moment of initial surprise, the patient would engage in conversation, so he would believe, with his father. Now suppose that the disguise has been arranged very poorly, that, in fact, the psychiatrist has put on a mustache like the father's but does not shave his head to a similar baldness or imitate the father's gruff voice or smoke

Downloaded from www.dbsurbur.org.in

cheap cigars. If, then, the patient still acts as if the psychiatrist is his father, the psychiatrist would have important evidence of poor discrimination.

By partially resembling earlier persons in the patient's life, the psychiatrist may stimulate the conditioned reflexes of his patients in many ways. Each deserves brief mention here and much attention in the interviews. First, as already mentioned, the psychiatrist's physical appearance influences the patient's responses. The psychiatrist's sex and age, especially, but other features of appearance hardly less, strongly guide the patient in thinking what it will be useful or safe to reveal. Secondly, the patient responds to the social role of the psychiatrist as he conceives it. In this he mingles his concept of the role of the physician. Two features usually blend: physicians have authoritative roles in our culture, with power to recommend and execute drastic treatments or to commit to certain hospitals. This aspect of our work leads the patient to confuse us with policemen, sergeants, judges, teachers, and, most important of all, with fathers. But physicians also have a role of succoring the sick and weak; in this connection a patient frequently achieves a mental montage of a physician and his own mother. Thirdly, our behavior may also stimulate, in the patient, patterns of behavior laid down in earlier experiences. Some of this behavior derives from our professional work. We ask questions and so we may remind the patient of his mother, who always asked her little boy pressing questions, requiring painful answers, when he came home from school. However, some of what we do our work does not require and may indeed be better off without. Thus suppose we, like the patient's mother, have an inordinate preoccupation with sex, and we question the patient excessively about this. He may then react strongly, although not necessarily irrationally.

In all these various ways the psychiatrist may evoke behavioral patterns in the patient which can partly, or sometimes entirely, interfere with that part of the patient which perceives the psychiatrist as a helpful expert to whom he should tell his story. Patients vary greatly in their capacities to see the psychiatrist as he is and to avoid confusing him with other people. If the psychiatrist is to study the patient's discrimination, he not only must attend to the patient's behavior but must also learn as much as he can about himself. If the patient falsely attributes a mustache to the psychiatrist, the psychiatrist can only evaluate the possible misperception in this if he can recall whether he himself has shaved during the last few days. He must know what he himself brings as stimuli into the interview. He must remember that the patient responds both to what the psychiatrist does and to what he is.

A physician-patient relationship is clearly not fixed or capable of permanent description. It is a shifting complex of behavior which includes changes in both patient and physician. The patient does not necessarily continue in his misperceptions of the psychiatrist, and his speed of correcting them furnishes an important point of prognostic value. During their further contacts, psychiatrist and patient have the opportunity to correct their initial and frequently false categorizations of each other. If first impressions repel, they may discover —with the ever-fresh pleasure this brings— that each is, after all, rather a pleasant person once one gets to know him a little. More often, first impressions attract, because each shows socially conventional behavior. In a new situation our behavior at first tends to conform to the social roles we believe the situation assigns to us. Afterward, closer acquaintance may bring to the fore traits at first concealed. For, with growing intimacy, there emerge various patterns of behavior learned in the less uniformly structured experiences of the family. Thus it happens that, after a time, the psychiatrist does something or fails to do something which frustrates one of the patient's expectations of him, or he may offend in many such ways. These events he must also study carefully.

The usual initial positive attraction of psychiatrist and patient for each other is largely sustained by their fantasies of what each can expect from the other. When the fantasies yield to closer inspection, and when, at the same time, intimate behavior begins to replace

Downloaded from www.dbraylibrary.org.in

more formal behavior, the relationship may weaken. At this point, one factor alone saves most physician-patient relationships from dissolving. In the time taken for the patient's irrational expectations of him to collapse, the psychiatrist has a chance to show, one should not say to display, his real professional competence. Then, as the patient learns that the psychiatrist is not what he first thought him to be—perhaps a doting mother or an eternally patient father—he may discover that the psychiatrist, as a helpful physician, can now contribute even more than the mother or father. This transition from a tenuous relationship based on fantasy to a firm one based on an experience of competence demands that the psychiatrist offer the patient something considerably more than he can find in ordinary social intercourse. The following sections of this chapter offer suggestions concerning the content of this "something."

The importance of the physician-patient relationship in influencing what the patient will tell the psychiatrist and what the psychiatrist should tell the patient requires that the psychiatrist constantly evaluate this relationship. He should note how readily the patient talks and all other behavior of the patient toward him. Psychiatrists notice minutiae of social conduct—for example, punctuality, hesitancy in smoking, deference in going through doors—which would and should be overlooked or not noticed at all in other situations. But in an interview psychiatrists should observe all these items of behavior as clues to the attitudes which such behavior expresses. The psychiatrist should also help the patient to use any opportunity which arises to state what he thinks of the psychiatrist. In initial interviews most patients cannot achieve much candor in such comments. The psychiatrist can usually expect conventional formulas. But often, and even in guarded remarks, the patient may say something revealing and relevant. In drawing out the patient's thoughts about ourselves, if we press the patient artificially we will usually only increase his conformity to socially acceptable platitudes. Natural opportunities will arise, however, which we can exploit. If the patient has referred himself or chosen the psychiatrist from several, we can ask him, "Why did you select me to consult?" If he generalizes about physicians or psychiatrists, we can say, "Are you including me in that?" Later, the special value and importance of the patient's discussing his thoughts about the psychiatrist, whenever the patient becomes excessively anxious, will be discussed.

## ¶ The Optimal Attitude and Behavior of the Psychiatrist

We should often ask ourselves in what ways we can be of more use to our patients than even their best friends can be. The difference may lie principally in the degree to which we show a friend's helpful qualities and, most of all, in the tenacity and patience which permit us (and the best of friends) to sustain a relatively stable relationship with another person over a long period of time. In addition, four other qualities for the psychiatrist—interest, acceptance, detachment, and flexibility—are recommended.

For his task the psychiatrist certainly requires interest in the patient and in his difficulties. This interest can include to a degree the biologist's curiosity about the wonders of living organisms, yet we cannot allow ourselves to become so preoccupied with the details of morbid anatomy and physiology that we lose interest in the whole patient. Our specialty particularly concerns itself with the responses of the whole man. Our interest should be in the patient and for the patient; it should not pursue, disguised as diagnostic fervor, our own special predilections and curiosities. We can rarely prevent these entirely from interfering with our guidance of interviews, but we can at least strive to become aware of ways in which our interest in ourselves may mingle with our interest in our patients. The interest we show in patients should include, and chiefly derive from, an attempt to understand them. Our limited success in this task may matter less than our efforts to try and to improve. We know that a fumbling medical student may learn much from a patient in a psychiatric interview. At present there is so little difference

Downloaded from www.dbraulibrary.org.in

in skill between the worst and the best of us that we must rank the wish to understand as hardly less important than the understanding. At any rate, patients respond well to both. Finally, our interest should always include attention to the assets of the patient as well as his deficiencies and difficulties. To this aspect of our interest patients also respond favorably, and with it we may help them to tell us more freely about their sufferings.

The psychiatrist should next try to reach a capacity for complete acceptance of his patients. Our profession does not ask that we approve all that our patients do or abandon our own ethical principles in favor of moral relativism. But we do improve our skill when we can accept patients unreservedly, regardless of what they may say or do which would be quite offensive in another context. Just how offensive people can be, the psychiatrist has a better chance than anyone to learn. But he also can learn more easily just how important it is to all of us to gain and hold the affection of others, despite our shortcomings. Here we can often be of more help than the patient's family and friends. Because they frequently have become alienated by his behavior or their own, so that the patient believes himself to be without the friends we all need, we should have the deepest reservoirs of kindness.

If the psychiatrist does surpass the performance of family and friends in this regard, he often owes his success to the cultivation of a third quality required in his work. We may call it detachment, separating this sharply from the aloofness with which it has sometimes been confused. Because we live outside the circle of the patient's family and friends, we are not so closely—and hence so emotionally—involved in the patient's difficulties as they are. What the patient does cannot affect us so much. It should affect us somewhat, or we would not want to help him or be capable of doing so, but it must not affect us to the extent that the strength of our emotions disturbs our judgment of the patient in the manner that the strength of his emotions has disturbed his judgment. His anxiety prevents him from thinking clearly. He needs a less troubled mind to help him correct his misperceptions and faulty reasoning. Here, again, we can establish maxims more easily than we can follow them, and for this reason among many psychiatrists should know themselves as well as they can.

Every internist taking a history and performing a physical examination finds that he omits less if he follows a routine order of procedure. The psychiatrist's study of his patient should be equally thorough and usually must be longer. But the psychiatrist cannot afford to impose a rigid form on his interviews and examinations. Although careful to think and ask about everything which might relate to the patient's symptoms or difficulties, he should not expect always to learn things in the same order. Nor should he expect ever to learn the same things in every interview, for different symptoms require different emphases in the discussions. Lack of space prohibits a review here of some of the common variations in interviewing which occur with, for example, patients who have depressions, hypochondriasis, schizophrenia, anxiety states, and psychophysiologic reactions. For these variations alone, flexibility becomes another desirable attribute of a successful interviewer, but he also needs this quality especially to ride over the resistances within the patients which often prevent their talking freely about many important topics. Some patients can talk easily about their wives but dare not discuss their parents. Others may pour out a cataract of information about their parents and close up like a bank vault when the psychiatrist inquires about their wives. Infinite variations occur in such resistances, but the physician can nearly always count on finding some. Fortunately, time helps the psychiatrist. Talking itself predisposes the patient to further talking. If the physician yields at first to the patient's reluctance to talk about certain subjects, he can keep the patient discussing other topics and thus prepare him eventually to return to the previously avoided material. This is not to say that the patient should be permitted to seize and retain control of the interviews. On the contrary, the physician should preserve guidance throughout and, if necessary, make his guidance explicit to the

Downloaded from www.dbraulibrary.org.in

patient, but he should not use his skill and power to confront the patient prematurely with subjects which are seriously disturbing. This can trouble and even shatter the developing positive attraction of the patient for the physician. The flow of the patient's remarks is sometimes delicately balanced between the wish for help and the fear of injury at the hands of those to whom he gives his confidence. If he experiences painful emotions too much and too early, he may (not unreasonably) confirm his expectation that he could be hurt, even though the interviewer said nothing intended to hurt him. We all turn away from pain and often also from those with whom we associate the pain, even when they have tried to help us. And so the psychiatrist should let things come gently and naturally, perhaps taking this lesson from skillful obstetricians.

## ¶ The Technique of Interviewing

### *Arrangements for the Interview*

In any interview, stimuli reach the patient not only from the physician but from the entire setting in which it takes place. The psychiatrist will find worth while a study of the setting of his interviews even if, and perhaps especially if, he cannot change the setting. Privacy and reasonable comfort for the patient and the physician are absolutely essential. A separate room best assures complete privacy, but not if telephones ring and secretaries run in and out. A public ward, with its chatter and other hubbub, gives more privacy than a semiprivate room. Bright precinct-station lights should not blind the patient as he talks. The physician and patient should preferably sit so that each can look at the other without having to do so continuously if they prefer not. The psychiatrist should reserve enough time for a satisfactory interview. In the present state of our knowledge, anyone who does not reserve at least forty-five minutes or an hour for an interview identifies himself as practicing some psychiatric formula which does not include listening to patients. Brief interviews may have their place in medicine, surgery, and even in certain authoritative and directive psychotherapies, but they have no relevance to diagnostic and therapeutic psychiatric interviewing at its best. (A later section will discuss reasons for this.) Moreover, one interview even of the length suggested rarely suffices for a thorough exploration of the patient's difficulties, and the psychiatrist will usually have to arrange for several further meetings.

The psychiatrist should always make notes after or during an interview. Apart from the value of having some record of the talk, the process of making notes passes the material through the mind of the psychiatrist again and thereby adds to his study of it. If he makes his notes during the interview, he should be reasonably certain that the note taking does not interfere with his own spontaneity. Some psychiatrists can pass this test, others cannot. And he should also be certain that the note taking does not trouble the patient. About this he should not necessarily expect to hear from his patients, many of whom will communicate their objections indirectly rather than with words.

### *Starting the Interview*

As patient and psychiatrist meet, the initiative lies with the psychiatrist. He should introduce himself, lead the patient to his office, offer him a chair, and start the conversation. One can begin well enough with a brief introductory statement such as, "I know about you only the little which Dr. X told me. So it would be best for you to tell me in your own words what troubles you." After this the physician should usually remain silent until the patient's first responsive flow has dried up. He can soon tell whether the patient can talk freely or needs additional help. If the patient needs help, the physician should give it promptly, not letting the patient bathe in the sweat of tense silences. Sometimes the patient does not know what he should give in the way of a history. Since psychiatrists do ask for kinds of information different from that required by internists and surgeons, the patient may simply need a little guidance. Sometimes the patient's

Downloaded from www.pdfbooksfree.pk

anxiety mounts so high that it blocks his free expression. In that case the physician can channel the conversation into something less painful to the patient. Often, he can reduce the patient's anxiety by asking questions which free the patient of the fear that he will say too much and of the responsibility for giving emphasis to important topics. Later, the patient may relax enough to talk freely. If such measures fail, often the psychiatrist should ask the patient about his anxiety and should suggest possible origins of it in order to encourage further expression. He can say, for example, "You seem frightened. Can you tell me what makes you so?" If the patient still blocks, the physician can suggest, "Perhaps you are afraid of how I will react to the things you may want to tell me about. Is that so?" The patient may then respond by verbalizing the origins of his immediate anxiety and can then continue with other parts of the interview.

Once the patient has begun to talk, the physician's task consists in helping him to talk freely and in guiding him to speak about the most relevant topics. These will be discussed separately, although in an interview they naturally intermingle.

## *How to Help the Patient Talk Freely*

If the physician has a strong interest in his patients, he can influence most of them to talk freely, because everyone talks better to an interested listener than to a bored and reluctant one. The awareness of the psychiatrist's interest reinforces the patient's wish to talk and his conviction that the psychiatrist merits his confidences. It may often be difficult to listen without interrupting. The psychiatrist's other medical training frequently impels him to intrude a question about a date or place so that he is sure to know all the data. Or something the patient says may infect him a little with the patient's anxiety or depression. Then he can quite unconsciously deflect the patient from such sensitive topics (for him more than for the patient, perhaps) by asking the patient about something else. Or the patient's depiction of his suffering evokes in the psychiatrist a natural wish to reassure, and he applies a soothing but gratuitous remark to alleviate the patient's fears. All these tendencies he must try to resist. He will not always succeed, because of severe temptation, but the effort to keep silent and to let the patient talk freely will make him a better interviewer. Each little interruption in itself may seem trivial, and usually is, but each adds to a cumulative effect on the patient which tells him "The doctor wants something from me. What is it? How can I tell him what he wants to know?" When patients become occupied in giving us the information they think we want, they can easily forget to tell us what they want and need to say, of which we as yet know nothing. Every time we let the patient talk as he wishes, we encourage him to say something else which, perhaps up until that moment, he thought he ought never to confide in anyone.

In addition to interrupting the patient's line of thought, the interruptions by the psychiatrist also tell the patient more about the psychiatrist. There are advantages to the patient's knowing rather little about the psychiatrist; the less he knows, the less he can censor what he says in accordance with the assumed attitudes of the psychiatrist. This may make for a freer revelation of the patient himself.

Should the psychiatrist then always say and do nothing as the patient talks? Certainly not. He should say and do whatever becomes necessary to sustain the patient's flow and to guide it. Silence may suffice, or it may not. Sooner or later, some further responses become necessary or additionally helpful. In offering these, the psychiatrist may move from silence toward levels of increasing activity, each designed to emphasize to the patient a little more strongly his wish to hear more. Thus grunts of "uh-uh" and leaning forward expectantly stimulate the patient a little more, or sometimes much more than silence. If such gestures prove inadequate, the psychiatrist can questioningly repeat the last word or phrase of something the patient has said. After this come gentle urgings such as, "What happened then?" "Go ahead," and "I'd like to hear some more about that." Should these fail, and assuming that the patient knows in general what he should talk about, his anxiety toward

Downloaded from www.cbmulibrary.org.in

the psychiatrist has probably interfered too greatly. The psychiatrist should then bring this into the discussion directly, help the patient verbalize it, and, if necessary, apply appropriate reassurance. Thus he can begin by saying, "Something makes it hard for you to talk to me about this matter. Can you tell me what it is?" Often the patient will respond satisfactorily to such leads. If not, the psychiatrist should suggest possible misperceptions of him by the patient (as in reducing initial anxiety mentioned above). He can say, for example, "Perhaps you are afraid of what I will think of you?" If all such efforts to loosen the patient's tongue fail, the psychiatrist's task usually includes pointing out to the patient his share of responsibility for their difficulties in talking. The psychiatrist might say, for example, "We have to work together on this, I'm sure you know. It's a collaboration between us, and I can do little for you unless you can tell me more about yourself." At this point the psychiatrist may learn of the patient's distrust about the privacy of his communications. On this matter and other similar doubts, the psychiatrist should provide firm reassurance based on actual performance. He should not, for example, assure the patient that what he learns from the patient goes no further and then schedule an interview with the patient's parents without the patient's knowledge.

With this repertoire of techniques increasing serially in stimulating the patient to talk, when should the psychiatrist use his influence? I believe he usually needs to increase his activity in the following circumstances: to show his interest, to reduce the patient's anxiety, to encourage the patient's emotional expression, to control garrulity and irrelevance, and to channel the interview toward topics of the greatest importance. I will defer discussion of the last two of these to a section on guiding the interview, but the first three pertain to helping the patient talk freely.

Some psychiatrists have more interest in their patients than they show. I think young psychiatrists are especially liable to make this error when they mistakenly apply, in initial interviews, the silence which is conventional and sometimes helpful in certain psychotherapeutic techniques. In attempting to stay out of the patient's way, a psychiatrist may say so little as to give the patient the impression he is mute. Some studies have shown that many patients leave psychiatrists after one or two interviews because they do not understand and become alienated by the psychiatrists' unresponsiveness to them. Most patients have already received training by internists and surgeons in the question-and-answer method of history taking. They may misinterpret excessive silence on the part of the psychiatrist as simple incompetence. Moreover, previously important persons have often communicated aloofness, indifference, disapproval of, or even anger toward the patient by means of silence. The patient may confuse the psychiatrist with these persons, and, if so, the interview can perish, or it can become unnecessarily uncomfortable for the patient as well as less productive, since anxiety interferes with thinking and with expression. It makes sense, therefore, for the psychiatrist to remain silent if he can and needs to do no more, but also to offer freely whatever signs of interest the patient seems to require. Such additional communications of interest he can easily insert often enough with nods of the head, with "uh-uhs," or with simple words such as, "Surely," "Naturally," "Of course," and "I see." Words matter less than attitudes. With a friendly attitude we will find the right words, expressing them in a gentle speech and with a kind face. The psychiatrist should also offer, from time to time, more explicit signs of his understanding of what the patient did or felt with remarks such as, "I can see how hard that must have been for you," or "That must have made you feel better." Remarks of this kind should articulate what the patient has rather clearly expressed and should not influence him to agree, against his own knowledge, with the psychiatrist's interpretation of events. When the psychiatrist does not understand what a particular experience meant for the patient, he should usually inquire further, but when he does understand, if he will occasionally echo what the patient says he can lubricate the interview.

Experience will teach the psychiatrist the

Downloaded from www.dbpublishing.org.in

level of anxiety proper with each patient for a flowing interview. When a patient's anxiety becomes too great, the physician should try to reduce it by some of the techniques mentioned earlier. As already mentioned, excessive anxiety during an interview usually derives from misperceptions of the psychiatrist as being more menacing than he is. Anxiety felt by the patient with regard to other persons drives him to talk, while anxiety felt toward the psychiatrist blocks his talking. The psychiatrist should generally try to reduce or keep minimal the patient's anxiety toward him in initial interviews. Certainly, he should note it and may subsequently wish to allow its full exposure, but if the patient becomes very anxious with regard to the psychiatrist before a strong attachment has developed, he may block harmfully or fail to return. Since the patient nearly always hungers for the psychiatrist's approval, his anxiety toward the psychiatrist can often be easily reduced by encouraging and praiseful remarks with regard to the patient's exposition of his difficulties. For example, the psychiatrist can say, at a moment when the patient hesitates and looks inquiringly at him, "Go ahead, you're doing very well. Keep going the way you were."

Yet we need to remember also that anxiety can run too low in an interview. Physician and patient can unwittingly exclude the patient's anxiety from expression and agree that he is much better than he (or a referring physician) thought he was. This comes about when the human wish to reduce human suffering urges the psychiatrist to offer reassurance prematurely. In doing this, the psychiatrist deprives himself of the opportunity of tracing the patient's anxiety to its specific origins. For example, suppose a patient says, "Doctor, I think I am going crazy." To this the psychiatrist can immediately reply, "Oh, no you're not. You don't have the symptoms." More useful remarks would be either, "What do you mean by 'crazy'?" or "What makes you think you are going crazy?" To such questions the patient may then answer with details of his anxious thoughts. It then turns out, perhaps, that he thought he was going crazy because his memory has faltered recently and an aunt who died in a mental hospital also complained of this at one time. Further inquiries remind the patient that she was, in any case, an aunt by marriage. To such specific details, the psychiatrist can then provide specific reassurance. The best reassurance comes from understanding and explanation. Patients can usually distinguish reassurance based on careful inquiry and explanation from shallow statements to the effect that "everything is going to be all right." Their ability to penetrate our weaknesses in this respect provides another reason for avoiding premature reassurance. Such reassurance can seal off further exposures of the patient's anxiety. He may think to himself, "Why should I tell my troubles to someone who minimizes them all as my family does?" Moreover, premature reassurance, when the patient does accept it, tends to promote the patient's excessive dependence on the psychiatrist. If we say, "'Everything is going to be all right" (and there may be times and places when we should), we should realize that we have thereby accepted responsibility for their being so. When we insist that the patient join us in a careful exploration of his symptoms and difficulties, we communicate firmly to him our expectation that he will also share responsibility for his getting well.

We can control the amount of anxiety in the patient rather well by changes in the amount of talking we do. As the patient talks more and the psychiatrist less, the patient's anxiety tends to increase, at least initially, although after catharsis it may decrease again. As much as possible, the psychiatrist should talk to modify the patient's anxiety, not his own. To do this, he needs to remember that patients often tolerate silences rather well and frequently use them to think before speaking. A patient occupied in telling his story may not even notice silences, and sometimes does not seem even to notice the interviewer. But if a patient uses a silence to delete some repellent thoughts, he usually becomes aware of the silence, and his anxiety mounts. Then, if the psychiatrist has not prematurely spoken in order to ease his own tension, the patient will speak to reduce it himself.

A common dissimilarity between the inter-

Downloaded from www.freeamanpdf.com

views of interested amateurs, such as sensitive internists, and experienced psychiatrists exists in the differing extents to which they permit, encourage, and facilitate the expression of their patient's emotions. This being so, we may ask why the free expression of emotions is encouraged. We do it first because, as I mentioned earlier, emotions give importance to an experience and at the same time communicate that importance to other people. They should also communicate its importance to the person himself. And this they do when the emotions become strong enough. But often patients have not expressed themselves freely to other people. Consequently, the related emotions may recede somewhat, and the patient may think himself untroubled by them. Talking brings the emotions to the surface, and if they come strongly enough the patient may be astonished at the extent to which he has been affected. Patients frequently comment on this with remarks such as, "I never cry when I think about these things at home, but when I come here and talk I seem to cry all the time." This illustrates Sir Charles Sherrington's comment that, in motor activity, talking lies midway between thinking and acting. And it brings us to an additional reason for encouraging the patient's expression of emotions—the therapeutic benefit to him. Although this subject properly belongs to therapy rather than to diagnostic interviewing, the psychiatrist can remind himself that initial interviews begin therapy by observing the simultaneous benefit for both diagnosis and therapy of the patient's freely expressing strong emotions. Moreover, the relief experienced by the patient usually cements his attachment to the psychiatrist and makes the patient eager to talk more at the next interview.

This does not always happen. Sometimes patients recoil in anger or guilt when they find they have talked too freely and shown some emotion they previously condemned and imagined they could not experience. A patient may resent the psychiatrist's hearing him criticize his parents perhaps for the first time, or seeing him cry, or eliciting the confession of some wickedness. One cannot easily predict which patients will react in this way. Fortunately, the best safeguards lie within the patients, for those who are most likely to be hurt by too rapid a release of emotions are those who are most inhibited in the first interviews. They will require several or many interviews before they talk freely. But the psychiatrist should still observe the patient's reaction to the interview itself and notice whether the patient shows concern about the things he says and the emotions he displays. Within the patient's tolerance, the psychiatrist should encourage the patient to express his emotions fully. Weak emotions, like mild pain, are often of doubtful significance, but strong emotions tell both psychiatrist and patient alike that they are working in relevant subjects.

Some of the chief techniques for encouraging the patient's expression of emotions have already been mentioned. The physician should sustain and show his interest over at least forty-five minutes or an hour. In brief interviews the patient rarely has time to overcome his almost invariable initial reserve. In a ten-minute interview, discussion of the weather may take five; in a fifty-minute interview, one can give five to the weather and still do much besides. In addition, emotions cut grooves for similar thoughts which, in turn, bring stronger emotions to the surface. The longer one talks about a particular subject, the more emotion accompanies the evoked thoughts. Fully developed emotions usually occur only in longer interviews, because shorter ones do not permit this self-fueling of emotions to occur.

Beyond the requirements of showing interest and allowing plenty of time, the physician can further increase the patient's emotional expression by careful attention to some additional technical points. These are emphasizing detail in the patient's narration, reinforcing the patient's emotion by communicating understanding of his feelings, and naming the experienced emotion.

When we tell others about a past experience, we partially relive the events we tell and partially experience again the emotions we then had. The extent to which we feel again the old emotions depends upon the vividness of reliving. Simple, uneducated people easily

Downloaded from www.freelibrary.org

slip into a present-tense style of narration in which they seem almost completely to relive what they describe. More educated and more controlled patients, on the other hand, tend to talk in the past tense or to confine themselves to general statements. The psychiatrist should press the patient to provide specific examples of what he says. For example, if the patient says, "My father was always mean to me," the psychiatrist should ask, "Do you remember that? What do you remember?" He should frequently ask, "Can you give me an example of that?" or "Such as what?" Such questions oblige the patient to focus on specific events and, at least partially, to relive them. Moreover, the discipline of documenting general statements contributes to the patient's understanding of his own misperceptions. Once the patient has begun to tell about an incident, the psychiatrist can easily heighten the portrayal of detail by interjecting questions which ask for further details such as, "What happened then?" "What did your father say to that?" and "What did you do after you left the house?" After a little guidance of this kind, the patient will continue to give detail on his own, partly because he knows what the psychiatrist wants and partly because he begins to experience the relief of catharsis which only comes with vivid retelling.

Remembering the influence of the audience on any speaker, the psychiatrist can increase the patient's emotional expression by showing understanding of his emotions and attitudes in the events narrated. This does not need to include or imply an endorsement of the patient's behavior; rather, it implies an awareness that what he then did was natural for him at the time. Remarks (offered in a questioning way) such as, "So you felt no one was on your side," and "At that point you thought your father was trying to control you," can tell the patient that he at last has someone to talk to who can understand him, so he wants to talk more.

Patients frequently come close to the expression of strong emotions without quite permitting themselves to do so spontaneously. Frequently, fears of the psychiatrist's reaction to strong emotion inhibits them. When a tear moistens the patient's eye, the psychiatrist can profitably tell the patient he has noticed the emotion with a remark such as, "I can see it makes you sad to talk about this." Such a statement says to the patient, as it were, "It's all right to cry in here. Go ahead." And frequently such little remarks will help the patient to cry or experience other strong emotions. The psychiatrist gains nothing if he runs too far ahead of the patient in using this technique. Many patients have great difficulty in acknowledging and showing anger. If the psychiatrist too rapidly confronts such a patient with a name such as "anger" or "rage" for these emotions, the patient may shrink back in horrified denial that he could house such feelings within himself. In that case, however, the psychiatrist does not need to retreat all the way. If he finds himself ahead of the patient and encounters denial, he could still say, "Well, of course I could be mistaken, but I think nearly everyone in your situation would have been annoyed at what happened to you." This provides the patient with a hint of the acceptability of some anger which he may later wish to use.

Although the importance of the patient's talking freely has been emphasized, the psychiatrist should retain general control of the interview. Free talking does not mean unlimited free association. The right of the patient to say what he wants does not convey also the right to babble on tediously about irrelevant matters. The psychiatrist has the privilege and even the duty of curtailing circumstantiality and garrulity. But before he does, he should first ask himself (and perhaps the patient) why the patient behaves in this way. There are many reasons, and it is worth finding out which applies. Sometimes the irrelevant chatter results from a long-standing inability to think clearly, a form of mental deficiency. Sometimes it indicates failure of memory, with the patient substituting quantity of detail for accuracy of recall. Sometimes the patient talks about something else in order to postpone talking about some more affecting topic, or to conceal it altogether. This commonly happens in the description of hypochondriacal complaints in which the patient,

Downloaded from www.pbookshop.com

by focusing the attention of himself and everyone else on his heart or stomach, withdraws it from his marriage or disastrous financial predicament. Sometimes the patient with such excessive talk tries to communicate covertly something he thinks about himself but cannot or dare not articulate explicitly, or of which he may even be unaware. The patient who offers unnecessary detail may never have thought that his affairs seem less important to other people than to himself. Or, when a patient recounts details of his previous illnesses and operations in uninvited detail, he may really want us to know in this way how much he has suffered and needs our sympathy.

Before cutting off the patient, or while cutting him off, the psychiatrist should usually inquire about the excessive talk. He can say, for example, "I notice you spend a lot of time telling me about your past illnesses. I can see that they are important to you, but I don't think I understand why. Can you tell me how they are important to you at this time?" If such inquiries prove futile to stem the flow of the patient's irrelevancies, the psychiatrist can then move gently, but if need be also firmly, to deflect the patient. He can say, for example, "Perhaps later we can come back to what you are talking about. But since our time is limited, I wish you would tell me about so and so." This brings us to the various techniques for channeling the interview toward significant topics.

### *Guiding the Interview Toward Significant Topics*

As in his encouragement of the patient's talking freely, the psychiatrist should guide the interview covertly when possible and only secondarily with more open directions. Often, he can use the devices mentioned previously for showing greater interest in a topic of special importance which the patient only mentions. Thus he can channel the patient into another topic without the patient's becoming aware of his influence. But the psychiatrist should be aware of it. He should know that he is guiding the patient, and for a definite reason. In experiments which all psychiatrists should study, subjects have been asked to utter at random all the words they can think of.[18] As they do this the experimenter stands behind the experimental subjects and mutters "uh-uh" after each plural word. These grunts have an extraordinarily powerful effect in increasing the number of plural words vocalized, the effect being somewhat greater when the subject judges that the experimenter means to communicate approval by his "uh-uhs." Now, a patient always knows or thinks that the psychiatrist wants something, and he usually wants to satisfy the psychiatrist much more than experimental subjects want to satisfy psychologists. Consequently, if the psychiatrist interjects his "uh-uhs" unconsciously and pursuing his special interests in sex, religion, money, or something else, the patient will almost certainly go along with him. Both may find the hour enjoyable, but it may be unrewarding because of a one-sided emphasis on their favorite topic.

If the psychiatrist's subtlest signs of increased interest do not guide the patient to talk more of some significant object, then he may direct the patient more openly. He should exploit as much as possible the associations and references already provided by the patient. For example, suppose the patient says, "My headaches are getting worse every day, and my wife says she can't stand it much longer." The psychiatrist can catch the patient's reference to his wife and inquire, "What does your wife say about your headaches?" This broaches the subject of the patient's marriage, and other inquiries and information naturally follow. Sometimes the psychiatrist should not interrupt the patient in order to pursue an association at that time. This can interfere with the patient's flow toward something equally important. But the psychiatrist can make a mental note of the patient's remark and return to it later. He can say, for example, "You mentioned five minutes ago that your wife couldn't stand your headaches. Will you tell me some more about that?" By using the patient's own references and associations, an experienced psychiatrist can conduct an entire and thorough history-taking interview without ever himself introducing a new topic. Since

Downloaded from www.pdfbooksfree.pk

the patient seems always to be elaborating further on what he himself first brought out, he cannot reasonably believe that the psychiatrist has forced him to talk of things he did not mention.

Even with the most skillful use of indirect techniques, the psychiatrist will, at times, have to ask questions, bring up new topics, or inquire directly for further details. Although, as already mentioned, the psychiatrist should defer questions about time, places, and details of events omitted in the patient's initial story, eventually he should ask for whatever facts he believes necessary to satisfy the requirements of a thorough history. The proper asking of such questions deserves attention. Slight differences in wording can greatly influence the patient and his responses. If our "uh-uhs" can tell the patient what we want to hear, our explicit questions provide a much more forceful and sometimes harmful guidance to the patient. The questions asked should provide the least possible clues to the answers expected and the least possible channeling of the answers. Most desirable are "open" questions which ask about a topic in general and to which the patient must reply with one or several sentences. The least desirable questions are leading questions to which the patient can answer "Yes" or "No" and then remain silent. Compare, for example, the differing values of asking the patient, "Do you and your wife quarrel often?" and "Tell me about your marriage." The first question, apart from its abruptness which can offend, may evoke a simple "No" from the patient and nothing else, unless irritation. The second question invites and almost obliges the patient to reply with a sentence or more. Moreover, it does not confine the patient in his reply to the present time. The psychiatrist can learn much from noting what the patient selects to talk about first in answer to such a question. To illustrate this important principle further, an exercise for a psychiatrist who wishes to improve his technique is to arrange opposite each other, in a list, closed questions and more valuable open ones. For example, one can ask a patient, "Was the pain severe?" but a better question would be, "What was your illness like?" "Did you miss your daughter when she married?" will yield less than, "How did you feel when your daughter married?" One can ask, "Do you have a bad temper?" but this can be improved by saying instead, "How is your temper?" I do not mean to proscribe all leading questions focused sharply on a specific point, but these should come after more general open questions have given the patient an opportunity to answer freely without the suggestions and guidance of leading questions.

In asking questions which broach new topics, tact and timing reward the interviewer for the extra care they require. Careful phrasing of questions can greatly improve their yield. For example, in talking to an unemployed patient one should avoid saying, "Have you been on relief often?" asking, rather, "Have you had much trouble finding work?" Or, to illustrate further, one can unnecessarily offend a patient by asking, "Have you quit many jobs?" The patient would give the same and more information if asked, "What has led to your various changes of jobs?"

The state of the physician-patient relationship should influence our timing of questions and opening of topics to which the patient may be sensitive. As the patient and psychiatrist became more attached to each other, the patient feels freer to disclose more of himself, and the psychiatrist feels freer to ask him to do so. We can ask questions in the last five minutes of an interview which we could not ask in the first five, and we can ask questions in the fifth interview which would have been inappropriate in the first.

We can make many questions less painful by embedding them, as it were, in a matrix of other questions to which the patient is less sensitive. Thus one can lead a woman patient fairly easily to talk about sexual intercourse if one inquires about this at the end of a series of questions on pregnancies. In asking about further pregnancies, the physician may naturally inquire whether the patient's sexual relations have been satisfactory and, if not, why not. Similarly, one can ask questions about impairment of memory right after asking about the effects of the patient's illness on his vital functions such as sleep and

Downloaded from www.dbraulibrary.org.in

appetite. With the question placed in this context, the patient is much less likely to believe that the psychiatrist thinks he is "crazy" than if a question about memory confronts him abruptly as a new topic.

Do not, however, confuse tact with timidity. The physician should never hesitate, out of feeling for the sensitivity of the patient, to ask a question which is necessary for thorough evaluation. In talking to a depressed patient, for example, the physician should discover whether or not the patient has had suicidal thoughts and the likelihood of his acting on these thoughts. Often, he can learn about such thoughts indirectly, but when he cannot, then he should ask his questions directly. A question firmly asked will usually elicit a more direct answer than one offered hesitantly.

The psychiatrist should try to avoid offering gratuitous comments and interpretations which can trip the patient as he tries to tell his story. Instead, he should try to offer simple questions which, while asking for more information, encourage the patient to talk further. For example, suppose the patient says "I feel I need affection and can't get it." One might respond to this with, "Well, we all need affection, and you're not alone in this." A much more useful response would be "What interferes with your getting affection?" This second comment reassures the patient that he needs affection, but it also inquires further about what he himself may do to deprive himself of it. Or again, a patient may say, "I'm afraid I may lose control of myself." To this one could reply with, "Would that be bad?" but an even better response would be, "What do you think would happen if you did?" Or as a final illustration, suppose a patient says, "I was afraid of my parents as a child." The psychiatrist could answer reassuringly, "Yes, many children are afraid of their parents." A more productive answer, however, would be, "What about them made you afraid?"

### *Ending Interviews*

When patients do express emotions freely, we should give them some warning of the end of an interview before it closes. This permits the patient to regain some calmness before leaving the office. About five minutes in advance, one can say something like, "I can see that all this is extremely important to you, and we need to talk about it some more. But our time for today will soon be up, and we will have to postpone the rest."

I find it helpful always to ask the patient at the end of diagnostic interviews if he has anything further he would like to bring out or has any questions he would like to ask. In these final moments patients frequently reveal some matter of great importance to them. Previously, anxiety prevented their reaching these subjects, but as they see the interview closing, they often decide to risk the exposure. Usually, time does not then permit a full discussion, but the psychiatrist can defer this until the next interview.

Much of the best work of interviews occurs after psychiatrist and patient have separated. The patient (and a good psychiatrist also) goes on thinking about the subjects of the interview. New associations and often new emotions come to the surface and provide additional material at the next interview. The psychiatrist can usefully ask patients, on parting, to think further about the things discussed and to note these additional thoughts. Such instructions often stimulate patients who have shown marked resistance to psychological explorations. In the interview itself, their great anxiety frequently prevents their talking or even thinking freely, and they often present defensive and obviously incorrect denials of symptoms and attitudes for which abundant evidence exists in other signs. After the interview and away from the psychiatrist, many of these patients relax and then begin to think constructively about the topics discussed. At the same time, the image of the psychiatrist becomes less awesome. After a few hours or days of rumination, the patient may eagerly welcome a second interview and may talk much more freely.

At the end of any initial interview, the psychiatrist should discuss with the patient plans for further interviews or for treatment. Often, the patient will press him for an immediate diagnostic opinion. The psychiatrist

Downloaded from www.dbtselfhelp.com

may then have to explain that he will need further interviews and perhaps other examinations and tests before offering an evaluation of the patient's illness. He can usually include some initial reassurance covering what he knows up to that point. He should avoid blanket reassurance which he may afterward have to revise, and he should avoid offering prematurely a diagnostic opinion or recommendations for treatment. But always he should tell the patient what he plans to do next. Attention to such details of courtesy and cooperation greatly aids the transition from initial and diagnostic interviews to treatment.

Few single interviews sufficiently reveal the patient's difficulties for the purposes of the thorough evaluation which sound practice requires. Not many healthy people can pass from strangership to intimacy with another person in any hour, or even in several. So we should not expect this of anxious or otherwise troubled patients. Therefore, we must turn to additional interviews and to additional informants, both of which are nearly always desirable. With the patient's consent (rare exceptions to this occurring in the cases of irrational, psychotic patients or young children) we should interview important relatives of the patient, so that we may benefit from their often quite different perceptions of the patient and his illness. The discrepancies between the patient's account of himself and that of a relative frequently astonish us and also remind us how differently people appear to different observers. Our psychiatric interviews can improve if we frequently remind ourselves of their significant limitations in giving us the information we need.

CHAPTER 10

# THE PSYCHIATRIC EXAMINATION

Ian Stevenson
William M. Sheppe, Jr.

Downloaded from www.dlrauilibrary.org.in

LIKE THE PSYCHIATRIC INTERVIEW, the psychiatric examination has changed considerably in the past fifty years. Once largely restricted to the examination of severe mental disorganizations, it has now become an extensive study of the whole personality, with special emphasis on thought contents and their accompanying emotions. Moreover, psychiatric examinations are no longer restricted to patients with severe mental illnesses. Although naturally varying in emphasis and detail with different patients, some psychiatric examination should now form part of every careful medical examination.

## ¶ Introduction

More specifically, the psychiatric examination may uncover significant data under any or all of the following headings:

1. Signs of psychological disturbances which are expressions of the patient's major illness, for example, organic brain syndromes or schizophrenic reactions.

2. Psychological factors which are (partially) causative of a major physical illness or which exacerbate it, for example, anxiety in a patient with peptic ulcer, essential hypertension, or angina pectoris.

3. Psychological reactions to the presence of another illness, for example, anxiety about his condition experienced by a patient with congestive heart failure.

4. Psychological factors which interfere with the patient's cooperation in treatment, for example, a denial of illness or a resentment of authority as represented by the physician.

In addition to studying psychopathology, the psychiatric examination should also encompass the individual characteristics and assets of the patient. Unfortunately, the preoccupation of physicians with ill health sometimes leads them to neglect the healthy aspects of their

patients. Yet the outcome of an illness is influenced fully as much by the patient's assets and strengths as by the nature or apparent severity of his symptoms or illness. Without some awareness of these assets, the physician cannot expect to promote healing by his efforts.

Although modern psychiatric theory emphasizes the adaptations which patients make to life stresses, it is possible to take a harmfully one-sided view of the patient's symptoms by considering them exclusively as defenses. Such narrowness can lead to absurdities such as the explanation of a schizophrenic psychosis as an "escape" from difficulties in living. The schizophrenic patient becomes psychotic because the stress to which he is subjected disorganizes his mental machinery. With this there may come some relief, but it is certainly secondary. Similarly, a young man about to go to college may develop an incapacitating dermatitis a few days before his departure. The illness prevents him from attending college, which he did not want to do. But he did not become ill in order to avoid going to college; rather, his dermatitis was an accompaniment and an effect of the anxious thoughts connected with going to college. Many symptoms have adaptive or defensive value, others do not.

Psychiatric symptoms therefore may be: (1) disorganizations or disorders directly produced by a lesion or learned during a stress; (2) efforts to compensate for these disorders; or (3) efforts to counteract the lesion or stress.

The psychiatrist should remember that his examination may not elicit adequately representative data. This point deserves brief discussion. In a manner quite impossible for the physical state to do, the psychological state can vary widely with changes in the external environment. Two physicians may obtain totally different evaluations of the same patient's mental state. The patient may have different feelings and attitudes toward each; he responds differently to the two different examiners and, consequently, they observe different data in their examinations. For example, if the patient's attitude toward one physician carries unpleasant tension, this tension may impair his mental efficiency. A patient of greater than average intelligence may thus appear intellectually subnormal when his mental efficiency is momentarily so reduced. Another physician, evoking a different response from the patient, might conclude that the patient was highly intelligent. These discrepancies can occur even when the patient consciously wishes to cooperate with both physicians. Although the patient's attitude toward the physician depends partly on the approach of the physician himself, it is also influenced by the distorted perceptions of the physician by the patient, who may misperceive him as resembling some similar past significant person more than he actually does. In addition, the physician is usually a stranger and, in this instance, a person with some authority to make important decisions relative to the patient. Any observer of human behavior, by his mere presence, may modify the very behavior which he would like to observe.

A difference in the evaluation of the mental state may arise not only from differing attitudes of the patient toward different observers; equally, the patient's emotional state may be changed by some other person or event, the effect of which may linger for many hours or days and may still be affecting him at the time of the examination.

Furthermore, the patient's anxiety may be aroused by the examination itself, altogether apart from the thoughts he has about the examiner. Some of this anxiety may be rational; for example, he may know that the physician may make important recommendations about him (such as admission to a hospital) as a result of the examination. Or the anxiety may derive from quite irrational ideas about the examination; for example, the patient may believe that the physician has been hired by the F.B.I. to trick him. Whatever its origin, anxiety about the examination can markedly alter the mental state as observed in the examination.

The examiner therefore needs to remember that the mental state at the time of an examination may be importantly influenced by: (1) alterations in the patient's psychological state induced by recent events; (2) the attitude

Downloaded from www.brainlibrary.org

of the patient toward the examining physician; (3) the attitude of the patient toward the examination itself; (4) the attitude of the examining physician toward the patient.

Thus discrepancies in the observations of different physicians do not always reflect different percipiences in the physicians. These differences can arise from changes in the patient's psychological state between one examination and another. The physician should therefore make his first examination as complete as possible, but he should also supplement his observations with the evaluations of other individuals, for example, nurses, occupational therapists, aides, members of the patient's family, etc., who have had an opportunity to observe the patient in varying settings. And he should himself make repeated observations of the patient's behavior, if possible in different settings. Like the history or physical examination, the psychiatric examination should be a continuing process in which the physician is ever observant of new data.

The psychiatric examination, as well as the physical examination, requires evaluation by two standards. In some respects, all healthy human beings resemble each other, and gross deviations from statistical normality may be safely labeled abnormal. In evaluating such deviations, the physician relies upon a broad knowledge of human nature and human behavior in the culture in which he and the patient live. But he must also remember that in some respects everyone is unique. For these aspects, the patient himself furnishes the standard of reference. The physician should therefore try to compare the patient's present condition with his premorbid level of function. Only in this way can he accurately evaluate the patient's mental state.

Sometimes the patient himself can reliably contribute information about his "base line." However, the physician rarely knows the patient's dependability in this regard, at least initially, and so should check the subject's statements with those of others who have known him closely. The patient's relatives and friends can often provide valuable information about the extent of deviation from his usual personality.

Before presenting an outline of the psychiatric examination, we think it important to remind our readers that psychological states have a wholeness the existence of which we can obscure by our habit of examining part functions. We cannot avoid examining parts, but we can reduce the attendant errors by constant remembrance of the interdependence of the parts on each other and of the quality which is given to each part by its membership in the whole. For example, we sometimes differentiate intelligence from personality, as if these two words denoted exclusive functions. Actually, the qualities included in the concept of intelligence, far from being separate, form a major part of personality. Personality may be defined as the sum of the habitual reactions of a person to external events. Perceptions, intellectual functions, and affective states all influence these reactions. We may usefully abstract for our discussions the processes of perception, integration, and response; in life, however, they merge inextricably. Almost any item of behavior may illustrate the instantaneous blending and the impossibility of really separating these processes. For example, suppose the patient angrily accuses the physician of not being sufficiently interested in him. He reveals his misperception of the physician as being similar to his neglectful father and dissimilar to his adoring mother. At the same time, he shows his inadequate understanding of the physician's role and usefulness and of the physician's genuine interest on his behalf. Such understanding might have corrected, to some extent, his initial false perception. He also shows how his own comfort depends upon the interest and affection of other persons, and how threatened he feels when this is lessened. Finally, his anger shows the pattern of his response to this anxiety and his lack of inhibition of the expression of his anger.

A mental examination reveals order or disorders of function. The physician does not examine a mental organ directly in the same manner that he can examine a physical organ, for example, when he auscultates the heart and lungs. His examination of the mental state cannot even be as direct as the examination of nervous tissue. In the latter case the nerves are

Downloaded from www.dbraulibrary.org.in

not seen and rarely are even felt. Disturbances of their function are usually deduced from noting changes in the activity of other organs, for example, the muscles. Similarly, in the mental examination, the physician infers disturbances by noting abnormalities in the way the patient perceives, integrates, and responds to external events. He cannot observe the mental processes directly. He must deduce their condition from the patient's verbal statements and from observations of his other behavior.

## ¶ Outline of the Psychiatric Examination

We shall next present an outline of the psychiatric examination, arranged in headings for easier memorization. Then we shall discuss individual parts of the examination. We offer this outline without any conviction that it surpasses all others. The value of an outline lies chiefly in the prevention of omissions in the examination, and one outline may accomplish this as well as another. Certainly, we should use no outline rigidly in our own thinking, and even less in our examination of the patient. Each examination should differ from every other, according to the needs of the patient and physician and other circumstances. However, our advocacy of flexibility does not condone casual or incomplete examinations. As mentioned earlier, details and emphasis will vary from one case to another, but in every instance the psychiatrist should consider, at least in his own mind, each of the major headings of his outline. Most errors arise from omissions, relatively few from faulty observations. Sometimes circumstances prevent as adequate or as complete an examination as we wish or the patient's condition requires. When this occurs, we should record the deficiency in our notes and never fail to remedy it as soon as conditions change.

The outline presented here has three main sections which correspond, so to speak, to the afferent, central, and efferent portions of a reflex arc. However, because the patient presents his emotions and behavior first to the observation of the examiner, we have placed these first. The physician can often complete this part of the examination during his interview with the patient. Through transitions that we shall mention later, he can then extend the interview into the more detailed examination of the other parts of the outline.

Outline of Psychiatric Examination

General Observations
- Circumstances and setting of examination
- General description of the patient

Emotions and Behavior
- Emotions
- Behavior

Central Organizing Processes
- Intelligence, including memory
- Thought processes
- Thought contents, including self-concept and insight

Perceptions
- Misperceptions
- Illusions
- Hallucinations
- Attention
- Orientation

### *General Observations*

In addition to the usual note about the date and place of examination, the physician should also make some mention of the actual setting in which the examination was conducted. As previously noted, human behavior may differ markedly in different surroundings and under varying circumstances. Strange surroundings, or those which might be interpreted as threatening, may induce such severe anxiety as to obscure other important aspects of the patient's psychological state. The setting and circumstances of examination therefore acquire their importance from the effect they might have on the patient. Any unusual reasons for making an examination—for example, at the request of a court—other than the patient's request for medical assistance should also be noted.

The physician should next attempt something akin to a novelist's sketch of the patient

Digitized by www.libraryofmedicine.org.in

as a person, using a photograph of words to convey to the reader a meaningful picture of the patient as an individual. By way of illustration, such a description may include noting the general appearance, demeanor, and clothing of the patient. A female patient who enters the office with hair unkempt, little or no make-up, no stockings, and badly scuffed shoes immediately communicates something of her attitude toward the social norms of dress. What this format means for her (for example, defiance of social customs, hostility to men, or lowered estimate of herself) will only emerge later, but its occurrence should be noted immediately.

To this general description the physician should also add a note concerning the patient's initial attitude toward the examiner, the interview, and the examination, his expectations about these, and his degree of cooperativeness.

## *Emotions and Behavior*

### Emotion

If the psychiatric interview is sufficiently complete and ranges widely enough to permit full expression of the patient's emotions in connection with the topics of major significance to him, the emotional content can often be quite adequately evaluated during the course of the ordinary history-taking interview. The previous chapter having discussed this extensively, we shall not here fully consider this aspect of the psychiatric examination.

**Dominant Emotions.** The physician should observe the dominant emotions of the patient, their intensity and duration, and their appropriateness to the patient's immediate situation and thought content. The physician should know whether a dominant emotion has recently arisen or is habitual, and, hence, more properly called a mood. Sometimes he may watch emotions come and go during an interview and thus gain information about the capacity of the patient to return to his habitual feeling state; at other times he may need to make special inquiries on this point. Thus, he may obtain considerable information about the lability or fixity of the patient's emotional life. He should also learn about the sensations experienced during a given emotion. Some persons have only mild changes of sensations during emotions such as fear and anger; others may undergo what amounts to a severe physiological storm.

Events acquire meanings through the quality of our experiences. As different experiences give different meanings to outwardly similar events, we must always learn the meaning of events for the patient. When we observe a strong emotion in the patient, we know that we have reached something important for him, but why it is important we learn only from getting him to tell us his thoughts. As the patient is frequently a poor witness of his own thoughts, we can often help him and ourselves to a better understanding of his emotions by learning what situations evoke the various emotions in him.

Since much human behavior and a great deal of psychopathology derive from efforts to control or suppress the expression of strong emotions, the study of the patient's various mechanisms for dealing with emotions forms a most important part of every psychological evaluation. Does the patient handle emotions such as anxiety in an integrative and constructive fashion? To what extent have the patient's efforts at controlling or concealing emotions succeeded, and to what extent have they failed? If they have failed, to what extent has the patient's mental organization become impaired?

To summarize and illustrate, if the patient is angry, the physician needs to know what has provoked his anger, why this angers him, how he feels, what he shows, and what he does when he is angry.

When the psychiatrist notices an important durable emotion, such as a depressed or elated mood, he should carefully evaluate the degree of mood change and its present or potential connection with irrational and perhaps dangerous behavior, for example, suicide in depressed patients or wild financial schemes in elated ones.

**Appropriateness of Emotions.** In evaluating the appropriateness of emotion to a

Downloaded from www.pharmbrain.org.in

given situation, the physician should remember the following modifying factors.

CULTURAL DIFFERENCES IN EMOTIONAL EXPRESSION. Wide variations in patterns of emotional expression occur. To the Scandinavian, the Italian may apear wildly emotional, while the Italian may think the Scandinavian cold and unfeeling. The physician must therefore know the patient's customary or cultural pattern of emotional expression before evaluating its appropriateness.

SUPPRESSION AND CONCEALMENT OF EMOTION. When the patient feels ashamed of his emotions or has other motives for their concealment, his emotional reactions to stressful situations may seem inappropriate.

MASKING OF OTHER EMOTIONS BY A DOMINANT EMOTION. Any strong and lasting emotion can dominate the experience of the patient so as to exclude other emotions from expression in situations which might ordinarily evoke them. For example, a patient extremely anxious or depressed will not smile or cry when stimulated by events which would previously have made him do so. A general decline in all emotional expression, known as apathy, can similarly exclude ordinary emotional expression.

DISPLACEMENT OF EMOTIONAL EXPRESSION TOWARD AN INAPPROPRIATE PERSON OR OBJECT. A person may inhibit the discharge of a strong emotion toward the person stimulating it and later discharge the same emotion toward someone else who, perhaps, precipitates a slighter degree of this emotion but receives the full force of the accumulated earlier emotion. Misperceptions of other people may also lead to inappropriate expectations of them and hence to inappropriate emotional reactions. Such misperceptions probably account for most inappropriate emotional responses. Their frequency emphasizes the importance of observing the roles which the patient assigns to himself and to others. Significant clues to these perceptions may often be found in the patient's emotional reactions to the examining physician.

Inappropriateness (apparent or real) of emotion to thought content may arise in a number of ways.

UNAWARENESS OF TRUE THOUGHTS. The psychiatrist may be unaware of the patient's true thoughts. First, the patient may conceal his thoughts. Secondly, he may reveal them, but the physician may not understand the special significance which they have for the patient. A patient with a schizophrenic reaction may smile or laugh as he mentions the death of his father; however, we may find that the father was a tyrant whose death brought joyful relief to the patient. Thirdly, the patient's thoughts may move so quickly that the physician may observe the occurrence of an emotion but fail to detect its accompanying thought. Apparently inappropriate emotional expression also occurs in schizophrenic reactions as a result of disrupted associations. In talking about something which is quite serious, the patient may be observed to smile or laugh in a manner quite inappropriate to the topic under discussion. Upon being questioned about this, however, the patient may state that an amusing thought entered his mind at the time he smiled. Thus again, the emotion expressed in the smiling may have been quite appropriate for the thought. The abnormality lay in the intrusion of this thought at this time, the result of the disorder in association which is a characteristic feature of this condition.

DISSOCIATION BETWEEN THOUGHTS AND EMOTIONS. The central abnormality here is not that meanings have changed but that thoughts no longer bring the usual accompanying emotions. This kind of dissociation can often be observed in dreams in which, for example, situations which would be quite alarming or quite ludicrous to the waking consciousness fail to evoke anxiety or laughter. When this condition is found in the waking state, it strongly suggests a schizophrenic reaction.

NEUROPHYSIOLOGIC DISORDER IN THE EXPRESSION OF EMOTIONS. In certain brain diseases, such as pseudobulbar palsy, so many cortical neurones are injured that an interference occurs with the modulation of emotional expression. Accordingly, a slightly amusing thought brings a shower of laughter, and a sad thought may precipitate tears. The patient

Downloaded from www.dbraulibrary.org.in

usually knows that his emotions are excessive and inappropriately expressive of his thoughts, but he cannot control these reactions.

### Behavior

Emotion and behavior overlap and merge and are, to a considerable degree, interrelated. Behavior generally refers to action and expression with the whole body or major parts of it. Behavior may express the same motives as those which give rise to the conscious experience and expression of emotions. On the other hand, a given attitude may not enter conscious awareness as a felt emotion but nevertheless may reach expression indirectly in behavior. For example, if a wife slights her husband, he may not experience conscious anger, but if he forgets his wife's birthday the next day, we might be justified in attributing this forgetting to a hostile motive provoked by his wife's remark. Or the husband, still without showing any anger, may bring into play techniques for making his wife feel guilty. He thus retaliates not openly but by a much more subtle hurting of his wife.

In evaluating the expressive and communicative significance of motor activity, it should be noted that some motor activity is a concomitant of a central neural state. The communicative aspect of this kind of activity is incidental and only medical. It may tell the physician about a central disorder, but it is not created for this purpose. Other motor activity has communicative intention but is not symbolically expressive. And still other motor activity communicates symbolically to those who understand the symbols. Thus we may observe motor activity of the hand in a kind of gradient of communicativeness, as follows:

1. Tremors of the hands associated with organic diseases of the brain, for example, Parkinson's disease. The symptom is a concomitant of a disturbance in the central nervous system having only a medical communicative value.

2. Tremors of the hands associated with anxiety states. No communication is "intended," but some may result if the tremor is noticed by those who can interpret its significance.

3. Tapping of fingers on a table during partially inhibited anger. Here the motor activity is partly an accompaniment of heightened psychological tension but also may have, and be intended to have, communicative value to other persons.

4. Banging the fist against a table. In this act the patient communicates symbolically his anger and his desire to hit another person.

The physician should note the patient's general level of physical tension. Is his activity random and unorganized, or is it channeled into some constructive project? Is he aware of periods of hyperactivity or hypoactivity, and do these disturb him in any way? Is he prone to act out or express his frustrations and anxieties directly through various behavioral outlets? If so, are these techniques successfully adaptive or self-defeating? Can he communicate readily with words, or does he communicate chiefly with nonverbal behavior?

The behavior of the patient with other people and the effect which he has upon them are of major importance in making a comprehensive psychological evaluation. One should note, for example, those persons with whom he shows anxiety, those toward whom he feels superior, those of whom he stands in awe, and those to whom he comes for help. In a similar vein, does the patient evoke pity, anxiety, anger, attention, friendliness, aloofness, etc., in most of the people he encounters? If so, is this a habitual, chronic pattern or one of recent development?

Any study of the patient's interpersonal relations should certainly not be limited to simple observations of his interaction with different persons. Although the patient's behavior with different people varies, he is a unique person with certain needs which dominate his behavior and give it a more or less consistent pattern. One basis for the concept of personality is that there are habits and patterns in behavior which give some predictability to each person's responses to his environment. Therefore, the physician should try to detect the dominant traits of the patient, or his

Downloaded from www.pbookshop.com

recurring patterns of activity as expressed in his behavior with different people. Such traits as ingratiation, aggressiveness, cautiousness, defensiveness, irritability, etc., will occur as leitmotivs over and over again in the patient's behavior with many different people. The major generalizations which he has made from his past experiences thus become expressed in the recurrent traits of his behavior in relations with other persons.

## *Central Organizing Processes*

Under central processes we include all those mental processes which occur between stimulus and response; that is, everything mental which contributes to the organization and utilization of experience. For purposes of study and discussion, the processes may be divided into a number of topics, such as intelligence, thought processes, and thought content.

### Intelligence

Intelligence is a term applied to a number of mental components and processes, including speed and accuracy of thinking, richness of thought content, capacity for complex thinking, and the ability to manipulate thoughts and objects. Although accurate and objective estimates of intelligence are often obtained by the use of standardized intelligence tests, motivational components usually modify the expression and influence of the factors measured by such tests to an extent which gives them important limitations in studying human behavior. Despite this reservation, the physician can often aid his evaluation of a patient by making some estimate of the patient's intelligence from the history and from considering the following factors:

**Vocabulary and Range of Information.** Both of these functions may be demonstrated during the course of history-taking interviews or other parts of the examination. Care should be taken to avoid confusion between intelligence and education.

**Memory.** The accuracy and extent of the patient's memory for the more remote past can usually be determined from his account of childhood and earlier life given in the history-taking interviews. Recent memory will usually be revealed in the patient's account of the events of the immediate past, such as the circumstances just prior to the examination. The importance of memory in behavior requires the careful examination of the patient with regard to any defect discovered. Do gaps of memory begin and end abruptly? Are they confined to one period or scattered over the whole span of life? Do they include unpleasant events only or pleasant and unpleasant ones indiscriminately? Is the defect of memory due to lack of attention to the environment or to poor retention or recall? Does the patient know he has a poor memory? Does he fill in gaps in memory with confabulations or compensate with garrulity?

**Judgment.** By judgment is meant a person's ability to use all the resources of his intelligence in solving constructively the problems which he meets. Although behavior supplies the only really reliable guide to judgment, some information about the patient's problem-solving techniques and the kind of decisions he makes may be derived by posing for him certain hypothetical dilemmas.

### Thought Processes

Although the processes of thought are chiefly evaluated through the patient's speech, other indicators, such as drawings and special tests, may be employed. In general, one may assume a rather close correlation between the patient's speech and his thought content. Certainly, speech expresses thought, but it often does so imperfectly. Some patients, such as those who are shy or uncooperative, may hide behind their few words an initially unsuspected clarity and richness of thought. And a smaller number of patients may acquire a verbal facility which successfully conceals blurred concepts and other limitations of thinking.

**Speed of Thought.** The speed of the thought processes communicates valuable information about the patient. Some people think faster than others all their lives. This greater speed of thought (often accompanied by greater speed of speech) may reflect superior intelligence rather than the mood of the person. The physician needs to know whether

Downloaded from www.dbmslibrary.com

there has been a change in speed of thought and speech from what is habitual for the patient. If so, this usually indicates a change in mood, since, in elation, thoughts and flow of speech are accelerated, and in depression they are retarded.

Besides changes in mood, other circumstances may alter the speed of thoughts and speech. For example, in delirioid states, and in schizophrenic reactions, thoughts ordinarily held unconscious may invade consciousness. The patient may react to this increased imagery by attempts to describe it or to respond to it. The resulting increase in speed of speech may therefore indicate an increase in imagery rather than elation.

**Accuracy and Clarity of Thought and the Capacity for Higher Forms of Thinking.** As the patient talks, the physician should study the organization of his productions. Various degrees of disorganization may be noted. Thus the patient may talk in grammatical, well-constructed sentences, but these may bear little relation to each other, giving a lack of coherence to the whole. Or individual sentences may be poorly constructed, disorganized, or asyndetic. Words may be fragmented, or new words may be invented. Such neologizing may result in words such as "bastitute" and "mental teleprosy," whose etymology and meaning are reasonably clear. The origin and meaning of other neologisms are often obscure, although they nearly always become intelligible through careful study of the patient and his past experiences.

The relation of individual sentences to each other may indicate some disturbance in associations. When associations are disturbed so that irrelevant thoughts intrude into consciousness, the disturbance is usually reflected in the speech. The interference may be manifest only as a blocking, so that the flow of speech becomes temporarily interrupted. This occurs commonly in states or moments of anxiety. The psychiatrist should note the topic about which the patient is talking at the time of blocking or hesitancy. The affect associated with the topic acts like sand in the mental machinery. Sometimes the intruding thoughts are themselves expressed, giving rise to more or less disorganization of speech. When every thought seems to be verbalized and all filtration of thoughts apparently suspended, the physician should suspect a schizophrenic reaction. A complete disinhibition of the expression of thought, that is, true free association, does not occur in a first interview or mental examination unless a severe mental disorder, for example, a dissociation, is present.

The examiner should note the ability of the patient to pursue a goal idea. When speech is accelerated, as in elation, thoughts often skip from one idea to another in what is appropriately called a flight of ideas. This rapid succession of ideas may result in the expression of no central theme whatever, so that although the patient may appear to have some goal idea in mind, he never reaches it. The physician should note the patient's ability to pursue a line of thought during distracting stimuli. Can he continue a theme after he has been interrupted?

The examiner should try to understand the reasons for a patient's inability to reach a goal idea. Is his stream of thought interrupted by intruding thoughts or by extraneous stimuli? If intruding thoughts interrupt him, are they repetitive, obsessional thoughts or the products of loosened associations? Or does the patient have one dominant thought content which crowds out all others?

The meaning of circumstantiality, in which the patient floods the psychiatrist with irrelevant detail, also deserves attention. Has the patient never learned to focus his thoughts, or does this symptom arise as a response to some anxiety? The patient may tell his story in great detail to win the psychiatrist's approval for "his side," or he may do this to avoid talking about something he wishes to deny or conceal. He may give much detail to evoke sympathy for his suffering, or he may be trying to substitute a wealth of other detail for important gaps in memory. Only careful study can clarify the distinctions between these motivational factors and disorganization of thinking due to organic brain disease.

The examination of thought processes should include study of the patient's capacity for conceptual thinking. Under this heading

Downloaded from www.utrasufficiency.org.ir

the physician should consider and, if need be, test the patient's ability to perform abstractions.

**Rigidity of Thought Processes.** The human tendency to form habits affects not only behavior but thought itself, which is a foundation of behavior. Many serious difficulties in living occur because the patient cannot entertain alternative explanations of events or cannot consider alternative responses to them. Earlier associations and generalizations become hardened so that they cannot be broken down to make way for new associations or more appropriate generalizations. Under this heading, one should, therefore, consider the extent to which the patient's mind is open to new ideas and thoughts. Is it closed to explanations and interpretations different from those he has worked out for himself? Or, on the other hand, is he abnormally suggestible and excessively liable to pick up the thoughts of others?

### THOUGHT CONTENT

**Central Themes.** From observations during the history-taking interview, the physician will usually have obtained much information about the main themes or central preoccupations of the patient's thoughts. However, judicious direction of the interview may be necessary in order to uncover central themes which are being avoided or unconsciously concealed. The examiner may be able to quantify somewhat the different values attached by the patient to different subjects by noting how frequently each comes up in the course of conversation. On the other hand, that which is obviously avoided or left unsaid frequently reveals as much about the patient as his overt verbalizations. Because affect is usually directly related to thoughts, central themes of thought should be correlated with the dominant affect.

**Abnormalities of Thought Content.** Under this heading one should consider such things as fixed ideas, phobias, obsessional ideas, delusions, and unrealistic fantasies. The degree of distortion of thought content and the tenacity with which the patient maintains his distortions should be noted. To what extent does the abnormality of thought content influence the patient's behavior? Are his abnormal thoughts of recent origin or habitual with him? Do they create further anxiety, or is he blandly content in his current situation?

**Self-Concept.** We consider of the greatest importance the set of thoughts which the patient has about himself, which we may collectively call his self-concept. What does the patient think about himself? Does he exaggerate or minimize his assets and deficiencies? Does his concept of himself and his behavior differ importantly from other persons' views? Does he believe himself to have changed? In what ways is he not his "usual self"? Does his concept of himself match his ideal self? In what ways would he like to change?

**Insight.** By insight is meant the patient's understanding of his situation, including the main facts of his illness. It includes his concept both of his condition and of his circumstances. Some patients do not know they are ill. Others know they are ill but do not know in what way. Still others know something about how they are ill but accept no responsibility for the illness, which they may blame entirely on other people. The highest forms of insight include understanding of the effect of one's behavior on other people, and also a constructive utilization of what one does know to modify behavior appropriately. Therefore, under this heading, the physician may note the extent to which the patient accepts responsibility for what has happened to him, the extent of his awareness of the effect of his behavior on other people, and the curiosity which he has about his illness and its treatment.

## *Perceptions*

Disorders of perception occur in a wide variety of forms and various degrees of severity. The patient may incorrectly perceive either himself or the external environment. The physician should often inquire first about simple variations in the intensity of perceptions, for example, hyperacusis, myopia, anesthesias, hyperalgesia, etc. Then he should inquire about the more severe disorders of perception. These may range, in approximate order of severity, from misperceptions of other people, through illusions and hallucinations, to states of disorientation and confusion. Intermediate dis-

Downloaded from www.ebrahimi.org.in

orders of perception, such as the hallucinations found in schizophrenic reactions, seem to arise from a combination of motivational influences and the disruptive effects of strong anxiety on mental processes. The more severe disorders of perception, such as confusion and disorientation, are usually noted in the presence of serious interference with cerebral function such as that encountered in toxic states or structural disease of the brain.

### Misperceptions

Simple misperceptions of the mildest degree consist of mistaking the role of another person, that is, expecting different behavior from him than he can reasonably be expected to show. These errors are usually based on past experiences, but they are also influenced by strong affects, especially fear. An example would be the patient's expectation that the psychiatrist will always treat him with tenderness and indulgence, just as his mother did when he was a child. To note misperceptions, the psychiatrist should study carefully the patient's comments on different people and his behavior with them. He should notice especially, since he can observe it most easily, the patient's behavior with the psychiatrist.

### Illusions or Misidentifications

In the simple misperceptions mentioned above, the patient does not actually misidentify objects and people but only misunderstands their roles. In illusions, an actual misidentification of objects and people occurs. The patient then may mistake the psychiatrist for, say, his brother. The examiner should avoid confusing illusions and delusions. In a delusion, which is a false belief, the patient might think that the psychiatrist was his brother disguised skillfully to look like the psychiatrist.

### Hallucinations

Hallucinations are sensory perceptions occurring in the absence of external stimuli. The following aspects of hallucinatory phenomena should be noted:

1. Sensory modality in which they occur.
2. Content of hallucinations, including resemblances of voices or visual appearances to those of persons known to the patient.
3. Circumstances associated with their occurrences or with fluctuations in their intensity.
4. Patient's insight into their occurrence, and his reaction to them. Does he communicate about them freely or does he conceal their occurrence?

### Attention

By attention is meant the patient's ability to focus his consciousness on a part of the field of awareness. It may be compared to focusing vision on a part of the visual field. The examiner should consider attention with regard to the following aspects:

1. General direction, that is, toward outside stimuli or toward inner thoughts.
2. Fixation. Can the patient's attention be diverted from its main focus to other stimuli? Is it too easily diverted so that he cannot concentrate? Sometimes we can distinguish active attention, that which the patient directs himself, and passive attention, that which occurs without his interest or willed participation. A combination of inwardly directed and fixed attention is a feature of dissociated states, in which the patient attends largely or only to his own stream of thoughts and responds less or not at all to outside stimuli. He is then said to be "out of contact" with the examiner. This can exist in all degrees and many variations.
3. Clarity of attention. Clarity of attention may become impaired as during toxic interferences with cerebral functioning. This is often referred to as a clouding of consciousness. Clouding of consciousness is not necessarily a feature of dissociated states. Clouding of consciousness can exist in all degrees from slight impairment to states of severe confusion merging into coma.

### Orientation

In the more severe disorders of perception, orientation becomes impaired. However, orientation may be preserved when there are other severe disorders, such as hallucinations and dissociated states. Orientation is usually studied under the following headings:

1. Time—knowledge of the hour, day, date, month, season, and year;
2. Person—knowledge of one's identity;

Downloaded from www.cbraulibrary.org.in

3. Place—knowledge of one's location, and spatial orientation. Sometimes, we also consider under orientation

4. Situation—knowledge of why one is in a certain place. This includes correctly identifying the people around one and their functions. Defects of orientation for situation are usually delusions. Sometimes the phrase "paranoid disorientation" is used for them. The patient, for example, knows that he is in a hospital ward but insists that it has secretly been changed into a prison and that the doctors are guards.

## ¶ The Technique of the Psychiatric Examination

### *The Approach to the Examination*

We cannot and should not sharply separate the psychiatric interview and psychiatric examination. The psychiatric examination begins the moment patient and psychiatrist meet. As the patient talks during the history-taking interview, the psychiatrist should attempt to evaluate his emotional state, his intelligence, his thought contents, or any other function of the patient's personality which may reveal itself. As the psychiatrist's skill in mental examination increases, he will find that he can conduct more and more of his examinations during the history-taking interviews, leaving ever smaller portions for some specific inquiries at the end of the interview or for another occasion. Thus the experienced examiner can often guide a history-taking interview so as to carry out a rather complete survey of the patient's mental state. On the other hand, errors can arise from careless reliance upon the history-taking interview as a substitute for a thorough examination, particularly in the hands of the inexperienced. Such deficiencies may occur if the psychiatrist fails to have the interview range over a broad enough area to provide all the data necessary for an adequate and comprehensive evaluation. The psychiatrist should not think that if he just keeps the patient talking, all the important data will simply fall into his ears. A great deal of essential material may be overlooked unless it is specifically sought, either by skillful direction of the interview or by specific and thoughtful questioning. In the course of such inquiry, the examiner may use the data of an earlier part of the same interview or of another interview to guide his questions so that they will be most appropriate and most tactful.

Any change of emphasis in the interview toward more detailed or specific examination should be made as subtly as possible and preferably without the patient's even being aware of such a transition. The examiner who inadvertently makes the patient feel that he is being "tested" or interrogated as a witness may succeed only in confirming the patient's worst expectations about himself and the nature of psychiatric therapy. A clumsy approach may intensify the patient's anxiety so that he becomes unable to cooperate in the examination to any significant degree. Tactfulness in examination, apart from sparing the patient discomfort and additional anxiety, may therefore add considerably to the information actually obtained.

The transition to more detailed examination of the patient can sometimes be made smoothly by an appearance of investigating the patient's complaints more thoroughly. For example, the psychiatrist can say, "You mentioned a few minutes ago that your memory wasn't working as well as it used to. I'd like to ask you a few questions so we can see just how much trouble you've been having." Abnormal thought contents such as delusions can often be studied ostensibly as part of a more detailed review of the patient's history.

However, some topics of examination do not lend themselves to such exploration, and these the examiner will nearly always need to present with a brief explanatory comment. These should also tactfully attribute maximal function to the patient. The following questions illustrate such introductions.

"I suppose you keep pretty good track of time, don't you?" The patient answers, and then the psychiatrist continues, "Would you know what the date is today?"

"Do you read the newspapers and keep up with the current events?" The patient answers

Downloaded from www.dbraulibrary.org.in

and the physician continues, "In that case I am sure you'd know who the President is. Can you tell me?"

"You said you went to the eighth grade, I think. Would you mind if I asked you a few questions in arithmetic? They're quite simple."

"You said your memory was pretty good. Do you mind if I see just how good it is?"

"You've told me a good deal about yourself. Now would you mind if I asked you some more specific questions about yourself and how your mind works?"

If the patient makes no objections to the inquiries, the psychiatrist need volunteer no further explanation. If, on the other hand, the patient seriously hesitates, becomes uncooperative, or asks what is going on, he is entitled to a reasonable explanation. The psychiatrist may explain that, as the patient has evidently had some psychological symptoms (reference being made in passing to these), additional information is needed to find out what can be done to help. The examination should never be presented to the patient as a "test" in which what he does may be compared to what someone else does. Such an analogy may evoke memories of failures in school and anxiety-laden thoughts of inferiority, and such feelings may reduce mental functioning further or destroy cooperation. Instead, the examination should be explained to the patient as an effort to compare what he does now with what he once did, and with what he is believed capable of doing when he is at his best. But it is altogether preferable if the examination can be accomplished with sufficient skill so that elaborate explanations are unnecessary.

### The Importance of Not Humiliating or Tiring the Patient.

Anyone can be chagrined by noting an inadequacy of function, especially a mental function, in relation to an assumed standard or to one's previous performance. The examiner should remember this especially with patients who are already somewhat aware of a loss of mental function as, for example, those with arteriosclerotic or other brain diseases. In such instances a few questions may quickly bring out some loss of intellectual capacity. The patient may well have managed to compensate partially for these defects by denial; if he is confronted with them through formal testing or insistent interrogation, however, the defensive denial may be torn from him with catastrophic results. Anxiety so aroused may impair function still further, which can lead to further anxiety in a vicious cycle. Inquiries should therefore be pushed only as long as they reveal information needed for the evaluation and eventual well-being of the patient. As always, the emphasis should be upon the welfare of the patient and not upon the completion of a routine medical form. Although the examination must be complete and eventually recorded in an organized fashion, the data derived from a skillfully conducted interview are seldom obtained in the final written form. Indeed, any attempt to adhere rigidly to a specific outline will often impair the initial relationship between examiner and patient to such a degree as to obviate the very purpose of the psychological examination.

### The Importance of Nonverbal Behavior

We wish to emphasize also that the words of the patient often form a relatively small portion of all the data used in evaluating the mental state. Observations of other forms of communication, such as posture, gestures, facial expressions, or other signs of emotions and thoughts, can, in many instances, provide even more significant information than the patient's overt verbalizations. The long-suffering hypochondriac's secret twinkle of enjoyment as she describes the effects of her many illnesses upon her family may supply invaluable clues as to the pathogenesis and meaning of her neurosis. The heavy-lidded, lusterless eye of the depressive frequently bespeaks more sorrow than his words could hope to encompass. The skillful examiner, like the good pediatrician, is exceptionally sensitive to that vast sphere of human interaction known as nonverbal communication. As in all forms of communication, however, specific components may be misleading, in that their function is that of defense, denial, or masking. The smiling depressive who is secretly planning the "perfect" suicide may illustrate the latter all too tragically.

### The Importance of Asking the Patient About His Condition

In our zeal to observe the patient, we can sometimes forget that he has the best opportunity of anyone to observe himself. We should try to enlist him as a collaborative observer. Certainly gaps and distortions will occur in his observations, as in ours, but if we omit to ask him directly what he has noticed, how he feels, and what he thinks, we lose some of the most valuable material we can obtain. The following questions may illustrate ways of inviting the patient's opinion of his condition: "What do you think about your condition?" "What would you say about your mood?" "How do you think your mind works now compared to when you were well (or compared to a year ago)?"

## *Special Points of Technique*

### Examining Emotions

The previous chapter included a description of the signals whereby one person communicates emotions to another, which we will not repeat here. As mentioned above, the examiner should always invite the patient to describe his emotions directly. Defensive concealment of emotions may cause discrepancies between what the psychiatrist observes in other signs and what the patient himself reports. Sometimes the patient may not understand the psychiatrist's question. To the question, "How are your spirits?" the patient may reply, "Fine," not because he feels well, but because he does not understand what the word "spirits" means in this connection. Questions about emotions and moods may need to be asked in several different ways before the patient understands.

In making inquiries about depth of depression and suicidal intentions, it is well to begin with the thought content of the depressive mood and work gradually upward toward the possible suicidal thoughts. This gives the patient a chance to volunteer whatever he will about suicidal thoughts and may also produce less of a shock when the psychiatrist finally asks direct questions. The frequency and importance of suicide require us to ask questions bearing on it whenever its possibility arises, as it does in most depressed patients and in many others.

We suggest the following group of questions as one series which can move the inquiry toward the subject of suicide:

"How low do you get when you are depressed?"

"What do you think about when you are depressed?"

"Do you ever think that life is not worth living?"

"Do you ever wish you could die?"

"Have you ever thought of killing yourself?"

"What did you think you would do?"

"What would happen after you died?"

"Why does that seem the only solution?"

In evaluating mood and suicidal intentions, the patient's verbal comments in response to the above questions furnish only a part and sometimes a small part of all the relevant data. The patient's speech, his motor attitudes and movements, his appetite and sleep, and his other verbalizations, for example, of hypochondriacal ideas or ideas of hopelessness, all constitute important information for the evaluation of his mood.

### Examining Central Processes

**Examining Memory.** Skillful guidance of the interview will often permit an accurate evaluation of both recent and remote memory. When it does not, more direct inquiries and examinations are indicated. These can begin with a question such as, "Have you had any trouble with your memory?" This gives the patient a chance to furnish further information. The psychiatrist may then continue with, "Do you mind if I ask you some questions to see just how good your memory is?" The patient assenting, specific questions which test the patient's remote and recent memory can be employed. For example, in testing remote memory, the patient may be asked the year of his birth, of his graduation from school, of his marriage, and of the births of his children. The psychiatrist may then wish to refine his examination by inquiring about items less likely to be well remembered, that is, less im-

Downloaded from www.brainlibrary.ir

portant events in the patient's life, such as the year of a change of job, or events in the nation's history through which the patient has lived.

Recent memory can be tested by questions pointed toward current situations or events just past. For example, the patient may be asked what he did the day before, where he lives, what he ate for breakfast, or who has visited him. If the examiner thinks the patient's memory markedly impaired, he may ask the patient to tell him his (the physician's) name. Assuming they were introduced at the beginning of the interview, this may test the patient's memory over a period of half an hour or more. Additional tests of recent memory can be accomplished by (1) showing the patient some objects, for example, a key, comb, coin, and watch, and asking him half an hour later to say what these were; (2) telling the patient a simple story and asking him to repeat it with all remembered detail; or (3) speaking a series of random digits to the patient and asking him to repeat them forward and backward. A healthy person of average memory should be able to repeat accurately a series of eight to nine digits forward and six to seven digits backward.

Recognition nearly always exceeds recall in disorders of memory. Consequently, in examining memory the physician may first test the patient's recall for a given item and then, if he fails, offer it to him in a series of other items. For example, the physician can first ask a patient who has visited him. If the patient says he thinks someone visited but he cannot remember who, the physician can next inquire: "Was it your wife, sister, brother, aunt, cousin?" With such assistance from the physician, the patient may remember the correct name.

**Examining Thought Processes.** Much of the data concerning the patient's thought processes will emerge during the history-taking interviews as the psychiatrist observes the patient's behavior and studies his responses to specific questions. Notwithstanding these ample sources of information, the psychiatrist should often ask the patient himself what he thinks about his thought processes. Suitable questions might include the following: "Does your mind work well, or as well now as it ever has?" "Do you have any difficulty in controlling your thoughts?" "Can you concentrate your thoughts now?"

Where doubt remains after the above observations or where diagnosis requires a more refined understanding of thought processes, the psychiatrist should proceed to more detailed testing. Sometimes he can accomplish this with a few simple questions, but sometimes he will need more elaborate tests administered by himself or a clinical psychologist.

The ability to manipulate mathematical symbols may be tested by asking the patient simple arithmetical problems such as: "Do you remember what 12 times 12 is?" or "Would you subtract 8 from 56 for me?" The subtraction of 7 from 100 serially provides an excellent test of calculation. Upon completing this exercise the patient may be asked to divide 7 into 100 with a view to noting whether the result agrees with that of the test of subtraction and, if not, whether the patient notices this discrepancy. This one test measures attention, the speed of thought processes, and the ability to detect errors and correct them. Moreover, when the test is timed, one patient's performance can be compared with that of another and also with his own performance on later occasions.

Sometimes calculations can be tested by asking the patient questions about his personal life which require him to calculate. For example, the psychiatrist may ask the patient naturally enough during the history for the dates of various important events, such as the patient's marriage or birth of his first child. Later in the interview he can ask the patient how old he was at the time of these events. This method has special value because it can be applied without the patient's being aware of any testing, which can hardly be the case when he is asked to subtract 7 from 100 serially. The subtler method can be used first, the more open method later if the first suggests a need for further examination of this mental function.

The psychiatrist will usually have had occasion during the earlier parts of the interview to evaluate the patient's ability for conceptual thinking. He should note whether the patient

Downloaded from www.UrduMaterial.org.in

can form and express concepts clearly. When important impairments in concept formation are suspected, this capacity can be examined more definitively by testing the patient's ability to abstract.

Abstraction may be tested by asking the patient to compare and state the differences or similarities between different paired objects. Pairs commonly used are an orange and an apple, a tree and a fly, a dwarf and a child, a man and a dog, a lie and a mistake, a church and a theater. In offering such objects to test abstraction, the psychiatrist must know that the patient knows them. Otherwise he may test only the patient's range of information. The patient may also be given a series of words such as high, cold, dark, near, etc., and asked to supply their opposites or synonyms.

The ability to generalize may be evaluated by asking the patient to give the meaning of well-known proverbs such as: "The proof of the pudding is in the eating" or "A rolling stone gathers no moss." To these proverbs the patient may reply with several different types of abnormal responses. In a correct response the patient should interpret the proverb as a generalization of human experience. A patient with a disorder of thinking may fail to make the transition from the concrete example of the proverb to its general application to human behavior. Sometimes the patient may "explain" the first proverb by another proverb without interpreting the first proverb, or he may become engrossed in thinking about and discussing the images of the proverb. Thus, to the proverb, "A new broom sweeps clean," a patient may reply, "Well, that's right, when you get a new broom it will sweep cleaner." The patient may also see personal references in the proverb. For example, to the proverb, "It never rains but it pours," he may reply, "That's the way it is with me. Every time I go out in the rain it pours." The intelligence of the patient must always be considered in evaluating the response to such proverbs. A person of low intelligence or poor education, however, usually gives no answer at all to the proverb, whereas a patient showing a schizophrenic reaction is more apt to supply a concrete answer, one having personal reference, or one with bizarre associations mixed in.

**Examining Thought Content.** In studying thought content, the psychiatrist should always prefer indirect methods of exposure. He should aim at having the patient talk freely and in such a way that he will, without being asked directly, tell the physician all of his important thoughts. This technique does not always succeed, or it may not succeed enough. Sometimes the psychiatrist may need to ask some patients about their central and preoccupying thoughts rather directly. He should not hesitate to do so when necessary. He can say, for example, "Can you give me an idea of the main things you think about?" "What do you think about most?" "What sort of thoughts come into your mind?" "Do you have any thoughts which keep coming back to you?" "Do you have any thoughts you can't get rid of?" "Do you have any special daydreams or fantasies?"

Many patients do not understand the word "fantasy" and may even be unfamiliar with the expression "daydream"; therefore the psychiatrist may find it helpful to ask the patient such questions as: "What things do you imagine yourself doing in the future?" "What would you ask for if you could have three wishes granted?" or "Do you often imagine how you would like things to be in the future?"

If the patient has not exposed his thoughts freely in the course of the history-taking interviews, he may not do so any more readily in response to the direct questions suggested above; the latter certainly do not guarantee a frank answer. On the contrary, direct questions may merely intensify defensiveness. When the psychiatrist does ask direct questions, he will have to judge each time to what extent the patient has been able to expose his thoughts.

The detailed examination of irrational ideas and delusions requires simply an extension of the principles already outlined. The psychiatrist must gradually evoke the patient's trust so that he can confide without fear. The psychiatrist must travel the often narrow path between endorsement of the patient's delusions and rejection of them as totally preposterous or "imaginary."

Note should be taken of the ease with which the patient talks about his irrational ideas or delusions. When a patient holds his beliefs critically and still tries to test them, he may

Downloaded from www.PsychiatryOnline.com

be unwilling to confide them in a physician. One does not ordinarily communicate an unusual idea to another person unless he either believes strongly in its truth or feels assured of the other person's acceptance of him. Therefore, delusions which carry strong conviction are usually readily revealed. On the other hand, skillful inquiry may be needed to discover maturing but unripe delusions. Material suspected of delusional elaboration must be approached tactfully and with an assumption of the reasonableness of the patient. If a critical, challenging attitude is adopted, the patient may avoid the subject altogether or at least conceal the existence of any idea, such as an incipient delusion, which he thinks the psychiatrist may doubt.

Some psychiatrists avoid all interrogation of psychotic patients about delusions or hallucinations on the ground that such questions can harmfully crystallize ideas which the patient still holds in solution, as it were. We have already advocated an examination in which the patient is guided to deliver the necessary data in a conversational way, with as much avoidance as possible of direct questions. However, sometimes questions are helpful and essential to the clarification of the patient's symptoms. We believe the manner of questioning is much more important than the questions themselves in promoting the patient's delusions or otherwise injuring him. And certainly the psychiatrist should carefully avoid any suggestion of forcing the patient to talk of what he wants to keep to himself.

When the patient does confide delusional material to the psychiatrist, the latter should also ascertain to what extent he has revealed his thoughts to other people. The psychiatrist should know whether the patient considers him a special person and whether he has delusional ideas about the psychiatrist. Failure to note the latter may seriously impair the validity of the entire examination.

Patients often spontaneously verbalize expressions of insight which have little relevance to a sound understanding or little application in their subsequent behavior. Consequently, it is often helpful and necessary to ask direct questions focusing more sharply on insight. However, as with responses to other direct questions, the patient's answers will take their place with other data which may prove more important in evaluating insight. The physician may ask such questions as: "How do you think you became ill?" "What do you think is the matter?" "What brought all this on?" "What do you think are the causes of your illness?"

### Examining Perceptions

**Examining Illusions and Hallucinations.** When inquiring about illusions and hallucinations, the examiner should start with questions about experiences resembling those anyone can have. Because illusions and hallucinations are unusual experiences, the patient may have difficulty in recognizing what he has experienced or in describing it in everyday language. He may need to be offered a variety of questions before he understands what is being asked.

The following examples of introductory questions may prove useful:

"Have you ever had something like a dream when you thought you were awake?"

"Have you ever had anything you might call a vision, or seen an apparition?"

"Have you ever thought you heard people talking when no one was around?"

"Do you ever seem to confuse your thoughts and someone else's thoughts, as if someone might be putting things into your mind or even saying things to you?"

When the patient answers such questions affirmatively, or when his behavior clearly indicates that he is hallucinating at the time of the examination, the psychiatrist should push the inquiry with further questions designed to learn as much as possible about such experiences. He can ask, for example: "What do you see (hear)?" "Who seems to be doing this (saying these things)?" "What's happening?" "Why are they doing this?"

The patient's complaints will usually include depersonalization and estrangement when these have occurred importantly in the illness. However, when he does not volunteer information about these symptoms which the psychiatrist nevertheless suspects from other data, they should be inquired about directly. One may ask, for example: "Have you ever felt as if

Downloaded from www.dbraelibrary.org.in

you were not yourself, or as if you had changed so you couldn't recognize yourself?" "Did you ever think that everything around you seemed different or strange or unfamiliar?"

**Examining Attention, Concentration, and Clarity of Consciousness.** Important defects of concentration will usually appear in the interviews without special testing. However, it may be desirable to test the patient's ability to hold his attention on some task, and this can be done by asking him to subtract 7 serially from 100. If the patient cannot subtract, he may be asked to repeat groups of digits of increasing length. Ability to subtract serial 7's from 100 provides a useful and semiquantitative index for comparing changes in the patient's condition from day to day as a delirium clears or becomes worse. Performance can be timed and notes made of errors, of whether the patient notices his mistakes and tries to correct them, and of any wandering of his attention from the task. If this test is used often, the patient's speed may improve through learning. Varying the test by asking the patient to start at 101 or 102 can reduce whatever distortion this might bring.

**Examining Orientation.** Much can be learned about the patient's orientation simply by careful attention to his remarks during the interview. If these do not provide adequate data, the physician should always turn toward more direct questions. Orientation may therefore be evaluated in several different ways:

1. Inferences made from listening to the patient's spontaneous references to people, places, and events during the earlier parts of the interview.

2. Questions designed to test orientation, but not asking directly about this. The patient may be asked where he was before coming to the office (or hospital), and whether he had difficulty finding the office. His reply may reveal whether he is oriented for place. Simple inquiries about recent events demonstrate whether he is oriented for time. Other questions may similarly test orientation for situation and person.

3. Direct questions about orientation. The psychiatrist should use these only after he has tried the other approaches, unless the patient seems obviously disoriented; in such cases he may proceed immediately to direct questioning. However, he should not hesitate to use direct questions when any doubt remains after use of the indirect approaches mentioned above.

The psychiatrist should usually begin with inquiries which suggest less extreme disorders and proceed from these to test for complete disorientation. For example, a first level of inquiry might include the following questions:

"Do you keep track of time fairly well?" "Would you know what day (date, month, year) it is?"

"Where do you live?" "How do you get there from here?"

"Why did you come here?"

A second and potentially more shocking level of questions might include the following:

"Do you know where you are now?" "What place is this?"

"Do you know who I am?" "What is your name?"

"What time of day is it now?"

A partially delirious patient may be disoriented without knowing this. Questions such as the above may alarm him by exposing the severity of his condition. This additional anxiety may actually increase his confusion. After such questions, the psychiatrist should therefore always offer some appropriate reassurance. And if the patient is not oriented, the psychiatrist should attempt to furnish orientation to the patient. He should say who he (the psychiatrist) is, where the patient is, briefly why he is where he is, and what he may expect next, together with any other information which he thinks the patient can usefully assimilate in his condition.

## ◧ Examination of Inaccessible Patients

Many psychiatric patients are inaccessible for effective verbal communication. This occurs when patients are mute (e.g., in catatonia and severe depression), excessively garrulous (e.g.,

Downloaded from www.cdeuniversity.org.in

in manic psychoses and some senile psychoses), or excited (e.g., in schizophrenic excitements). The inaccessibility of different patients of this group varies greatly, and varies in the same patient from time to time. Indeed, few patients are totally uncommunicative with words. The psychiatrist should try to discover under what circumstances the patient becomes more communicative with him or with others. Certain persons or certain remarks of the psychiatrist himself may open up the patient's verbal communications. These successful stimuli should be carefully noted in order to utilize them in further developing contact with the patient.

While waiting for the occurrence and use of such stimuli, the psychiatrist may still learn much from observing a patient who does not talk at all or talk usefully. The patient will signal much about himself with the movements of his face and body or with his gestures or other behavior. A sudden grimace, a single glance, or a series of body movements may reveal more than a thousand words. The following are some of the areas to which the examiner should carefully attend.

### *Facial Expression*

Both the habitual expression of the face and changes in expression should be noted. The hangdog faces of the depressive and the fatuous grin of the hebephrenic communicate immediately to the observant. The eyes, especially, deserve attention. The poets have referred to the eyes as "the doorway to the soul." In a more mundane but practical sense, an awareness of ocular expression can be of immense assistance to the astute clinician. Patients whose life experiences have conditioned them to distrust verbal communication, for example, certain schizophrenic patients, may be quite sensitive and adept in this sphere.

### *Bodily Activity*

Posture, gait, and other motor activity may be quite informative. The despairing slouch of the depressive and the proud, defensive posture of the paranoid vividly communicate important attitudes. The patient may employ such communicative signals as grunts, grimaces, or gestures with his hands. Motor expressions of hostility and anger often tell much about the thoughts of a mute patient. A seemingly disinterested catatonic may revealingly clench his fist or shift his position when his defensive isolation is challenged too aggressively. Semiseductive posturing and unconscious gestures may portray attitudes which could not otherwise be communicated.

### *Response to Stimulation*

The patient's responses to environmental changes, verbal greetings, or direct physical stimulation should be noted and recorded. The examiner may also observe the patient's reactions when personal topics relative to his home or family are discussed within his hearing. Will he cooperate with such routine requests as suggestions that he open his eyes or change his position? Does he disregard noxious stimuli such as glaring sunlight or an obviously uncomfortable posture? Does he let his cigarette burn his hand? Many mute and seemingly unresponsive patients with schizophrenic reactions can be brought into activity by throwing them a ball and engaging in direct motor activity with them. Such stimulation apparently causes them to leave their inner world temporarily and enter into contact with others.

### *Other Behavior*

The spontaneous behavior of the patient should be noted especially with respect to his responses to other persons who approach him. When left alone, what does he do? Does he make any effort to communicate his needs? Does he accept cigarettes or food when offered? Is he incontinent? Does he feed himself? Does he preserve some concern for his appearance or neglect this altogether? The psychiatrist might note, for example, whether a mute female patient continues to comb her hair or use some lipstick, because such behavior usually indicates a degree of self-esteem and some continuing interest in others.

CHAPTER 11

# AN INTRODUCTION TO MINOR MALADJUSTMENTS

Clara Thompson

Downloaded from www.dbraulibrary.org.in

THE LITTLE DIFFICULTIES IN LIVING have always existed, but, until the advent of psychoanalysis, they were not considered problems for the psychiatrist. The old-fashioned family physician heard about them and, consciously or unconsciously, reacted to them as though they were connected with the health of his patients; that is, he listened and gave advice, sympathy, or support, as the situation indicated. Or when the difficulties arose from moral conflicts, the clergyman stepped in, listened to the confessions, and pointed out ways to relief from guilt. Today, the old-fashioned family physician has faded from the scene, and religious absolution is not convincing to many unhappy people, who must now seek a psychiatrist's help.

In entering this field, psychiatry has stepped out of the role of a specialty dealing with obvious disease. The people with these difficulties are not patients in the usual sense; they are usually "going concerns," and are generally considered as normal as one could hope to be in this society. The maladjustments fall into four general categories: There are the difficulties of relationships—interpersonal in the narrowest sense. Then there are difficulties in productiveness—work problems, especially related to those who do not have routine patterns to follow, that is, the creative person. There are value problems, such as conflicts over ways of living in an ethical sense. Finally, there are specific difficulties produced by the society in which we live, and these difficulties often add characteristic color to the other three.

Underlying these four general types of difficulty is the character of the person. Psychoanalysis uses the term "character" in the sense of characteristic, habitual patterns of behavior. These have both constructive and defensive aspects and are formed very early in life in response to the characters of the significant people in childhood. They may be altered by later life experiences, but they tend to be blindly repetitive, and the blindness is reinforced by the fact that a pattern of behavior tends to evoke a companion pattern of be-

havior in others. For example, an aggressive, dominating personality tends to form relationships with people with submissive trends, and to repel or antagonize people similar to himself. Thus, he is left with the impression that his way of life works, although he may sometimes wonder why all his friends seem to be the same kind of people.

Habitual patterns of behavior are not necessarily pathological. To the extent that they are constructive and effective ways of coping with life, they are not the concern of the psychiatrist. For example, an effective, receptive character would be a broad-minded person, open to new ideas and easily adaptable. On the other hand, a nonconstructive receptive type would be a person with no convictions of his own, espousing the ideas of his most recent acquaintances, incapable of integrity. Similarly, an aggressive type may simply be a person who knows what he wants and undertakes to bring it about in an effective way, or he may be a person who ruthlessly exploits others and succeeds in being generally hated. In general, the more effective character types are the products of good early life situations. The significant people who were the means of producing the young personality were not destructive or unnecessarily cramping in their attitudes. They loved the child and did not have to compensate for their own difficulties in the relationship to him. When the parents have greater difficulties, the child may be unloved, or there may be ambivalent feelings toward him. This may result in his being spoiled or overprotected, in compensation for the parents' guilt. This can produce a dependent character or one in need of constant attention in order to assure him of his acceptability. If, on the other hand, the rejection is more overt, the child may grow up in a constant atmosphere of derogation and rejection. He can have no positive self-picture, and although he may always be seeking love, he can have no belief in it when he finds it. As a consequence, he often develops a hostile, defensive attitude, especially when threatened with any form of intimacy. Obviously, these are greatly oversimplified examples, but they will serve to illustrate the way in which character is molded by early interpersonal experience.

Everyone has his own characteristic way of coping with life, evolved from his early life experiences. This is not, in itself, pathological. It is, in fact, the way in which we become human beings. Through early contacts, we learn the rules for living which make us acceptable to our fellow man in the particular society in which we must live. Some rules are more inhibiting of potential development than others; in fact, some societies have more destructive patterns than others, and finally, some parents, because of their own personal difficulties, are more destructive than others.

The psychotherapist comes into the picture when the individual's habitual patterns of behavior create for him difficulties in living in his relation to people, to work, to the sense of his own value, and in response to the cultural pattern. The sufferer is usually partially or wholly unaware of his own contributions to his difficulties. It is therefore the psychiatrist's function, through observing what the patient is doing to and with other people, to lead him to insight into his own behavior, which usually includes coming to an understanding of the way in which the personality difficulties were developed in the first place. This insight becomes all the more convincing when the patient's behavior can be observed directly in the "me-you" situation with the therapist.

Here the analyst can observe the way in which the patient's defensive and manipulative attitudes affect other people, and, by pointing this out to the patient instead of reacting to it, the therapist is able to help the patient see the meaning of his behavior. For example, a person may be habitually very ingratiating, seeking to be liked through flattery or trying in other ways to please. The analyst sees this taking place in relation to himself; he does not respond to it, but, instead, points it out to the patient. Another example is the case of a person who is very competitive. For him, the analyst's position of authority in the therapeutic situation is intolerable, and he is driven to belittle the analyst in some way. He may criticize his technique, or remark that the papers he has written are mediocre, or object to his office furnishings, or try in other ways to humiliate him. The good therapist does not react to this, but sees in it evidence of the pa-

Downloaded from www.pharmacybrary.com

tient's character pattern. When this is pointed out calmly and without anger, the patient may be able to see for the first time one of the ways in which he makes enemies. These two illustrations are examples of ways of relating to people which do not create good relationships and are defensive attitudes—attempting to cope with an underlying feeling of insecurity and anxiety which was fostered by early life experience.

How do such character patterns create difficulties in living—maladjustments, restlessness, and boredom? I shall discuss this under the four categories already stated, namely—relationships to people, relationship to work, relationship to oneself, and the effect of the cultural patterns in these relationships.

## Interpersonal Relationships

Problems of intimacy are among the most disturbing interpersonal difficulties. Marriage counseling has become a subspecialty in itself. People who live together on the most intimate terms suffer most from the rough spots in the mate. In the first place, the choice of mate is usually determined by the character pattern. The aggressive person attracts submissive people, the masochist attracts those who will make him suffer, the "sucker" is fascinated by the exploiter, etc. Freud has pointed out that the victims of unhappy marriages usually choose, in their subsequent attempts at finding mates, people with difficulties similar to the first mate, and the marriage tends to come to grief in the same way. This, he called "the repetition compulsion." Our present knowledge of character patterns makes more clear why this is so.

When a man or woman consults a psychiatrist about marriage difficulties, attention must first be paid to how each is contributing to the situation. There is no such thing as an innocent victim of interpersonal difficulties, except in the case of a very young child. The wife—suffering from a domineering husband, who puts endless obstacles in the way of any personal development on her part, unless he controls it—has asked for it in her way, perhaps by an excessive need for guidance and approval. Unless she can gain sufficient confidence in herself to believe in her own goals, not even divorce will solve her problem, for she will immediately look for someone else to run her life—not deliberately, of course, but driven by her own unconscious needs. The basic marital problem is that mutual neurotic dependency is mistaken for love. Fromm has called these "symbiotic relationships." Only mature people, who are capable of caring for and respecting the needs and interests of the partner as much as they are concerned with their own, are capable of the mutual relatedness of adult love. Marital difficulties flourish in symbiotic relationships because the gratification of personal need is more important than concern for the welfare of the other, and the solution lies in analysis of the personal need.

Fromm has described several types of symbiotic relationships which are confused with love (Fromm, *Escape from Freedom*, Chap. V). There is the "magic helper" situation, in which a relatively benevolent exploitation of the one by the other occurs; that is, the one who appears to be more helpless looks to the other for solution of his difficulties. He has nothing to fear so long as the magic helper is near and gives him support. But the magic helper does not give support because he is strong; he is also dependent on his partner's helplessness for a belief in his own powers. He lacks a strong conviction of his own worth. However, this type of neurotic solution often works very well, because each wishes the other well, and the results of the mutual dependency are not destructive.

The type of symbiosis in which most often one or the other partner seeks psychiatric help is that in which cruelty or suffering is a part of the bond, for example, the tyrant who has the martyr wife, the henpecked man with the nagging mate, or the pathologically jealous man or woman who sees disaster if his partner attempts to make other friends. The partner here, incidentally, often finds a secret satisfaction in the jealousy and, wittingly or unwittingly, keeps the jealous one anxious. These cruelty motivated maladjustments are characteristic of one group who often seek the psychiatrist's help. Advice and guidance are sel-

Downloaded from www.pdfbooksfree.pk

dom sufficient help in these cases. Only a probing of the character pattern, effective enough actually to change the way of relating to others, can make for any permanent amelioration of the relationship. As I have already said, changing partners seldom solves the problem as long as the basic pattern of relating remains.

Another form of interpersonal difficulty is that of isolation. The inability to make contact may be due to a hostile or even a destructive attitude. The individual feels so threatened by others that he must either drive them away or destroy them altogether. There are also detached people who are not particularly hostile, who live as onlookers to life. They have an impersonal warmth so long as no closeness is involved, but they fear any entanglement of their emotions. They are lonely people, but unable to remedy their state through their own efforts. Again, the solution must come from a radical exploration and alteration of the character pattern.

I have stressed the aspect of intimacy in interpersonal difficulties. Many of these people get along very well in more superficial relationships. In fact, they may be the "life of the party" or "the hail fellow well met" so long as no permanent warmth or friendliness is demanded. However, some have difficulty in even these tenuous contacts and succeed either in making enemies through their arrogance or hostility, or in withdrawing so completely that no one feels the urge to seek them out. None of these interpersonal difficulties is easily resolved, and when people seek help for them, a thorough character analysis by a trained analyst is indicated.

## ¶ Relationship to Work

Work difficulties are confined to two general types: one is the person who moves frequently from one job to another or fails to make the advances commensurate with his abilities, and another is the person doing independent creative work who has difficulty producing. The man who drifts from job to job is more apt to be brought to a psychiatrist by his family than to seek help spontaneously. His difficulties may be due to almost anything which comes under the heading of psychiatric diagnosis, for example, a psychopathic state or even an ambulatory psychosis, but they may also be due to a character problem. The man may have grandiose ideas of his ability—no job he has is good enough for him, or he is not appreciated and he must keep seeking in an employer for a parent substitute who will admire and favor him.

A more unusual type of problem is that of a young man who seems afraid to grow up. He did excellent difficult work as long as he could think of the job as temporary, for example, work during summer vacations in college days. As soon as he began work which was to be his life career, he became panicky, and before he sought psychiatric help, he was in danger of failing altogether. He had had similar scholastic difficulties. He did very well in college as long as he was browsing around and had not fully made up his mind what he wanted to become. As soon as he made his decision, his marks went down and he flunked a course. Analysis revealed that he had a deep feeling of worthlessness, and that he could not imagine himself as an adult, responsible person. The casual jobs had been a kind of child's play, and it didn't really matter whether he succeeded at them or not. On further treatment it became apparent that his mother had continued to treat him, far into adolescence, as an irresponsible person. She made his major decisions according to her whim, often depriving him of his own spontaneous interests. It was more important to keep his mother from criticizing him than to follow his own tendencies—except when he could avoid her supervision by being the amateur. In fact, when he came for consultations, it was not clear for some time whether his work difficulties were due to his having been pushed into the wrong career or not. In time this doubt was resolved. He liked the work, but he feared taking his own initiative. It was as if he were always expecting his mother's interference—so why try!

A frequent type of problem in the work field, brought to the psychotherapist chiefly by writers and artists, is the complaint that they cannot produce as they feel they should.

Downloaded from www.cbspd.org.in

Here an impossible perfectionism is often a factor. They long to be world-shaking, and all their efforts fall short. They cannot bear to expose themselves to the test of reality to evaluate their actual capacities. Another hazard is that they need approval so much that they cannot risk the possibility of not being loved and admired. There is often a need to be inconspicuous, hoping thereby to avoid disapproval. If no one notices you, you can't be criticized, but it is self-defeating because neither can you be admired. These people are tortured by this conflict and sometimes attempt to solve it by following the reasoning: If you turn out work similar to what everyone else is doing, perhaps it will be praised because it is "in style." But here we encounter a new conflict which is related to our third category—namely, how can you follow the current fashion and, at the same time, be true to yourself.

For example, the objective artist today is not in vogue. If he paints according to his convictions, he will be unpopular and will be called old-fashioned. If he is tempted to imitate the current style, he will be untrue to himself and become depressed. This is a very real dilemma, for the person who goes against the market not only suffers isolation but may be endangering his livelihood. These issues are not always clear to the sufferer. He may simply feel depressed and unproductive. The therapist must help him find the cause. All problems are easier to handle when they are within awareness.

I think it is clear from the above discussion that, even in the case of work inhibitions, relationship to others and the search for approval are very big factors in creating the difficulties. Only those with genuine confidence in their own powers can withstand disapproval and remain true to their own selves.

## ¶ Relationship to Oneself

This question of integrity really belongs to the third division—the conflict of values. Many people consult an analyst because of a feeling that they are not living the kind of lives they want to live. On the surface, they seem to have achieved much, and yet there is a feeling of emptiness and nonfulfillment. They do not have a pathological depression, but they are unhappy. Fromm has pointed out that the marketing orientation of our present culture has much to do with producing an alienation from the self (Fromm, *The Sane Society*). We have become submissive to an anonymous tyranny. We must be what people desire us to be.

We are subjected to the high-pressure campaigning of advertising. We are advised to follow the crowd. "Everyone smokes ..... brand of cigarettes," for instance. So, although no harsh dictator threatens us with extinction if we don't conform, subtle and not so subtle influences exhort us to conform. And many succumb to the lure, hoping for acceptance, perhaps even prestige and fame. But the price is the unlived life, the failure to develop potentialities. This illness of the soul brings many people to analysts today. It is clear that one cannot compromise with one's convictions for expediency's sake without suffering feelings of frustration and guilt. The psychotherapist's job here is to help the patient understand the fears of isolation, loss of status, etc., which led him into the compromise, and to help him, through insight, gain sufficient ego strength to live according to his convictions. It is true that realistic problems may stand in the way for many, but most people can gain some degree of freedom to live their own lives if they understand the situation. The above topic will become clearer after a discussion of the role of cultural factors in difficulties in living.

## ¶ The Effect of Cultural Patterns

Although the types of problems dealt with in this chapter are certainly, in every case, the result of the impact of interpersonal difficulties beginning with the parents, nevertheless, these people show more clearly than do the more gravely disordered the results of conflicts growing out of a specific cultural pattern, because these people are not so disturbed that they withdraw from some degree of acceptable participation in the life of their social group.

For example, a young girl blossoming into

Downloaded from www.ohnetrauer.org

adolescence was presented with a problem which seemed to change her whole way of life from one of outgoing friendliness and popularity to one of introversion and withdrawal. She had been brought up under the influence of a Protestant sect which taught the necessity of denial of the pleasures of the flesh. In childhood, this had not particularly affected her, because her companions had similar backgrounds. She was perhaps more serious minded than some of her playmates, but she was a good sport and a leader and enjoyed deserved popularity until she reached the age when sex became a factor in relationships. In high school, she encountered, for the first time, another cultural group, but she still continued to be popular with boys and girls until she came to the first high-school dance.

She had been taught that dancing was wicked, and she had never questioned this teaching. She had not been allowed to take dancing lessons, and she had not been fully aware of how this made her different from others until she went to the party. At the dance, her friends came and asked for dances, and suddenly she found that she was all wrong—different. She had to say, "I don't know how to dance," and "My parents don't want me to dance." That evening, she experienced, with horror, the feeling that she was a wallflower, and from that day she could not regain her old self-confidence. It was not so much that her friends proceeded to drop her as that she lost confidence in her ability to interest them, and she withdrew from their advances. It was, of course, not the simple fact that one evening had been ruined; she saw ahead years of similar parties. She was confronted with a whole reconsideration of her beliefs. Before she would be able again to feel that she belonged, she would have to think through her convictions about attitudes she had accepted without question up to that point.

Here we have a subcultural attitude making a person an outcast. Had she continued to associate only with people with standards similar to her parents', she would not have had this problem and might have reached a healthy, untroubled maturity in a limited milieu. The problem of mixed cultural attitudes is especially characteristic of the great melting pot of American life. I am convinced that many who get confused by it are not basically very emotionally disturbed—their problem rather grows out of positive assets. They are seeking growth in new ways of life, but, in the process, they come into conflict with their earlier cultural patterns.

This has been especially dramatically shown in the rapid movement of the last fifty years toward the "emancipation" of women. In the nineteenth century, women were beginning to show open discontent with their position. Nevertheless, they had a position. They had learned from their mothers the duties of woman and wife. The pattern had not yet radically changed. But in the last sixty years, women have moved far from the patterns of their childhood. In the "roaring twenties," sexual freedom, thought of as equality with men, was advocated. But women had not been psychologically prepared for it. It brought many new problems. In the minds of many a girl, the old-fashioned-wife idea continued to exist, side by side, with the right to be sexually promiscuous. In the same way, the right to a career versus the desire to be a wife and mother stirred new turmoil. This conflict was given additional fuel by the fact that homemaking was no longer a full-time job. Much that once was the province of the woman has been taken over by modern invention, in the form of frozen foods, manufactured clothes, and the many gadgets that make housekeeping easy. Often college-educated, woman found herself, after marriage, relatively unemployed and therefore restless. At the same time, for a few years at least, she had the care of her children which kept her from complete freedom in following her interests. Gradually, she is finding a new place for herself in the world, but the world has not yet sufficiently considered her particular problems of motherhood versus other interests, and she has as yet to make a specifically feminine place—that is, one that considers her particular necessities. Freud saw the beginnings of this revolution and called it "penis envy." Perhaps what he did not realize was that it was a necessary step toward a new orientation. All states in transition are anxiety-

Downloaded from www.pbookshop.com

producing until a new solution has been found. Women will undoubtedly continue to struggle for many years in search of the solution. This problem cannot be ignored in its impact on the interpersonal difficulties of marriage. Men have also been affected by this restlessness in women. With the tradition of being the lord of the household, he may well resent finding himself on the way down—as he experiences it. Although specific marital discord can always be understood in terms of the specific people involved, the cultural background of a relationship in process of change lends its color to the conflict. Undoubtedly, out of the transition state will come a new relationship between the sexes which may be better or worse but, at least, will be different from the old pattern. The therapist, in listening to marital problems, cannot honestly pull out of his card index a prescription for the happy marriage, except in terms of encouraging mutual tolerance and exploration of difficulties. So, among the interpersonal difficulties is that of the changing relationship of men and women to each other. Needless to say, when a man and woman, free from neurotic anxiety, seek the solution to this, they do not need a psychiatrist. But, for the person already burdened with personality difficulties, the failure of the culture to "be a good mother" and tell them dogmatically what is right and proper constitutes an extra hazard.

Another hazard of the culture—that our present society has a marketing orientation—has been treated extensively by Fromm, especially in *The Sane Society*. This must often produce a conflict between the "true" convictions of the individual and expediency, in terms of acceptance by others. If one has subscribed to the importance of being successful, being what is expected of him with the hope of winning power, it is very disrupting to personal integrity and even to sanity if the price of this means denial of valued basic principles. An example is the following: A man believing in the rights of Negroes is in a position of authority in a Southern state. He can belligerently espouse the cause of Negroes and probably, thereby, lose whatever status he has. He thinks maybe he should take a middle-of-the-road course—but then he becomes confused. Is he deciding upon this course because it will produce the best results in the long run, or is he influenced by his personal ambition to be accepted and win a more impressive position in the community? A state of conflict between the two ideas develops, so that he no longer is able to decide what is best for the cause of the Negroes, a cause to which he thought he was dedicated. What got in the way was his marketing need for personal success, and his final choice was determined by his personal ambition. But some part of him could not accept his decision, and presently he consulted a psychiatrist because of depression and suicidal thoughts. In stating his problem, he said, "I cannot understand why I am so unhappy. So far I have accomplished everything I set out to do, and it looks as if I would get the next position I am seeking." Because he was a person unusually honest with himself, the cause of his unhappiness soon was made clear to him. The issue here is not whether the more effective course is to be radical or middle of the road, but the fact that the need to be successful personally was obscuring his judgment. This man might have gone on to the end of his days, pursuing his personal ambitions without realizing their marketing character, if he had not come into conflict with the prejudices of his community, which forced him to face his values. I have chosen this case because this man was not so completely involved in a marketing orientation that he could not relatively easily become aware of the cause of his difficulty. In other words, he was not a full-blown marketing personality. In general, his ambition had followed the lines of his sincere convictions, and it was relatively late in his life when the great temptation to sell out to expediency confronted him.

The much more difficult problem is that of the person who has accepted the marketing orientation as his way of life. Inculcation into how to make his personality of sales value may begin very early in life. One is taught how to sell his personality, how to listen to the market, and so forth, until any spontaneous potential not fitting into the market value becomes completely submerged. These are much more diffi-

Downloaded from www.uratmirary.org.in

cult cases. Although we are not accustomed to thinking of them as sick in a psychiatric sense, they are certainly unhappy and unfulfilled people. They give the impression of being driven without opportunity for relaxation. *What Makes Sammy Run* is one of the finest literary descriptions of this product of our culture. In dealing with this situation, the psychiatrist needs a real orientation in human values as to "what is good for man," as Fromm expresses it. This does not mean that the circumstance of the individual situation should be ignored; rather, it means that it must be seen in its larger cultural setting.

An important thing to remember in considering the people described in this chapter is that the obviously neurotic person suffers from his failure to adapt, but these people I am discussing suffer from the compromises they have made in order to adapt. Both types suffer more basically from the need of approval, that is, from the need of support from without, and it is just as important for the apparent "going concern" to find his orientation based on his own inner strength as for the obvious neurotic to find his orientation based on the same.

As stated earlier, we are dealing in this chapter with the ordinary everyday problems which confront many of us. This, however, doesn't mean that they can be easily solved by a slap on the back, a "Buck up, you're all right," or a piece of practical advice. Analysis of the defensive attitudes and of the individual values is usually indicated. The goal is the emergence of a self-reliant person, free from restricting dependencies. When this is achieved, the problems of intimacy, work, and personal creativeness can be solved. This is called ego-analysis by the psychoanalysts and is not to be accomplished in a few sessions. It has the drawback of requiring considerable time, as do all analytic procedures. However, the results with this type of problem are often very gratifying, and short cuts are no real substitute. Trying to reform from the outside in will never achieve the type of permanent strength needed for the successful mastery of living.

CHAPTER 12

# TRAUMATIC NEUROSES OF WAR

Abram Kardiner

Downloaded from www.dbraulibrary.org.in

The neuroses incidental to war alternate between being the urgent topic of the times and being completely and utterly neglected. Although there is no such thing as a specific neurosis of war, those of a similar character that occur in peacetime are swallowed up in oblivion.

These neuroses are important for several reasons. First, they are of great importance as a practical problem of the conservation of human resources in time of war. We learned a great deal about these neuroses after World War I, and World War II showed vast improvement in our ability to manage them. Secondly, these neuroses contain a syndrome which is of the highest importance for psychodynamics, particularly for psychoanalytic dynamics.

In general, there is a vast store of data available on these neuroses, but it is hard to find a province of psychiatry in which there is less discipline than in this one. There is practically no continuity to be found anywhere, and the literature can only be characterized as anarchic. Every author has his own frame of reference—lengthy bibliographies notwithstanding.

In many cases, war neuroses have been named after the occasion during which they occurred, and the symptomatology has remained the guide to pathology and nosology. This practice has led to the fact that there appear to be hundreds of syndromes produced by war. There is a widespread theory that war neuroses can only be a continuation of a preexisting neurosis and that the war situation acts only as a precipitating agent. Although it is true that a war situation can revive preexisting syndromes heretofore dormant, it can also create new ones.

No one exposed to war experience comes away without some of the symptoms of the traumatic syndrome, however temporary these may be. These symptoms are transient and disappear with rest or withdrawal from the danger situation.

The neuroses that develop in wartime can be considered from the following points of view: (1) the wartime environment; (2) the nature of the self-preservative crisis; (3) types

of reaction to this situation; (4) psychodynamics of the traumatic syndrome; (5) treatment of acute and chronic phases; and (6) forensic issues.

The wartime situation is so complex that there is no facet of the human personality that is not put to the severest stress in it. This includes the whole psychophysical apparatus, the capacity to withstand hardship of infinite variety, the ability to be a member of a team, and the ability to have affection for and cooperate with one's fellows. The soldier-to-be has a preinduction panic, and, after he is in, he lives and functions in a social milieu that has little resemblance to the one from which he came. Whatever protections the soldier had as a civilian, where "allowances" could be made for his weaknesses, all these vanish in military service. These are, therefore, the conditions under which any schizoid types are soon likely to collapse. On the other hand, for many schizoids this is the favored environment. They do better than in civilian life, because they enjoy the protection of a great father and need only to be obedient. Some of them break down after they get home. The same paradox is found in connection with neuroses existing at the time of induction. Each person is, in this regard, a law unto himself.

These, however, are not the neuroses created by the stress situation, that is, by the self-preservative crisis due to the danger of destruction. This reaction to impending threat of destruction is the pathological nucleus around which a new style of adaptation can be organized. It is this new organization and the reactions of the subject to it that constitute the syndrome we call the "traumatic neurosis."

## ¶ Principles of Evaluation

Notwithstanding a voluminous literature, principles to be used in evaluating this syndrome are rarely explicit. Most of the time there is no evidence of any frame of reference—only circumstantial explanations. The fact is that this syndrome is at the very heart of the psychoanalytic conception of neurosis. Freud used the phenomena of this neurosis as the basis for his study of hysteria (*Unfallsneurosen*) and later employed some of the phenomena as a starting point for the revision of his instinct theory.

There are only a few basic ideas about the pathology of this syndrome. The most obvious thing about this pathology is that it should be related to the apparatus that has to do with the accommodation of the organism to the outer world. It should, therefore, have to do with the whole sensorium and to the neurophysical apparatus for mastery. We could, of course, say that this neurosis is concerned with the instinct for self-preservation, but, however useful it may be to isolate a "sexual" instinct from others, it is quite absurd to attempt to isolate an instinct of self-preservation, which consists of many inborn reflex devices and a great many cultivated and learned devices. Its locus is the entire organism. It is therefore quite difficult to isolate a specific instinct involved.

The ideas about pathology can be described as follows:

### *The Organic Conception*

The "trauma" was thought to have given rise to some specific damage to the central nervous system. This notion was held, especially by neurologists, for a long time. There was much difficulty in establishing the actual damage, and, even when demonstrated, the relation between the damage and the symptoms was never established. During World War I the issue was decided in favor of the so-called "functional" point of view.

### *The Psychoanalytic Interpretation*

A symposium,[3] data for which were gathered in 1918, purported to be a survey of war neuroses from the point of view of the libido theory. It contained some important ideas and was a resumption of a discussion, originated by Freud, concerning the origin of neuroses in traumatic events. Freud revised the whole connotation of the concept of trauma and finally settled upon its definition as an influence that initiated an arrest of development. Subsequent traumata revived the return to the point of original arrest of develop-

Downloaded from www.freelibrary.org

ment (fixation) by a process called "regression."

These four authors all employed this basic idea of psychopathology. The arrest of development was naturally at one of the libidinous stages during ontogenesis—oral or anal.

This little symposium contained a short preface by Freud in which he failed to endorse the views of these four authors with any great enthusiasm.

Perhaps he was not satisfied with these explanations, as he was already engaged in a new approach. This appeared in *Beyond the Pleasure Principle* and is known as the "Reitzschutz theory." Here Freud announced a new definition of trauma as a break-through of the defense against stimuli. This break-through set up a great amount of anxiety identifiable in dreams and was an effort on the part of the organism to free itself of this anxiety by abreacting the anxiety piecemeal by constant repetition. In fact, it was in this tendency to repeat that Freud saw a new principle that lay at the bottom of all instinctive phenomena —the repetition compulsion.

This conception of Freud's, that the pathology was caused by a break-through of a protection against stimuli, was a very powerful one, but it did not describe what the protection against stimuli consisted of, how it was built up, or how it was destroyed. The other idea, that the dreams represented abreactive attempts, is really a revision of an old theory of abreaction that he had long since discarded.

Freud's Reitzschutz theory was the starting point of my own reflections on the subject. My own experiences were with the chronic cases. I had, therefore, a good opportunity to observe the effects of this neurosis on the adaptation of the subjects. Moreover, this neurosis furnished the opportunity for the study of neurosis as a form of adaptation rather than as a form of illness.

The study of the pathology began with the study of the particular personality functions involved, how these functions were integrated into systems of action, what the traumatic experience did to these systems, and what the end products of the reaction were. The dominant pathological device used was akin to repression, the purpose of which was to eliminate the painful environment and to diminish the anxiety created by the curtailment of resources. The neurosis consists of the establishment of a new style of adaptation based upon the truncation of resources. Naturally, it induces a parasitic form of existence compatible with these diminished resources.

Rado, in essence, endorses this basic conception of the pathology, but he is concerned more with the systems of control rather than with the systems for action. Basically, this concept does not alter the pathology. Rado believes that the symptoms of the neurosis have a high demonstrative value to elicit pity and support for the patient's now-diminished resources. In addition, the subject protects himself fiercely against the possibility of a repetition of the trauma—traumatophobia.

The really important issue, stressed by Rado but unrecognized by other authors, is that the existence of a pathological syndrome has an effect on the rest of the personality. The patient may be depressed by this, or he may invoke a long series of other reactions to this syndrome.

The most complete account of war experience in World War II is that of Roy Grinker and John Spiegel. There are only two things in it that are different from the preceding accounts of Kardiner and of Rado. Grinker does not explicitly recognize the traumatic syndrome as such, accounting for the pathology in much the same way as does Kardiner, but he includes in the war neuroses a group of reactions that are no different from those that occur in peacetime, that is, conflicts concerning pride, self-esteem, *esprit de corps*, etc. Secondly, Grinker insists on an explanation that takes into account the neurological paths through which the pathological reactions take place. This really adds nothing to explaining the symptoms, and, for the greater part, this discussion is gratuitous.

## ¶ The Soldier and His Job

The transition from civilian to military life is a difficult one. The individual becomes a member of a social organization that has no resemblance to the one he left. It is now a nonfamilial hierarchy, in which cooperation is obligatory. He has lost his freedom of choice, for all activity is prescribed. He must carry

Downloaded from www.dbraulibrary.org.in

responsibility but also must be subordinate. It is therefore not surprising that he lives in a state of resentment. The difficult physiological stress conditions under which he now lives can only add to the subject's irritability and resentfulness. Since all these factors have to do with the matter of morale, in the American forces absolute democracy in the distribution of risk was of the highest importance, whereas it did not matter so much in the German military forces.

All in all, there are, in this social environment, a vast number of new adaptations, new conflicts, and new stresses—particularly physiological ones—that predispose the individual to decompensations, but the greatest of all stresses is the actual danger of destruction—complete or partial. The regulation of peacetime activities according to physiological tolerance is broken down during war. The soldier lives in an atmosphere of continuous fatigue, anxiety, and boredom, deprived of sex and opportunities for complete relaxation. Moreover, his weaknesses are exposed to public gaze, and his failure to be an effective member of a team may inflict a blow to his self-esteem from which he may never recover.

On the other hand, the soldier is protected by his teammates, by his trust in effective leadership, and by the effectiveness of his weapons. In addition, he is protected by the idea of invulnerability. The latter lasts only as long as no one in his team is injured or killed. This breaks it up.

A soldier's morale will be high if he is well fed, effectively led, rested, on good terms with his teammates, confident in his weapons, and on the winning side; his morale will be low if he is underfed, thirsty, and exhausted, has poor relations with his fellows, is without trust in his leaders and confidence in his weapons, is poorly led, and is on the losing side.

## ¶ The Acute Phase

The syndromes that are described under war neuroses do not appear on the battlefield. All one sees there are tired, exhausted, and frightened men. In the past the tendency was, on the part of novice field psychiatrists, to send all exhausted and tired men to the rear. They discovered, however, that when the ruling was "no going to the rear," nothing disastrous happened. On the contrary, morale improved. This illustrates the point that the field psychiatrist can improve or worsen his subjects' immediate reaction by his own tacit evaluation of the situation as "what he expects" or that it "is serious." Those on field duty found it to be most advantageous to the soldier, and to the army, to recognize the exhaustion and the fear but not to remove the soldier to the rear. An assignment to kitchen duty, still subject to battalion discipline, not only saved face but often saved a soldier. It is preferable not to retire a useful man beyond carshot of guns, and not prematurely to allow him to get the feel of being away from his unit. This is demoralizing and encourages retreat.

The impending signs of a soldier's approach to a breaking point are poor appetite, carelessness, jumpiness, heedless exposure, freezing to the ground, fear of noise from his own artillery, inability to relax, and characteristic inability to sleep because of perpetual nightmares. The symptoms do not form immediately; they take time to consolidate. How they do this depends on the previous personality of the subject. Thus one person began with tremors and went on to develop a tic and then a profound depression. Another exhibited choreiform movements, stammering, amnesia, irritability, and insomnia.

The symptoms are the outcome of conflict in two areas: (1) the relation of the subject to his own resources and (2) his relatedness to the group. When both are disturbed, the external danger becomes greatly exaggerated, and the attitude of surrender is thus encouraged. Naturally, the relatedness to the group is affected much more severely in a defeated force.

## ¶ The Chronic Phase

It is my conception that the nuclear condition is a pathological syndrome that becomes incorporated into the personality in different ways; hence, its manifestations differ. This traumatic syndrome consists of the following:

1. An altered conception of oneself in rela-

Downloaded from www.dbraynbrary.org.in

tion to the outer world. How this comes about is the task of psychodynamics to explain. This is what is commonly known as a fixation on the trauma. The concept of fixation on a trauma is really a misnomer. It is what happens as a consequence of an altered conception of oneself and of the outer world.

2. Typical dream-life. The catastrophic dream is probably the most universal earmark of the traumatic syndrome. These constant dreams of the failure to consummate successful actions are, in fact, the key to the pathology. It was this phenomenon that gave Freud the idea of a new property of instinct, "the repetition compulsion."

3. Irritability and startle pattern. The irritability is primarily accoustic but spreads over to other forms of stimuli.

4. The proclivity to explosive aggressive reaction patterns. These can be carried out in fugue states, with diminished states of awareness if not states of complete unconsciousness.

5. Contraction of general level of functioning, including intellectual ability. This contraction of interest is a common accompaniment of constant struggle with the fear of annihilation. The individual's affectivity begins to suffer, and his interest in the world generally shrinks. Some of these subjects undergo a kind of deterioration that is not dissimilar to that which occurs in schizophrenia. This diminution of interest in the outer world is generally the result of a long and unsuccessful battle to maintain meaningful contact with the world. In fact, the subject suffers from a kind of delusion that the world has become an unbearably hostile place. The diminution of interest and intelligence is due to the continuous shrinkage of the field of effective functioning and the gratifications derived therefrom.

This syndrome is central to the neurotic style of adaptation. It is elaborated with different end products.

### *Phobic Elaboration*

As a general rule, these neuroses are not subject to much symbolic elaboration. It was this feature that gave me the idea (in 1932) that we were dealing here with a kind of bound energy. This was a way of describing energy involved in physiological functioning. It was presumably in contrast to energy that was mobile and hence capable of symbolization. I no longer believe that this differentiation is necessary or valid. The phobic elaboration makes these cases look as if the traumatic syndrome were merely engrafted on a long-standing neurosis. In fact, some of these cases create the impression that they are actively engaged in a two-fronted neurosis—one pertaining to their relations with people, the other with their relations with the outer world.

### *Defensive Ceremonials and Tics*

These are largely constructed like those above, but they have more resemblance to obsessional characteristics. More commonly, these ceremonials are purely protective in intent, although the subject does not know why. Thus one soldier (Ref. 3, p. 109) spontaneously discovered a cure for his insomnia; if he would lie prone in bed with his hands over his head, he could sleep. This subject had been gassed during World War I; he had been taken by surprise and failed to "take cover." His prone posture was a belated "taking cover," under the influence of which he felt sufficiently protected to fall asleep. This still has the obsessional character of a sleep ceremonial, illustrating the point made about the patient living constantly in the environment of the traumatic experience.

## ¶ Autonomic and Psychosomatic Disorders

Sometimes the presenting symptoms are largely concerned with the autonomic system, including violent oscillations of cardiac rhythm; spasms of smooth muscle and, occasionally, voluntary muscles; tremors; and stammering. Some of these subjects have every symptom of Graves's disease except increased metabolism. Most of them, in whom the presenting phenomena are largely autonomic, have no awareness of anxiety. These were the cases

Download from www.dhalibrary.org.in

that were most commonly called neurocirculatory asthenia.

During World War I, most of the subjects with spasmodic phenomena of the gastrointestinal tract found themselves in the internal-medicine wards and treated for symptoms of ulcer. This was altered in World War II. There is a wide discrepancy between the psychosomatic disorders in the two wars. Some authorities consider this to be evidence that the symptoms of overt anxiety were less well tolerated in World War II and therefore were driven to express themselves psychosomatically. I do not believe this was the case. All psychosomatic disorders went unrecognized in World War I.

## ¶ Sensory-Motor Disorders

Sensory skin disturbances were very common, with or without wounds. All sense organs were susceptible to complete or intermittent cessation of function. In some instances all sense organs were temporarily obliterated.

Motor disturbances varied from complete hemiplegia or paraplegias to tremors of every conceivable variety. Head tremors were common, as were disturbances of gait. These latter were less common in World War II.

Some of the sensory disturbances were of a kind that told the entire story of the original trauma. Thus one subject complained of numbness, pain, coldness, and sweating from the chest to the toes, together with other symptoms. When asked to close his eyes, he said, "I feel as if I were in cold water." He was on a raft for eight hours when his ship had been torpedoed. This is another illustration of the conclusion that the subject lives in the environment of the traumatic event.

## ¶ The Epileptic Symptom Complex

There were very few examples of the epileptic symptom complex in World War II, but a considerable number in the earlier war. This is a recurrent paroxysmal syndrome accompanied by syncope and sometimes preceded by an aura. The unconscious state may last minutes and, occasionally, hours. Most of the cases I saw did not have myoclonic twitchings but, during the state of unconsciousness, executed coordinated movements accompanied by great rage, agitation, and cursing. In twilight states and fugue states, the subject acted out either repetitions of actual traumatic experiences or adventitious, destructive, and quite meaningless activities, such as biting furniture or ripping the sheets and bedding apart. In some instances there was a trigger mechanism such as an odor or the sight of something being cut (a slice of bread or bologna), all of which were reminders of actual battle experience. In many instances the fugue state is an actual repetition of a battle scene or of an actual state of unconsciousness cued off by one of the adventitious accompanying circumstances. Thus one veteran lost consciousness only when it rained and he got his feet wet.

## ¶ The Problem of Psychodynamics

What we are trying to do with psychodynamics is to unravel the sense behind the symptomatology. What kind of adaptation lies concealed behind these varied manifestations? We are not interested in "explanations"; we are interested only in whether this syndrome can teach us anything we have not already learned about adaptive processes. We have been altogether too absorbed by the medical contrast between sickness and health, so that we tended to lose sight of effective or ineffectual modes of adaptation. For the greater part, those syndromes which we call pathological are really ineffectual or miscarried adaptations. We require a theory that can give us information, act as a guide to intelligent therapy, and be consistent with what we have learned from other syndromes.

The moment we talk of adaptation, we are describing a relationship between an organism and an outer milieu—be it natural or human—in which we are observing what takes place in the organism to the end of continuing favorable conditions or avoiding unfavorable ones. How the organism does this is at the center of our concern.

We start with the inborn equipment of the organism and study how this equipment has

Downloaded from www.dbraulibrary.org.in

been molded to meet conditions outside itself. The adaptive equipment is therefore an inborn equipment accustomed to a certain range of adaptive maneuvers in an expected environment. When we speak of trauma, we always mean that some feature of the expected environment has been altered, so that the adaptive maneuvers suitable to the expected environment no longer suffice.

This is really nothing new. The expected environment alters its character when the resources of the organism become diminished. This is the state of affairs that takes place in fatigue, in the ordinary act of attention, in slight accidents, and in organic disease (particularly of the central nervous system). The state of fatigue has as its manifestations some of the features of the traumatic neurosis—irritability, explosive rages, and some features of its dream-life. A sudden pain may cause syncope. Minor accidents will show in the dream-life a transient break in the adaptive apparatus. The same is true of organic disease of the central nervous system. Brain tumors can occasionally be diagnosed on the basis of dream-life resembling that of the traumatic neurosis.

In other words, imbalance between the organism and its adaptive resources is often established in states that seem not to be traumatic in their abruptness but nevertheless create either an unexpected environment or a diminution of adaptive resources to meet the expected environment. Both are traumatic. There is, in other words, a balance between the organism and its adaptive equipment to the expected environment. When this is broken, a new adaptation becomes imperative. The trauma is therefore only the provocation. The neurotic process that becomes consolidated on top of this altered situation is what we call the symptoms. The most noteworthy of these is the wish to avoid the traumatic situation, what Rado has termed "traumatophobia." This urgent wish—to escape from the traumatic environment—and the efforts to construct a new expected environment constitute the new adaptive undertaking. Most of the time it fails, because the subject is completely unaware of the devices he has mobilized to ensure his safety and of the fact that these are incompatible with the goal of recreating a new environment. One adaptive device, generally used, ruins the chances of any such successful solution: The subject usually institutes a series of maneuvers that end in shrinking the ego to a degree that any kind of effective reconstruction becomes impossible. The general course is then to accommodate the organism to its shrunken inner resources.

We are accustomed, in the study of the neuroses, to consider orderly retreats to entrenched positions already established during the course of ontogenesis. However the case may be with the sexual instinct, in this neurosis the methods of adaptation discarded during growth are now of no value as adaptive devices. One does see massive regressions to early childhood, incoordination, inability to speak, and, in rare instances, regression practically to birth. But, on the whole, one sees much more of disorganization rather than regression. This raises the question about what becomes disorganized. One could say that the ego becomes disorganized, but this would not mean very much, because a disorganized or fragmented ego is something that we see only in cases of delirium. There is no such thing in these neuroses. The ego, so to speak, remains organized, all too alert, dedicated to a specific job of ensuring the security of the organism and, particularly, of trying to protect it against recollections of the original trauma. This is a most unsuccessful maneuver, because, for the most part, the entire world has been transformed into a traumatic environment. What therefore becomes disorganized is the whole series of action systems that carry out the intentions of the ego. This takes in the cognitive, coordinative, executive (sensory-motor) apparatus and the autonomic system. The protective process is very closely allied to repression. We cannot quite call it by that name, because repression generally involves the keeping out of awareness of ideas, affects, and memories. In this case, more is involved; whole systems of action are subjected to a similar order of treatment. In the ordinary hysterias and obsessional neuroses, some efforts at substitution for the impounded impulses or ideas are possible. In these traumatic syndromes, no such substitution seems possible.

Downloaded from www.pdfbooksfree.org

The operational schema used in the Freudian system is not as applicable to the traumatic neurosis as to the neuroses of peacetime. We cannot isolate any instinct or component instinct that is disturbed, nor can we account for the pathology on the basis of substitutions. The neurotic syndrome cannot be accounted for on the basis of interference with the instinct of self-preservation or ego-instincts. There is no unitary instinct of self-preservation, and ego-instincts have no standing in pathology. Why talk of instincts in a creature whose adaptability depends not on inherited patterns of behavior but on learned and integrated systems of action? These latter are therefore our effective units of action.

The most useful normal prototype of the traumatic syndrome is the phenomenon of fatigue. Here there is no disturbance in the composition of the action systems, but there is a discrepancy between the available resources of the organism and the demands made upon it. In this state of fatigue there are marked diminution in the accuracy of perceptions, irritability, tendency to outbursts of rage, and the wish to have done with the outer world. The recuperative agent is rest and sleep, a controlled and elastic inhibitory process.

In the traumatic syndrome the breakup of the action systems becomes the starting point for a new adaptive pattern. We can try to follow this new pattern from the situation in which the personality is overwhelmed—the traumatic event.

We have learned that no consistent ego or constant action systems can be built up in an environment that remains persistently traumatic. The ego can only accommodate itself to an expected environment within a limited ambit of variation. The traumatic event breaks up this balance between the ego and the environment by overwhelming the coping devices which the ego has at its disposal. The anxiety is overwhelming, and the ego shrinkage can be so complete that death can ensue. The entire adaptive equipment is thus disintegrated.

This has a specific meaning to the organism: it has now begun a contractile maneuver, that is, it parts with those adaptive devices through whose agency it maintained meaningful contact with the world. Shorn of these protections, the world takes on a hostile meaning. Either consciousness is lost, or its character is so altered that the capacity to derive pleasure from the world is sharply curtailed. The organism becomes occupied with a defensive attitude that chokes off the possibility of further pleasurable outside contact. The contractile device used is ego contraction. No one knows how this is accomplished, but we can identify the fact that it has taken place, be it in the form of loss of sense-organ function, paraplegias, hemiplegias, or other manifestations. The organism itself cannot shrink, but it can withdraw those devices through which it maintains contact with the outer world. The action systems are inhibited and tend to lead independent existences. Meanwhile, the organism tries to maintain contact with the outer world with these truncated resources and has a most uncomfortable time of it.

From this point on, fresh attempts at readaptation are undertaken. Depending on factors we cannot yet identify, some of these cases go on to a spontaneous rehabilitation. In others—in fact, in most cases—there ensues a fruitless struggle to recapture the tools of mastery, lost through this miscarried defensive process, ending in a complete acceptance of defeat, only to live marginally, with diminished resources and a low pleasure return.

From the psychodynamic point of view, the active symptomatology is created by the attempt to satisfy the demands of living with an executive apparatus that is either completely impounded or operating with spastic inelasticity. The effects of this impounding operation are that some parts of the action system are not susceptible to any control or inhibition. This is notably true of the autonomic system. This system therefore goes on creating the intraorganismic conditions for action (increased pulse rate, etc.), but, instead of action, there follow irritability, hyperacusis, and preparedness for flight instead of eagerness or curiosity. The self-confidence is gone. The subject cannot conjure up the image of a completed action and can get no satisfaction from his ineffectual efforts.

Downloaded from www.allpsychology.org.in

The consequences of the impounding operation are disastrous. No substitution is possible, and regression is of no avail in maintaining satisfactory contact with the outer world. Such is the case with regressive reinstatement of oral mastery. Masochism or passivity to the outer world means destruction.

The consequences of the ego contraction are therefore:

1. Changes in effective adaptation to the outer world. The most important manifestation of this is the lack of interest in activity. The incentive is blunted, because the apparatus is defective. Organized channels of action are broken up, and their place is taken by periodic outbursts of disorganized aggression.

2. The endopsychic conception of oneself has been altered; confidence is lost, and retreat instead of enterprise becomes the objective. The world is now a hostile place, and the subject lives in constant dread of being overwhelmed by it.

3. The altered conception of oneself and the outer world is what lies behind the catastrophic dreams. No action can be completed. Instead, the ego is overwhelmed as it once was. Since the implements for keeping the world at bay (mastery) are now impounded, the world is overwhelming the ego. Hence the hostile world and the impoverished self are two facets of the same pathology. The *Weltuntergangsphantasie* of the schizophrenic is an allied phenomenon. The internal structure of the ego is falling apart, but what the subject perceives is the change that is taking place in the outer world. These dreams were the feature of the pathology on which Freud based his *Reitzschutz* theory. This type of dream attracted Freud's attention because it contradicted the wish-fulfillment theory. Whether or not the dream may be a wish-fulfillment, it is the best indicator of the structure of the personality. In fact, these dreams teach us a new principle in psychopathology: We have the tendency to regard dreams from the point of view of motivation. But the motivation is contingent on the resources available to carry it out. In other words, the dream gives information about motivation and of the structure of the personality *at the time.*

This state of affairs cannot lead to a masochistic adaptation, but the diminution of resources may—and most often does—lead to a parasitic existence.

The autonomic phenomena point, as do all the other manifestations of this traumatic syndrome, to the breakup of the systems for carrying out executive ends of action. The latter are inhibited, but the autonomic phenomena continue to lead an independent existence. Needless to say, the autonomic activity is maintained by a constant undercurrent of anxiety and expectation of disaster.

## ¶ Treatment

The treatment of this syndrome depends on the length of time that it has had to become consolidated and incorporated into the total adaptive pattern. By and large, the prognosis for the efficacy of treatment varies directly with the time factor. When the subject has had an opportunity to consolidate his adaptation on a parasitic basis, it is extremely difficult to break this up and reinstate a more healthy plan. The great issue in the treatment is not to permit the syndrome to become entrenched in the personality.

### *The Acute Phase*

No one has yet discovered the predisposing factors for this neurosis. It is therefore very difficult to distinguish the malignant conditions from the more benign. Generally speaking, those subject to syncopal attacks have the poorest prognosis.

In the acute phase the therapeutic job is to prevent the soldier from capitulating and taking refuge in escape from duty. The fear and exhaustion states must be admitted by the physician, but the subject must be encouraged to believe that he has not reached a breaking point. Permitting the soldier to admit fear is a policy that has paid off well.

The first requirement is to keep the soldier within his combat unit after his first break. Kitchen duty and rest routine are excellent, combined with sedation at night. There should

Downloaded from www.freelibrary.org.in

be four or five days of this program, followed by a return to active duty.

Only those already too disturbed at the clearing station should be permitted to go to the evacuation hospital. These include individuals with gross tremors, delirious states, agitated terror states, and stuporous states. Acute "homosexual" panic states also belong in this category.

In this stage the most active therapy is indicated. Its objective is merely to prevent consolidation of the retreat process. The most effective implement is to keep alive the relation between the symptoms and the traumatic event. Any other procedure permits the isolation of the symptoms from the traumatic event. These patients literally try to forget the traumatic event. This amnesia is a protective device, but, unfortunately, the repressive process drags with it all action systems. Whether this connection is kept alive by hypnosis or is done in the conscious state is of little import. Naturally, when the subject is too disturbed for direct approach, the use of drugs or hypnosis is indicated. Hypnosis cuts through a great deal of peripheral resistance that is time-consuming. The demonstrative value of hypnosis can also be very high. On the other hand, the conscious approach is more effective because the ego is not narcotized. The choice is really a matter of taste, but by and large, hypnosis saves time.

### *The Chronic Phase*

Cases that are permitted to become chronic, that is, after six months, have a poor prognosis. The reason is that the subject develops a pattern of existence suitable to his reduced resources. The longer this consolidation is permitted to go on, the harder it is to dissolve. New patterns of gratification become organized and are difficult to break up. The chief obstacle in these chronic cases is the complete collapse of self-esteem. These subjects no longer have any pride in themselves or in their accomplishments. Hence, without being criminal, they expect nothing from themselves, and take from society quite ruthlessly and without even a sense of triumph.

The choice of technique must be decided within a narrow ambit: (1) conscious approach, (2) barbiturates, and (3) hypnosis, or all three in turn. Each has its advantages. One cannot expect an integrative job to be done if one narcotizes the instrument of integration. On the other hand, in the conscious state this integrative instrument is not available, being clogged up with defensive maneuvers. This is the dilemma of treatment. A skilled therapist picks his own combination.

A brief summary of two chronic cases will suffice to indicate both problems and methods.

The first concerns an epileptiform case with fugue states of seven years' duration. There was an old epileptiform anlage from early childhood, dormant for twenty-four years. The subject was thirty-three at time of treatment.

At the initial interview, he showed rigidity of bearing and a Parkinsonian expression. His speech was choppy and monosyllabic.

Initial response to inquiries was disturbing to him. He refused to talk about circumstances of his traumatic experience. His complaint was "spells," which turned out to be fugue states with destructive behavior during these states. Regression to "oral mastery" was a conspicuous feature of the fugue states; that is, he chewed up the furniture, and his teeth, worn down to the gum line, were testimony to this regression.

Seven years of spontaneous recuperative efforts landed the subject in a position where he was engaged in a constant battle with an environment he conceived of as hostile. As a result, he was living in an emotional strait jacket.

My initial probings about the traumatic event only led to reinforcement of his defensive efforts. The traumatic experience was completely fragmented, and it was the subject's spontaneous effort to keep these fragments from reuniting into the total traumatic event.

When finally reconstructed, the "event" was as follows: (1918) "We were to take a line of trenches at seven P.M. The order was revoked and dinner was served—carrot soup. The command was given again. It was dark, stormy, searchlights were playing on us, shadows played. I went over the top, heard someone scream, 'Duck.' I got over the first trench. A shell landed. Everyone was running. I was trampled underfoot. I lost consciousness." The shell did not explode. It was a dud.

Downloaded from www.psychiatry.org.ir

It took seven months of distressing labor and enormous suffering on the part of the patient to reunite these events into their proper sequence and ultimately to enable him to envisage the experience in its totality and to tolerate it.

What he was trying to do before was to keep each item of the experience separated from any other, but he reacted to each item as if it were the whole experience. For example, he would react to twilight, shadows, loud unexpected noises, the word "duck," and several other stimuli. He had lost all power of coordination and had to take work that required less and less skill. It would take him hours to do a task that would ordinarily take minutes. This made him lose job after job. He couldn't hold anything in his hands, and he stumbled all the time.

This case gives a most complete inventory of the traumatic syndrome. His dream-life was typical. His vulnerability to slight pain or a scratch was such that it would reduce him to utter helplessness. A slight automobile accident, in which the taxi he was in collided with another vehicle, landed him in a hospital for several days.

Long before there was any theory about the nature of these neuroses, empirical observations demonstrated the value of abreaction. As a matter of fact, it was not abreaction but the reconstruction of the traumatic event and filling in the amnesias. This is a rather late date to talk about the value of abreaction, since its usefulness has been exploded as far as the ordinary neuroses are concerned. Why should it be of value here?

In the light of recent experience we would now say that, as far as these abreactions are concerned, Freud was a bit mistaken. The phenomenon of amnesia is not purely a matter of memory. It is quite true that amnesia for traumatic events may be one of the features of hysteria, but the amnesia is attached to a system of action. It is the latter that one tries to alter in the neuroses. Recovery of memories does not do this by itself. This is why abreaction, as such, does no good at all if the system of action involved is not altered.

In the traumatic neurosis one sees the relation between amnesia and the total pathological picture. The amnesia is merely an *indication that the action systems involved are broken up*. By reuniting all the fragments of the amnestic picture, one is able to re-establish for the subject the conviction that *he did not die* and was not disintegrated by the experience itself but by the fear of annihilation. Just as a parent guides a child through an experience he regards as fearsome, the patient learns to master the anxiety under the protective aegis of the physician.

In the case of our subject, the reconstruction did take place. His fugues ceased, and the nightmares took on a much more attenuated form.

One other feature of this case is worth noting. During the height of his symptoms, he was much troubled by guilt caused by constant dreams of aggressive activities to those whom he "loved" in so far as he could. There are two ways of accounting for this: (1) in the form that it takes in the obsessional neurosis (it is the currency of aggression instead of affect); and (2) that the decomposition of the patterns of action affects relations to human beings as well as to the outer world.

A second case with a similar syndrome concerned a soldier who fell with a wrecked aeroplane. The phenomena of the illness and of the reactions to treatment were quite the same as the previous case. There were marked diminution of effectiveness and syncopal attacks. One feature of the convalescence cast some light on the pathology of the illness.

The active treatment of this case lasted some six months after his syncopal attacks had ceased. His dream-life became more normal and his compensation was reduced. This led to a flare-up of symptoms, but not the same syncopal attacks he had before. He now had a phobic elaboration of the conflict, namely, a fear of insanity.

The subject was recalled for a routine checkup about six months after discharge. He then observed that he had had one "attack" in the interim, but he exclaimed, "This was the worst one I ever had in my life."

The patient realized, after the attack was over, why he had it. It was the seventh anniversary of his fall. The remarkable feature was that in the last "attack" the patient had a hallucinatory reproduction of the actual fall from the plane in which

Downloaded from www.pbhauthority.org.in

all the amnesias were recovered, down to the finest detail. The subject was himself convinced that he would never have another attack. He did not.

Though several cases have been reported as rehabilitated after neuroses of seven years' duration, by and large the prognosis for chronic cases is very poor. Traumatic neurosis is a disease very closely related to schizophrenia, both from the point of view of central psychodynamics and from the ultimate withdrawal from the world which it set in motion. The deteriorations undergone in both conditions have a striking resemblance to each other. In a manner of speaking, the traumatic neurosis is a kind of persecutory delusion. The persecutor is, however, the outer world. The entire syndrome is produced by what now appears to be a prominent device in the establishment of schizophrenia, namely, ego curtailment.

## ¶ Some Forensic Issues

Because of the common incidence of traumatic neuroses in wartime, this neurosis is not a private disease. It is a public concern, and its treatment and cure must be a public charge. But this disease entity ought not to be considered a compensation neurosis. The subject does not get the neurosis because he wants compensation; he wants compensation because it is the natural tendency of this neurosis to curtail effectiveness, and, therefore, it secondarily encourages parasitic attitudes.

In this connection it is of considerable importance to note that the handling of this particular veteran's problem was far more successful after World War II than after World War I. This was true of treatment of the acute cases on the battlefield, in the base hospitals, and in clearing stations. The knowledge gained in the interval between the two wars paid high dividends in sparing many a soldier from permanent incapacitation. First, soldiers were better screened in World War II, and the indoctrination included education in permissible forms of fear under stress. This made it possible for soldiers to be more overtly afraid without loss of self-esteem. Secondly, the soldier was not permitted to go to advanced stages of breakdown before recognition and opportunity for recuperation. As a consequence, some of the most dramatic types of World War I were greatly diminished in the second war.

Concerning the problem of public responsibility, there is no question whatever that this is a service-connected disability. It would take the most extraordinary circumstances in civilian life to produce this kind of sustained self-preservative crisis. It is safe to say that no soldier with a traumatic syndrome would ever have developed this condition outside of the conditions prevailing in war.

The prime social consideration is the conservation of man power, with particular emphasis on the return of the intact soldier to his original environment. This syndrome is for the greater part (80 per cent) preventable. This can best be done by preventing the chronic forms from consolidating. The chronic forms create a special problem only because an enormous organization is required to take care of them. The acute form is a clearing-station affair.

The rehabilitation of the traumatic cannot be affected by altering his vocation. The inhibition he suffers is general, and the theory that one task would be easier than another is entirely in error. Traumatics should resume their original vocations.

After World War I the issue of compensation was an exceedingly troublesome one. No compensation should be given except during the time of treatment. Once the traumatic becomes entrenched in a parasitic existence, the idea of rehabilitation excites the most violent opposition. One does not effect a cure—or even the disposition to it—by withholding compensation, but, just as a soldier is inducted with the idea that the community expects him to face danger, he can be made to feel the pressure of public opinion with regard to his rehabilitation—which is treated by the patient as a *danger*.

Perhaps the issue of the method of compensation is a bit out of fashion today, but should it ever arise again, the lump-sum method is the most effective. The continuous-maintenance method is a drag on the govern-

Downloaded from www.dbraulibrary.org.in

ment and an encouragement to remain ill. The G.I. bill was a happy compromise and created an incentive for rehabilitation that was absent in World War I.

The issue of compensation is one on which neither the soldier nor the government got a fair deal. I have seen many cases in which government money was squandered in maintaining subjects who could be rehabilitated, and I have seen the government abandon totally disabled veterans simply because they could appear in court with their hair neatly combed. They could convince no one of their disability, except the physician who treated them, and even he was helpless before the court of uninformed and misguided opinion.

CHAPTER 13

# NEURASTHENIA AND HYPOCHONDRIASIS

Gerard Chrzanowski

Downloaded from www.dbraulibrary.org.in

IN MODERN PSYCHIATRY there has been an increasing awareness of the fact that technical terms are not merely static entities. The nature of particular terms used in verbal operations plays an important part in interprofessional and therapeutic communication. For instance, when Bleuler introduced the name "schizophrenia" to replace "dementia praecox," he did a great deal more than coin a new term. He opened the way to a new era in clinical psychiatry.

These comments seem in order in introducing the topic of a chapter called "Neurasthenia and Hypochondriasis." We are dealing here with time-honored concepts which have a most undynamic quality. From an operational viewpoint, "neurasthenia" and "hypochondriasis" are awkward, antiquated pieces of furniture, not much good for anything. Nevertheless, both terms have gained a powerful foothold in psychiatric terminology. For the time being, they seem to be here to stay; rather than complain unduly or coin new names, we may as well look into the nature and the implications of the old-fashioned terms as they appear in sundry clinical phenomena.

## ¶ Neurasthenia and Hypochondriasis: A Single Syndrome

As is well known, the term "neurasthenia," in its original meaning, indicates literally a state of nervous weakness. On the other hand, hypochondriasis once was thought to refer to a topographical localization. The notion was that the soft part of the abdomen below the ribs and above the navel was considered to be the seat of hypochondria. Both terms are used today as indicating conflicts in living. There is still some obsessional preoccupation with the sequence of events—whether organic etiology provides the channel for psychological manifestations, or chronic psychological conflict eventually leads to organicity. The chances are that one chain of events does not present the one and only basis for neurosis or psychosis.

When we come to the nosological classification of neurasthenia and hypochondriasis, we

are confronted with a confusing picture. There is not even complete agreement in regard to the definition of the clinical syndrome. It usually is characterized by a wide variety of symptoms. Ordinarily, there are chronic feelings of weakness and fatigue, various aches and pains, as well as strange physical sensations. Insomnia and irritability may occur in conjunction with a feeling of more or less chronic distress in an organ or organic system of the body. Whereas some patients experience vague, general discomfort, others center their attention upon a particular organ. Any part of the body may be affected. However, there is a high percentage of gastrointestinal symptomatology. The clinician, who is compelled to arrive at a psychiatric diagnosis, does not have an easy task when confronted by a multitude of symptomatic manifestations.

When Freud dealt with the syndrome of neurasthenia, he considered the following symptoms to be characteristic: headache, spinal irritation, and dyspepsia with flatulence and constipation. In regard to hypochondriasis he said, "It is the form favored by true Neurasthenics when they fall victim to anxiety neurosis as they often do."

In "An Attempt at Analysis of the Neurotic Constitution," Adolf Meyer stated that the term "neurasthenia" should be reserved for the cases combining the symptoms of great exhaustibility and irritability, depending largely on the mental attitude of lack of repose and of ready recoverability, frequent head pressures, palpitations and uneasiness of the heart, gastric disorders, phosphaturia and oxaluria, and, in men especially, abnormality of sexual responsiveness. He went on to state:

> Frequently associated with other traits of nervousness, we meet with hypochondriasis, usually built on a feeling of ill-health which leads to self-observation and explanations. These are apt to become the center of thought and interest, are elaborated, or the person merely is troubled with vain fears over trifles, consults quack literature, etc. On the whole, the impressions are apt to become dominating.[22]

Since Bleuler's day there has been an increasing awareness of the clinical observation that neurasthenia and hypochondriasis can serve as a mask for severe mental illness.

Furthermore, it has become clear that, as psychiatrists, we are always dealing with people who suffer from unfortunate life experiences with other people. Disease entities are considered to be more or less durable end states of warped interpersonal interactions from childhood onward. However, classifications of mental disorders are essential for communication in treatment and in research.

In the British Classification of Mental Disorders, as printed in Henderson and Gillespie's *Text-Book of Psychiatry*, we still find neurasthenia listed under the Exhaustion States which are grouped under the heading of Neurosis and Psychoneurosis. In the nomenclature of the American Psychiatric Association, there is no specific diagnosis of neurasthenia or hypochondriasis. Instead, there is a category of Asthenic Reactions and one of Hypochondriacal Reaction. It is possible to classify some neurasthenic and hypochondriacal manifestations under Conversion Reactions or under Anxiety Reactions. The latter diagnosis is described as "anxious expectation frequently associated with somatic symptomatology." Furthermore, there is a group of systematized paranoid hypochondriacal states which are classified as Schizophrenic Reactions, Paranoid Type.

In arriving at a particular diagnosis, there has been increasing emphasis on the premorbid personality. Precursors of neurasthenia and hypochondriasis in children are fairly common. Some of the early complaints are occasionally described as "growing pains." Other children are always tired, have frequent aches and pains, but are wide awake when their bedtime approaches. Gastrointestinal symptoms, paresthesias, and hypesthesias are not unusual in some of these children. Another occurrence in childhood is a disturbed sleep pattern. Some of these children may be lethargic, others are compulsive chatterboxes, some seem to be autistic, others chronically cranky, etc. There are numerous variations of these precursors of neurasthenic and hypochondriacal manifestations.

In other words, neurasthenia and hypochon-

Downloaded from www.dbraum.org.in

driasis represent complicated life careers in people, and the terminology frequently distorts particular warpings of long standing.

Regardless of how misleading the terms may be, the fact remains that neurasthenic and hypochondriacal manifestations are almost ubiquitous in all types of psychiatric practice. Furthermore, the phenomena associated with these concepts are widely represented in our culture, without being given much psychopathological significance. Feeling excessively tired as well as being deeply concerned about one's health are relatively conjunctive aspects of our social pattern.

Many people feel righteous about being entitled to a reactive state of weariness as a result of labor and exertion. For instance, it is considered quite respectable for a professional person to feel worn out at the end of the day; for the housewife and mother to be exhausted from her many chores; or the businessman, after a day of pressure at the office, to be very tired. On the other hand, we can frequently observe how certain interpersonal aspects can aggravate the fatigue markedly, whereas others can make the person forget how tired he is. I am not talking here about occasional states of overwork, etc. What matters is the recurrent nature of the syndrome—a state of affairs where feeling exhausted forms a more or less consistent pattern. As far as the reaction of the environment is concerned, it ordinarily does not seem to be practical or in good taste to quarrel with people's justification for being tired, regardless of the circumstances. Furthermore, it is to be understood that special allowances are to be made for the person who is afflicted by debility and potential ill health. The victims of neurasthenic and hypochondriacal symptoms can always claim that they wish it were otherwise, but they just can't help feeling the way they do. Obviously, the more absorbed a person is with his mysterious predicament, the less available is he for personal relatedness to others. The "I don't feel myself" preoccupation impoverishes the nature of all other communication and insulates the person from more direct contact with the environment.

Despite this obvious dilemma, the nature of the insulation is such that it still permits a tenuous relatedness to others at a time when more meaningful contact might not be possible. As long as at least one marginally structured channel of communication is preserved, this may suffice to prevent a disintegration of the personality.

Another significant aspect is demonstrated by the fact that almost every practicing psychiatrist has seen patients who seemingly feel tremendous relief when a "real" organic villain is found. The patient who gets X-ray evidence of duodenal ulceration, kidney stones, herniated disk, etc., may be highly pleased. The point is that he has something which he considers to be beyond his personal control. It exonerates him from a peculiar kind of blame by himself or others. Such people often are hounded with the illusion of imaginary ailments. They frequently believe that they can turn symptoms on or off at will if there is no specific organicity involved. Everything is done to conceal from themselves and others long-standing, unhappy life experiences involving the total personality. The compulsion to negate personal misfortunes is so great that some of these patients readily submit to a surgeon's knife, painful treatments, prolonged use of medication, etc., in situations which therapeutically do not demand drastic steps.

Here is a situation illustrative of the point made. I had seen a sensitive and troubled woman patient in her late thirties, who had suffered a transient psychotic episode. Part of this profound upheaval was triggered off by her belated awareness that her husband had much in common with an older sibling of hers whom she despised. On the surface it all started with an attack of acute abdominal distress on her part. She was admitted to a general hospital and kept for ten days' observation. There was some idea of a gall bladder disorder. The findings, however, were inconclusive, and she was told that she had been severely run down. From the time she returned home things went from bad to worse. Finally she accused her husband of having poisoned her food and similar uncharitable acts. The situation deteriorated to the point where he felt compelled to institutionalize her. Her hos-

Downloaded from www.dbraunton.org.in

pitalization was relatively short. During her illness it was brought home to her that she owed deep gratitude to her husband's kindness and thoughtfulness. It turned out later that she had never faltered in her conviction that the mental hospital had been a punitive act on his part. At a later point, when my patient had made major strides toward recovery, her husband began to ail. He had always been known as a hypochondriacal person, who suffered from headaches, backaches, gastric ulcers, and neuralgias. Suddenly he developed an excruciating back pain which his wife suspected to be psychogenic in nature. Despite her urging, he refused to consult a psychiatrist. After several weeks of acute misery, he had an orthopedic surgeon operate on him for a dislocated nucleus pulposus. The result of the surgical intervention was miraculous. Now the dragon's tooth which had been bothering him for years had been extracted. His relief was so great that he did not even complain about having to maintain prolonged sexual abstinence. My patient was not unduly affected by this restriction. It soon came out that there had been no sexual relations for more than two years prior to the operation. When my patient became fleetingly interested in sex again, her husband's physical symptoms reappeared temporarily.

As the history unfolded in therapy, several aspects in the situation became clearer. In the past my patient had experienced several spells of depression and ill health, which usually coincided with her husband's feeling on top of the world. There were times when my patient had been highly successful, and her devoted husband almost invariably came down with a physical illness. Furthermore, it became clear that my patient's feelings of well being were usually enhanced by feeling needed. This seesaw pattern had been familiar to the patient within the setting of her own family. In their later years, both of her parents had taken turns in feeling down in the dumps. At such times the low-ebb marital partner was taken to a shock therapist by the solicitous spouse. As a matter of fact, there had been a similar interplay between the patient and her oldest brother. She always came to his help when he was physically ill or in a jam. Once he was well again, she felt all worn out. He would, however, always make her feel she had not done enough for him. On the whole, he led a glamorous life and had always been his parents' favorite. Anyhow, certain aspects of the hostile integration between the siblings had found their way into the marriage. We can see, then, a highly intricate and morbid interplay in a family setting, where alternating hypochondriasis and neurasthenia occur. By the time the husband seemingly blew a spinal fuse, a serious crisis had occurred which threatened to break up the old, familiar pattern. The surgical removal of the man's emotionally exaggerated pain served as a *deus ex machina*. An obvious villain for much obscure difficulty in living had been found. Everybody could point to the tangible intervention and the resulting success. One might add sadly that the patient's psychosis had almost been suffered in vain. Nobody talked, however, of mutual suspicions, resentment, power struggles, and humiliations. A cause had been found that could be reactivated if necessary but which was placed outside of psychological boundaries.

So far the terms "neurasthenia" and "hypochondriasis" have been used together. It is not always easy to draw a line of demarcation between these two conditions. However, when we follow the respective roles these two concepts have played in the evolution of psychiatric theory and practice, the situation is somewhat different.

## ¶ Neurasthenia and Hypochondriasis as Separate Syndromes

There was a time when the theory of irritability and exhaustion of the nervous system was very much in vogue. In England, John Brown (1735–1788) concerned himself with this concept and attracted some followers. The idea was introduced into American psychiatry by George Miller Beard, who coined the term "neurasthenia" or "nervous exhaustion" in 1869. He described it in terms of exhaustion of the nervous cells through deple-

Downloaded from www.dbraulibrary.org.in

tion of their stored nutriment. (There were about one hundred symptoms which Beard ascribed to this cause. The underlying principle was similar to the analogy of a battery running down.)

This conceptual model was largely retained when Freud first studied the vicissitudes of neurosis. In 1894 he stated that neurasthenia as described by Beard covered too much territory; he detached anxiety neurosis as a particular syndrome from neurasthenia.[9]

He grouped neurasthenia, anxiety neurosis, and hypochondriasis together as actual neuroses. In his original formulation Freud thought of an automatic, economic process. His approach was essentially neurophysiological in nature. The symptoms in actual neurosis, according to Freud, were not caused by "mental conflicts." He thought of them as simple physical processes having "no signification in the mind." They arose, in Freud's opinion, through direct toxic affects of dammed-up sexual energy.

Freud placed the problems of actual neuroses outside of the reach of psychoanalysis. However, he formulated the concept of a potential link between actual and psychoneurosis. He observed a connection between neurasthenia and conversion hysteria as well as between hypochondriasis and paranoia. On this basis he conceived of the symptom of the actual neurosis as a core of the psychoneurotic symptom in many instances.

The following illustration of this process was offered: Suppose a person has a hysterical headache. Freud speculated that at one time the pain was real, caused by a sexual toxin. This serves as a focal point of irritation around which psychoneurotic symptom-formation takes place.

In 1908 Ferenczi gave a paper on Actual and Psycho-Neurosis.[6] He elaborated on Freud's investigations by referring to actual neurosis as physioneurosis, in contrast to psychoneurosis. According to Ferenczi, Freud's idea was that sexual excitement withheld from orgasm evokes physiological effects. He stated that Freud was pledged to a chemical explanation of actual neurosis. It was regarded by him as a chronic intoxication by sexual substances.

Ferenczi points out that Freud thought that he could deduce the direct cause of certain neuroses from the nature of the neurotic symptom. A mixture of symptoms was considered to be based on "actiological blending." For instance, masturbation and sudden abstinence from masturbation would lead to neurasthenia and anxiety neurosis simultaneously. Furthermore, he recognized mixtures of actual neurosis and psychoneurosis. In such cases, it was taken for granted that only the psychogenic symptoms could yield to analysis, whereas the physiologically determined symptoms would remain unaffected. The only available treatment for the latter group was in the nature of appropriate sexual-hygienic measures.

In regard to hypochondriasis, Freud was greatly dissatisfied with the obscurity of the concept. He complained to Ferenczi about it in a letter dated March 18, 1912. Freud formulated hypochondriasis as a withdrawal of interest and libido from the objects in the outer world. The relatedness of certain hypochondriacal symptoms to schizophrenia was recognized early. Freud thought that hypochondriasis had the same relation to paranoia as anxiety neurosis has to hysteria.

The concepts of neurasthenia and hypochondriasis have remained relatively unchanged in analytic literature. Fenichel[5] gave a lucid description of these syndromes but stuck closely to the economic concept of libido theory. He affirmed that many an actual neurosis required only adequate sexual outlets. It is interesting that he recognized alterations in the muscular attitudes of people with neurasthenia. He appreciated the inability of such people to concentrate, because they are unconsciously preoccupied with defensive activities. He pointed to the impoverished life activities leading to restriction of the personality, etc. There were many other important insights offered by him, including the appearance of apathy against aggressiveness. However, he still considered an improved sexual technique to be an adequate treatment in some of these patients. The fact that a change in sexual pattern indicates a reorientation in the total personality was not mentioned.

As far as hypochondriasis is concerned, Fen-

Downloaded from www.PsychiatryOnline.com

ichel saw it primarily as a transitional state between reactions of a hysterical character and those of a delusional, clearly psychotic one.

## ¶ Economic Theories of Neurosis

It is of interest that Freud did not follow through with his early studies in the actual neuroses. He did not elaborate on the formulations he made in 1894. Accordingly, he never revised his notion that certain neurotic manifestations result primarily from a toxic effect of undischarged libido. Even after Freud recognized the psychological nature of neurosis and anxiety, he left a loophole for his original neurophysiological theory. As a matter of fact, there is no indication that he ever abandoned his original economic formulation.

The conceptual schism between a neurophysiological and an emotional psychological origin of neurotic manifestations has made it hard to work out theoretically and therapeutically meaningful psychiatric formulations. There is a tendency to see symptoms related to the classic triad of neurasthenia, hypochondriasis, and anxiety neurosis as mechanical in nature without the presence of a mental conflict—the sort of situations where some technical readjustment in attitude, performance, or environment will dissipate the symptom. It could be argued that people with such simple managerial problems do not need the help of a psychiatrist. Needless to say, there are some people in this category. Better living conditions, improved social and sexual habits, various modern pills, etc., will go a long way toward making for a happier and healthier future for some. However, these people are not our main concern. The great number of people we encounter in psychiatric and medical practice are not actual neurotics but people with major difficulties in living. It is for this and other reasons that the dualistic standard in psychiatry (which created the monstrous concept of the neuropsychiatrist) is not helpful. The use of the term "neurosis" to denote mechanical malfunctioning as well as distorted life patterns representing restrictions in the over-all growth of the whole living individual is confusing.

Since Freud, the concept of neurasthenia and hypochondriasis has not been subject to intensive study. Bleuler,[2] a contemporary of Freud, did not go along with the literal meaning of the term and rejected the concept of exhaustion of the nervous system. He observed that overexertion and exhaustion seldom lead to neurosis, and in his opinion never to psychosis. (As a matter of fact, people who work very long hours year in and year out—even those who do not get much opportunity for sleep and rest—seem to be the ones who are relatively immune from neurasthenic and hypochondriacal difficulties.) He thought little of the idea that neurasthenia occurred in people with a weakened health conscience (*geschwaechtes Gesundheitsgewissen Kohnstamm*). Instead, he emphasized the occurrence of neurasthenia as a preschizophrenic symptom.

In regard to hypochondriasis, Bleuler realized that it was no disease entity. He found hypochondriacal phenomena in schizophrenia, in certain depressive states, in neurasthenia, in early organic psychosis, and in all forms of psychopathy.

From a historical viewpoint it seems appropriate to include Janet[10] in a discussion of neurasthenia and hypochondriasis. He introduced the term "psychasthenia" in denoting practically all neurotic manifestations which he did not group as those of hysteria. Janet made particular reference to neurasthenia as a long-lasting feeling of fatigue without physical basis. To him, neurasthenia is a state of psychological depression—a general lowering of mental tension.

A glance at some of our present psychiatric textbooks does not add much to the picture. Henderson and Gillespie[14] make reference to a description of the syndrome by Adolf Meyer. In pure form one expects to find complaints of mental and physical fatigue. These are associated with sensations of pressure in the head, poor memory, inability to concentrate, irritability of temper, increased reflexes, poor sleep, and various aches and pains. It is doubtful that many modern psychiatrists would

Downloaded from www.pdfbraille.org

diagnose as neurasthenia this combination of symptoms. The authors of the textbook are alluding to sundry etiological theories—heredity, constitution (asthenia), autointoxication, and prolonged emotional disturbances. Hypochondriasis is depicted as indiscriminately distributed among a host of psychiatric disorders. It is said to occur in depressions, particularly in the involutional variety. Furthermore, it can be found in schizophrenic pictures, in hysteria, in chronic anxiety states, in delusional episodes, and in paranoia.

In another textbook, Noyes's *Modern Clinical Psychiatry*,[24] we find the author dissatisfied with the term "neurasthenia." He would like to group some of the clinical syndromes listed as neurasthenia under the definition of anxiety reactions. Noyes considers the cause to be diffuse nervousness and sustained tension resulting from deep-lying personal maladjustment. In his opinion, neurasthenia does not usually lead to structural, visceral changes. He considers hypochondriasis to be an organ neurosis.

Masserman, in *The Practice of Dynamic Psychiatry*,[21] stresses the principle of multiple factors. He speaks of neurasthenia as an exhaustive-regressive state, which he believes to be due to unrecognized, cumulative, internal tensions.

In *Conceptions of Modern Psychiatry*, Harry Stack Sullivan[29] states that, as a student of personality, he finds no virtue in the conception of neurasthenia. From a psychiatric viewpoint, chronic fatigue and preoccupation with fancied disorders which cannot be explained on an organic basis form merely a panoply obscuring the nature of various interpersonal events. Although Sullivan had no patience with the concept of neurasthenia as such, he described certain interpersonal phenomena connected with the syndrome. The manifestations most applicable in this connection would be fatigue, somnolent detachment, and apathy.

One interpersonal formulation of psychogenetic fatigue alludes to an atmosphere of hostile interaction. A state of mutual insecurity may be assumed in which hurt feelings or a motivation by resentment may be prevalent. Unresolved anger which leads to concealed resentment, out of fear of punishment and disapproval, can become a source of "not feeling well," "being tired," "fatigued," etc. (This is somewhat similar to Rado's concept. He connects the fear of illness with the fear of punishment. He sees beneath the hypochondriacal fear repressed rage and hurt pride.)

There is still a somewhat different type of fatigue. This is conceived to be a regressive act in which the more recently evolved patterns of satisfaction-seeking behavior fall apart (like the child who takes to thumb-sucking just before falling asleep at a phase of development when such infantile behavior no longer normally occurs).

As far as the terms "apathy" and "somnolent detachment" are concerned, they stem from efforts to reconstruct events early in childhood. Both phenomena are considered to be protective devices in response to disturbed significant relationships from infancy onward.

Somnolent detachment is thought to be the result of inescapable and prolonged anxiety. It decreases the vulnerability to excessive interpersonal tension. In apathy, all the tensions of needs are markedly attenuated. It is called out by severe frustration when personal needs have become extremely aggravated.

In contrast to his dislike for the concept of neurasthenia, Sullivan was much interested in hypochondriasis. He considered hypochondriacal preoccupations to be an expression of chronically low self-esteem. It represents a field of substitutive activities which channel anxiety and other disjunctive motivations. The intense concern about malfunctions of the body reflects dissociated interpersonal experiences. Much that belongs in Sullivan's conceptual formulation of *not me* is projected into somatic distress signals. There is emphasis on the social isolation which is so often combined with hypochondriasis. Furthermore, it points to the restriction of meaningful, verbal communication. The main topic of conversation with others is the constant interest in their state of ill health. All other interests are subordinated to their thoughts about infirmities. Accordingly, there is a marked curtailment of intimacy and of any hedonical strivings.

We find in Sullivan another observation. He noticed in some people an interweaving

Downloaded from www.dbraylibrary.org.in

and alternation of hypochondriasis and paranoia. The idea is that these patients are hypochrondriacal when they are not overtly paranoid and openly paranoid when they do not show hypochondriacal preoccupation.

## ¶ Concepts of Human Reality

The terms "neurasthenia" and "hypochondriasis" have been discussed separately only because this has been the prevailing practice. From what has been said, it seems obvious that there are many overlapping phenomena. In the literature there is every indication that hypochondriasis is usually seen as the more ominous condition. Clinical observation would support this concept. However, the dynamic nature of neurasthenia and hypochondriasis is such that one may think more of a difference in degree than in kind. The common descriptive denominator is the somatic preoccupation. This concept brings up the question of methods for the study of human reality. We all know of instances where people have been given a clean bill of health and suddenly come down with illness or even died. Illness cannot always be defined as clearly as we might wish, and a definition or demonstration of absolute health or freedom from disease seems impossible. Among other factors, one could single out the strictly personal reality which consists of a multitude of factors (time as a continuum, discontinuous processes, nature of life experience in social, interpersonal terms, etc.).

Another consideration has to do with the much misunderstood concept of psychosomatic disorders, the unfortunate implication being that what is not organic is psychic, and vice versa. Much confusion can be avoided by showing less interest in dividing man into his dual nature. Instead, we appreciate the fact that psyche and soma complement each other. Our psychiatric interest, then, is focused on the transactions, that is, on how the constant interplay of psychical and physical factors affects the personal mode of living of the individual. So we come to think of symptoms never as purely physical or as purely mental, but always as expressive of personal life patterns; these represent the highly personalistic* responses to various and variant experiences in the course of a total human life span. The line of demarcation between the living system and the environment cannot any longer be drawn with precision. Consideration of what is inside a person and what is outside of him is often time-bound. Conceptual notions of entities and essential qualities have given way to more relativistic and transactional models. We have come to think in terms of a continuum, a process with multiple factors (at play) *having an effect* often at the same time.

It has proved helpful to study human personalities on the basis of mutual activities in a field. By stressing the operational aspects, our interest has turned toward how people affect each other and what impact the social and cultural setting has upon them. This has largely taken the place of being preoccupied with intrinsic factors. There has been less need to think in terms of strict causality alone. Today, it does not suffice to diagnose an organic disorder or rule out overt somatic involvement. Even in the predominantly organic disorder there are involved some sociocultural as well as some interpersonal components. The individual and his environment are an interdependent system at all times. Any effort to isolate one or the other produces major artifacts. Every disorder tells something about the person in terms of specific life experiences. It points to potential vulnerabilities or sensitivities in the total life history. The area which is of interest to the psychiatrist is always of a strictly personal nature. It has to do with personalistic, experiential data which can become communicable in increasingly more meaningful terms.

When we encounter neurasthenic and hypochondriacal manifestations in our patients, we have to think largely in terms of symbol processes. They tell something about what the

* "Personalistic" or "psychiatric" is used in terms of a definition by Edward Sapir ("Why Cultural Anthropology Needs The Psychiatrist," in Mullahy[23]). It refers to a transformation of form or meaning which is capable of communication effected by a lone individual to other individuals. This is considered to be in contrast with those aspects of behavior which various people share and which provide data for social science.

Downloaded from www.traditionalmedicine.com

patient thinks of himself and of his personal world in his communal existence. There has been increasing interest in denial of illness[32] and bodily feelings in general.[31] The nature of people's self-image ("I and my body," visual, tactile, auditory modes of perception) is a wide-open field for study. As a conceptual scheme, the notion of a nexus (as used by Whitehead)—a central relay station, where all sorts of things get together—is a fascinating concept.

The clinical study of neurasthenia and hypochondriasis brings another consideration to mind. It is as if the person were attempting to cling to some reality when the world seems in danger of slipping away. There seems to be a focusing on that which is closest as a means of warding off interpersonal tension or losing oneself. Much of the bodily preoccupation has the appearance of a miscarried effort at finding oneself. The more intrapersonal fear is experienced, the less attention will be paid to interpersonal difficulties. Some of the symptoms found in neurasthenia and hypochondriasis can best be understood in terms of the patient's role in his family constellation, in addition to sociocultural and other factors. It is of interest that certain somatic preoccupations are widely fostered in our culture. The interest in weight for reasons of health is highly acceptable. To climb on a bathroom scale twice a day is not an unusual occurrence in the American family. For women, the intense interest in the surface measurements and contours of legs, breasts, waist, etc., is encouraged; the way eyelashes are curled, hairdo's are fussed about—all these are deeply rooted in the culture. For this reason it may be more difficult to detect severe personality disorders in women where there is a camouflage of socially acceptable preoccupations. Some people are aspirin, laxative, patent-medicine, or Christian Science addicts. It may be possible to get by on this basis without showing overt symptoms of hypochondriasis or neurasthenia.

There has been an increasing awareness of the interdependence of environmental factors and personal, adaptational aspects in the continuum of an individual's life space. We have a great number of variables to consider, and the conceptualization of static units closes the door to meaningful new insights.

We have long been aware that fashions are not confined to the outer wrappings of the distaff side, but that neurosis and psychosis, in all their diversity, have something of "a latest look of their own." The modern way of life in the atomic age will undoubtedly produce relatively novel aspects of human aberrations which are not yet in vogue. It is that much more remarkable how durable the phenomena called neurasthenia and hypochondriasis have remained.

## ¶ Considerations of Social Psychiatry

We still have a great deal to learn about the intricate relationship between culture and symptomatology. However, several pilot studies by social psychologists and allied scientists have thrown light on possible connections between the gestalt of psychopathological phenomena and cultural determinants. Epidemiological investigations have been used to focus attention on the occurrence of certain psychiatric manifestations in various cultural and social settings. Much interest has been shown in the part which the tradition of an ethnical group, sex, age, level of social achievement, etc., play in the particular shape and form of mental illness. With it there has been increasing understanding of the degree to which the definition of mental disorder constitutes a social phenomen.

Opler, in *Culture, Psychiatry and Human Values*,[25] has alluded to how certain ethnological groups tend more toward some symptoms than do others. For instance, he points to the difference in attitude toward illness of Italians and "Yankees."

Then we have the New Haven study by Hollingshead and Redlich, published in *Social Class and Mental Illness*.[15] This study is limited to people under psychiatric treatment and, accordingly, is not a study of the community at large. It stresses the influence of social and cultural conditions on the development of sundry deviations in behavior. Particular interest is shown in the impact of

Downloaded from www.library.org.in

different class levels of a given society on the type of disorder which can be observed. In the New Haven study the percentage of patients who tended toward somatizing their complaints was highest among the lowest two classes in the group studied. These two groups consisted mainly of the people whose educational and economic level was at the bottom of the scale. Although the tendency toward somatization is not synonymous with the existence of neurasthenia and hypochondriasis, it seems to be a factor worthy of consideration.

In private psychoanalytic office practice, where patients from middle- and upper-middle-class groups are prevalent, I have encountered a fairly large number of hypochondriacal patients. However, the great majority of these patients suffered from recurrent episodes of preoccupation with their health. There were some patients in whom the symptoms of concern over ill health were more or less constant. These people invariably showed severe pathology and were classed with the tortoise as far as speed of recovery is concerned. Despite grave distortions in the personality, these patients usually did not create an impenetrable wall by means of their somatic complaints. Similar observations were made in supervising the work of some of my colleagues.

The situation was quite different in consultation work in a community clinic located in a low-income borough of Greater New York. There the incidence of somatic preoccupation as a primary complaint was much higher. In several instances it seemed most difficult to get beyond the level of neurasthenic and hypochondriacal preoccupation. Many of these patients had been referred by general practitioners, who prescribed psychiatric treatment. Not infrequently, the patient insisted on side-stepping any interpersonal complications and expected to be magically liberated from physical distress.

## ¶ Management and Therapy

Earlier in this chapter reference was made to the frequent occurrence of neurasthenia and hypochondriasis in psychiatric and medical practice as well as in the culture in general. In some communities patients with this symptomatology constitute a large number of referrals to the psychiatrist. Others go around and change physicians frequently, or they become more or less permanent fixtures in a doctor's practice. Some of these patients show up in a psychiatrist's office with the challenge, "I have tried everything else, this is my last resort!" The urgent question arises as to what to do with these patients. Should they all be analyzed or tranquilized? Would it be in their best interest to receive mild reassurance by the medical practitioner, or would they do better with expert psychiatric help? Is it helpful to distract them, help them change their environment if possible, stimulate other interests, etc.?

I need not state specifically here that it is not possible to devise one formula for all cases. The management or method of therapy depends on a multitude of factors.

Generally speaking, I have not found tranquilizers given in moderate amounts to be very helpful. Most patients today have tried one kind or another by the time they come to the psychiatrist's attention. It seems that relief is usually not adequate or lasting. There is undeniable merit, however, in having the psychiatrist attempt chemotherapy which does not make the patient unduly drowsy. Great care must be taken not to offer the medication as a miracle pill. I am opposed to all forms of shock treatments in these conditions. In hospital, clinic and private work I have seen no indication of even minor improvement in hypochondriasis and neurasthenia, as a result of various shock methods. On the other hand, I have encountered distinct difficulties in psychiatric and psychoanalytic treatment with patients who had undergone this procedure. Every neurasthenic and hypochondriacal patient requires individual consideration. In a somewhat schematic evaluation, we might distinguish between the following possibilities: Neurasthenia and hypochondriasis may occur in connection with structural visceral changes. Regardless of whether the organic or the psychic malfunction comes first, by the time there is a demonstrable preorganic or organic

Downloaded from www.dbraulibrary.org.in

situation, we do not have a primary psychiatric problem at hand.

Occasionally there can be considerable relief, or even cure, as a result of straight medical treatment. In a great many people, however, there is a concomitant disturbance of the personality. This may require attention in its own right.

We may find neurasthenic and hypochondriacal phenomena in conjunction with character disorders, neurotic difficulties, etc. Here we have a different situation. Not all patients have the motivation to change; not all patients have the opportunity to rearrange their lives. There are people who would have to undergo tremendous changes of the personality. Their patterns of relating to others would have to be grossly modified if they were to become less neurasthenic and less hypochondriacal. The decision as to whether the patient is amenable to treatment should be left to highly experienced psychiatrists. Doubtful cases should be worked up carefully, including projective psychological tests, whenever possible. There is grave responsibility involved in arriving at a thoughtful and adequate conclusion.

Some patients can be found to be preschizophrenic; others to be full-blown schizophrenics, some with delusional ideation. The latter group frequently is markedly paranoid, and some offer a poor prognosis. Among the preschizophrenic or schizophrenic patients (without a fixed delusional system), treatment by a highly skilled analyst in office practice may be successful. Occasionally, a patient has to be hospitalized when all communication is broken off as a result of suicidal tendencies, preternatural preoccupations with somatic symptoms, etc.

We may also encounter people with neurasthenic and hypochondriacal complaints who develop the characteristic symptoms after experiencing an acute existential predicament—that is, a state of affairs where professional, marital, or other difficulties have been prominent. Once the crisis is over, these people are apt to suffer from neurasthenic and hypochondriacal symptoms. In other words, it can be observed that pressing reality problems are capable of obscuring the existence of neurasthenia and hypochondriasis. At the end of an emergency situation, we may find a flare-up of difficulties which, at times, had been subclinical until then.

Some people are prone to have a chain reaction of highly unfortunate life experience. Once the external pressures subside and life seems to offer more satisfaction and happiness, that is the time when long-standing personal insecurities come to the fore. As long as there is a powerful distraction by more or less constant, external misfortunes, there is less opportunity for coming in contact with unfortunate aspects of the person's self-image. The low self-esteem inculcated early in childhood was always there, but the patient did not suspect his grave personal vulnerabilities and hypersensitivities until actual living conditions became much more promising.

We have to appreciate that there can be actual, current conflicts largely beyond the individual's control. People cannot be expected to undergo excessive existential stress and strain without showing some aftereffects. It should be kept in mind, however, that many situational factors have to be understood in terms of people's character patterns. The vicissitudes of life which call for change of environment if possible, for less strenuous activity, more rest, and other managerial rearrangements, etc., are not in the realm of psychiatric practice. More often, history tends to repeat itself, and personal difficulties have to be analyzed so that there will not be just a shift of symptoms.

I should like to add here that some people in our culture are bored, find their living conditions dull, and entertain themselves with interesting physical symptoms. To some of these patients the psychiatrist has little or nothing to offer. They often go on and on, without improving or deteriorating much.

In closing, it should be emphasized that the distinction between so-called real and so-called imaginary illness is unfortunate. All symptoms are real, whether or not our methods are adequate in explaining them. We seldom find hypochondriasis and neurasthenia among peo-

Downloaded from www.kobabulmer.org

ple who are just plain fakers. Whatever a person feels is based on some perception and some experience. We do not have the right to suggest figments of the mind, precisely because our over-all understanding of the nature of the complaint may be lacking. The assumption that a complaint without demonstrable organic basis is a senseless complaint needs to be dispelled.

In summing up therapeutic considerations, I must repeat once more that neurasthenia and hypochondriasis are indicative of particular warps in the personality. It is doubtful that the formation of either syndrome is connected with any standard set of circumstances responsible for the syndrome's existence. There seem to be variable traumatic events which manifest themselves in more or less circumscribed patterns. As is common with syndromes and symptoms in medicine and in psychiatry, they cannot ordinarily be cured as such. In psychiatry the elucidation of particular, personal life experiences is a highly skillful and time-consuming procedure. When Mr. Jones complains of always feeling tired, and Mrs. Smith of never enjoying good health, we must assume that common-sense approaches have been tried in most instances. Patients should not be expected to waste good money and time just to be told the obvious. It is not advantageous to be told that the trouble is in the head and not in the body. We have to realize that patients frequently cannot hear us when they are highly defensive about the nature of their actual difficulty. Standard clichés of our common language are often sterile channels precluding mutually meaningful understanding. The patient who says "fatigue" and the psychiatrist who hears "neurotic syndrome" obviously are not talking in the same tongue. Any attempt to exchange the word "fatigue" for "neurosis," or vice versa, will do nothing to improve communication. As long as there is no common meeting ground, it does not even matter whether the patient nods his head in approval or shakes it in disbelief.

In discussing therapy, I object strongly to any kind of do-it-yourself manual in psychiatry. At the same time, I recognize the necessity for formulating technical procedure. It seems to me that illustrations are best offered in terms of a particular approach without creating a model for direct imitation.

Suppose Mrs. Smith consults you with the following story: She has been to many medical doctors for pain around her heart, headaches, backaches, and thyroid trouble; she had been treated for gastric ulcers, but she has always feared it might be cancer. Nobody so far had been able to help her. A chiropractor offers her occasional relief, but it is never for very long. Her family physician has prescribed tranquilizers and barbiturates but they do absolutely nothing for her. Another physician had recommended a different medication, which helped only in the very beginning. Finally she had come to see a psychiatrist. She repeats her complaints to him, but the quality of her voice is such that she sounds as if she did not actually expect to be believed. After taking in her recital, with an occasional query here and there, the psychiatrist deliberately changes the focus of the interview. He comments something to the effect, "I hear that you have not been well for some time. Suppose you tell me how it all started." If there is a more-or-less definable starting point, he may go on to inquire what life was like at that time. Was fate smiling, or were there hardships or misfortunes? If all goes well, interest may be stimulated in relating experiences of stress and strain of a familial, social, economic, or other nature. The emphasis is not on a single traumatizing event, but on repeated experiences of unhappiness, friction, disappointment, etc. Then a brief glance is attempted into the past, with such nonthreatening questions as, "How happy a childhood did you have?" If you get a rigidly defensive answer, then, "I suppose there were at least some fleeting moments of unhappiness, as we find in the life of all children?" Should all answers point to a Hollywood Class C movie with a happy ending, it would be appropriate to say so. Anyhow, the attempt is made from all directions to get the patient interested in talking about himself in areas which present potential difficulties in living. You may find that you have gently and

Downloaded from www.pbookshop.com

skillfully helped point to the way in which the patient may eventually find help. Almost invariably, however, such a patient will counter with some sundry version of, "That is all very well and very interesting but how about my various ailments?" Then it seems appropriate to explain that psychiatrists do not know how to cure tangible or intangible physical disorders as such. They do know, however, something about frustrations, tensions, and anxieties. It is often possible to get a new slant on what gets in a person's way. There can be no promise of the disappearance of the physical symptoms, but it has been found that in some instances discomfort has been greatly reduced when certain difficulties in living are better understood. Under no circumstances can we afford to have the patient sit back while the psychiatrist is expected to do his stuff and melt the patient's complaints away. If there is to be any measure of success, the principle of collaboration has to be stressed from the very beginning.

It is most important that we do not offer things to patients which we cannot deliver. The reassurance is much more profound when it is made clear that direct verbal communication may lead to a better understanding of one's life situation, but that one cannot assume that bodily complaints will fall by the wayside as soon as insight is gained. The psychiatric facts are often otherwise, and it is our duty to inform our patients honestly and knowledgeably.

CHAPTER 14

# HYSTERIA

D. Wilfred Abse

Downloaded from www.bdbraulibrary.org.in

Conversion hysteria and dissociative reactions display dramatic somatic symptoms and personality disturbances: gross paralytic, spasmodic, and convulsive motor disturbances; exaggeration, diminution, or perversion of sensation; dumbness, deafness, or blindness. Amnesias, fugues, and somnambulisms may attract first attention. Any of these symptoms may occur together, though there are characteristic ensembles; or a symptom may present separately or in alternation with another or others. Such flamboyant symptoms may subside temporarily in response to equally striking modalities of treatment, magical or magico-religious. Historically, the "cure" of such symptoms has been exploited both consciously and unconsciously by the power of the magician, the priest, the king, and the quack, or by this nostrum or that god.

## ¶ Introduction: A Brief Historical Perspective

The word "hysteria" means "wandering of the uterus" and was used by the Greeks at the time of Pericles, who recognized the relation of the disorder to sexual disturbance. In Plato's *Timaeus* it is stated:

> In men the organ of generation—becoming rebellious and masterful, like an animal disobedient to reason, and maddened with the sting of lust—seeks to gain absolute sway; and the same is the case with the womb of women; the animal within them is desirous of procreating children, and when remaining unfruitful long beyond its proper time, gets discontented and angry, and wandering in every direction through the body, closes up the passages of the breath, and by obstructing respiration, drives them to extremity, causing all varieties of disease.

Hippocrates held a similar view of those priestesses afflicted with the sacred disease who chanted their oracles after convulsing. In many cases the sacred disease was not epilepsy but hysteria. However, Hippocrates, like many a modern physician, found it difficult to distinguish convulsive hysteria from idiopathic epilepsy.

During the Middle Ages the naturalistic viewpoint of the ancient Greeks was rejected. In the medieval witch trials, for example, the stigmata of hysteria were relied upon as a

method of ascertaining possession by the devil. In Europe, this belief in the demoniacal origin of hysteria dominated such a large proportion of the population that it became, clinically, an epidemic of delusion—and led to an outbreak of persecution. Only in recent times, since mass communication media have created the possibility of rapid, wide diffusion of popular delusions, has society witnessed parallel epidemics and results.

With the resurgence of an age of reason, the more educated and influential rejected these medieval notions. In the eighteenth and nineteenth centuries, though the womb theory of Hippocrates could no longer be maintained in its crude form, many observers continued to find a connection between hysteria and the sexual emotions. According to Ellis,[14] Villermay asserted in 1816 that the most frequent causes of hysteria are deprivation of the pleasures of love, griefs connected with this passion, and disorders of menstruation.

The development of the sciences of anatomy and physiology in the nineteenth century created a tendency in medical circles to interpret all mental phenomena in terms of diseased structure of the brain. The main current of opinion agreed with Briquet,[8] who denied any connection between hysteria and sexuality. In short, after 2,000 years of discussion, hysteria came to be regarded as an organic disease rather than as primarily a mental ailment, and the role of sexual disorder in its pathogenesis was minimized. However, this narrow conception of the disease was soon challenged by the work of Jean Martin Charcot. The traumatic power of emotional disturbance in provoking the manifestations of the disease, and elimination of the manifestations through suggestion under hypnosis were clearly demonstrated by Charcot's work. Thus the ground was laid for renewed investigation of the psyche of the patient suffering from hysteria.

Pierre Janet, a pupil of Charcot, proceeded to investigate the psychological aspects of hysteria with great care. As a pertinent example of his case studies,[32] an abridgement of the report he gives of his patient Irene may be selected.

This girl nursed her mother during terminal illness, at which time she toiled away also at a sewing machine in order to earn a livelihood. The mother died, and Irene attempted to revive the corpse. The body slipped to the floor and she desperately attempted to drag it back into the bed. Shortly after these events, Irene commenced to have somnambulistic attacks. Janet writes of these attacks:

> The young girl has the singular habit of acting again all the events that took place at her mother's death, without forgetting the least detail. Sometimes she only speaks, relating all that happened with great volubility, putting questions and answers in turn, or asking questions only, and seeming to listen to the answers; sometimes she only sees the sight, looking with frightened face and staring at the various scenes, and acting accordingly. At other times she combines hallucinations, words and acts and seems to play a singular drama. [Janet writes of his patient between such attacks]: We shall soon notice that even in these periods she is different from what she was before. Her relatives who had conveyed her to the hospital stated: "She has grown callous and insensible, she has soon forgotten her mother's death, and does not remember her attacks." That remark seems amazing; it is, however, true that this young girl is unable to tell us what brought about her illness, for the good reason that she has quite forgotten the dramatic events that took place three months ago.[32]

Janet concluded from cases of this kind that one series of ideas had become isolated from consciousness generally, in a process of dissociation. Thus, in the case of Irene in the periods between attacks, she knew nothing of what had happened at the time immediately prior to her mother's death. There was a gap between the idea of her mother's death (and associated ideas) and the larger system of ideas she evinced in the intervening periods.

Janet concluded that hysteria may be defined as "a malady of the personal synthesis." He emphasized the factors of retraction and of dissociation of consciousness evident in the disease. These he thought to be due essentially to a "preliminary ailing tendency." In postulating this inherited ailing tendency, he followed the view of his master, Charcot, who

Downloaded from www.dbraubrary.org.in

had insisted upon the hereditary predisposition of the nervous system of sufferers from conversion hysteria, both convulsive and nonconvulsive forms, and forms of the disease now designated as dissociative reactions. Janet, however, connected this inherited predisposition with an inadequacy of mental tension to hold together under conditions of stress (toxic, exhaustive, or psychological) partial systems of thought which thus separated from the main body of consciousness.

In 1893 Josef Breuer and Sigmund Freud published an account of their experiences concerning a new method of investigation and treatment of hysterical phenomena. This preliminary communication, entitled "The Psychic Mechanism of Hysterical Phenomena," was followed by a series of case histories and theoretical explanations constituting the *Studies in Hysteria* published originally in 1895.[1] These studies presented the evidence for their view that disturbance of sexuality, as a source of psychic traumas and as a motive of defense in the repression of ideas from consciousness, was of outstanding importance in the pathogenesis of hysteria.

Breuer and Freud, in 1893, found that individual hysterical symptoms subsided when, in hypnotherapy, they had succeeded in thoroughly awakening the memories of the causal process with its accompanying affect, and the patient circumstantially discussed the emotionally exciting situations in the most detailed manner and gave verbal expression to the affect. It was necessary that the original emotionally exciting memories be reproduced as vividly as possible, so as to bring them back into the *statum nascendi*, and then they could be thoroughly "talked out." Recollections without affects were of little therapeutic value. In other words, they found that "the hysteric suffers mostly from reminiscences." Very often these were found to be experiences dating back to childhood—experiences that had established the soil out of which further emotional excitation in later years could yield more or less intensive morbid phenomena.

It is apparent that, in their joint work on the problem of hysteria, Breuer and Freud were opening up a path to the crepuscular light of psychoanalysis, a path that Freud later energetically took alone. They had found that their method of treatment worked through abrogating the pathogenic efficacy of the original nonabreacted ideas by affording an outlet for their strangulated affects through speech and bringing them to "associative correction by drawing them into normal consciousness."

## ¶ Clinical Manifestations

Hysteria is manifest in many different forms, some of which are readily confused with the patterns of organic disease. Because of its inner nature, hysteria is a great imitator; in order to avoid confusion between it and organic disease, it is necessary not only to comprehend its characteristics but also to be familiar with the patterns of organic disease. The protean forms assumed by hysterical disease have given rise to a carnival of literary expansiveness, whereas the problems of diagnosis have been largely neglected. For this reason, only the more common and some of the more dramatic forms that it assumes are dealt with briefly here; the more important topics of psychopathology and diagnosis will occupy our attention later. In any case, the possible symptoms are so numerous that it would be impossible to discuss them all without making the text encyclopedic. It often happens that the disease is not seen in pure culture; though predominantly hysterical, an illness may contemporaneously present features of other neuroses, of psychosis, or of organic disease. This serves only to increase the need for accurate diagnosis. Typically, the clinical features are:

1. A group of physical symptoms without an ascertainable structural lesion.
2. Complacency in the presence of gross objective disability (*la belle indifférence* of Janet).
3. Episodic disturbances in the stream of consciousness when an ego-alien homogeneous constellation of ideas and emotions occupies the field of consciousness. This may exclude the normative stream of consciousness in the individual so affected.

Downloaded from www.freelibrary.org

It is characteristic of hysteria that, whatever the result of dissociation, be it a localized muscular paralysis or an alternate personality, the operative mental function is a homogeneous whole—affect and idcation are not utterly incongruous, and there is no primary thought disorder, as in schizophrenia. In hysteria the splitting of the personality is molar—not, as in schizophrenia, molecular. Some cases evince a transition from hysterical disorder to schizophrenia, and in transitional phases it may be difficult to predict the movement, whether in a reaching back to reality accompanied by a consolidation of hysterical symptoms[3] or in a deepening withdrawal accompanied by molecular disintegration. The direction of change often depends largely upon management and psychotherapy.

This diagnostic problem of the differentiation of hysteria from organic disease on the one hand and from schizophrenia on the other will be apparent as a crucial concern, to which we will return later. With this general orientation as a background, specific symptoms are discussed below.

## *Amnesia and Multiple Personality*

The simplest form of dissociation is shown in the absence of recall of a circumscribed series of events in the patient's life, events which later investigation reveals as associated with strong emotion. In some cases the amnesia includes the total existence of the patient up to a recent point of time. Amnesia is sometimes the sequel of a fugue (that is, a restriction of the field of consciousness which becomes dominated by a homogeneous series of ideas and emotions hitherto excluded from awareness). At this time a patient may leave his usual abode and way of life for a journey which has no immediate connection with his former activity. The patient later typically evinces a complete amnesia for this episode. Under the stress of military conditions, such cases occur not infrequently; here is one example:

A soldier was found wandering at a seaside resort by the military police and was unable to give a satisfactory account of himself. Psychiatric investigation revealed that one day he had suddenly left his unit and boarded a train, presumably for his home in another part of the country. However, he changed trains at a junction and made for the seaside resort. This resort had many pleasant associations for him. He had spent his honeymoon there, and he and his wife were in the habit of going there for their annual holiday. In the Army he had become preoccupied with the impulse to leave, to the exclusion of all other considerations. His activity in making for the resort could only be made meaningful to him as an attempt to recapture the palmiest of palmy days of peace and security. Before the psychiatric intervention, he could give no adequate account of himself to the police, for he could not recall how he had got into the situation with them.

This example demonstrates the usual findings in dissociative reactions limited to a hysterical level. The reaction is not aimless, as the wandering might at first appear, but purposive. Moreover, the present is exchanged for the past and is met as though indeed it were the past. The patient sought to return to a time and place when—and where—gratification was maximal, and to escape from the frustrational current situation in his life. Janet's somnambulic Irene, discussed in the previous section, combined hallucinations, words, and acts in a dramatic reliving of the traumatic situation which precipitated her illness. This demonstrates also the exchange of the present for a remembered situation, in this case in an effort to master it. When these somnambulic episodes are not spontaneous, they can be evoked in hypnotherapy for the purpose of helping the patient to abreact the strangulated affects and to bring the memories to associative correction by drawing them into the normative stream of consciousness.

A more complex and extravagant clinical manifestation of severe dissociation than that exhibited in fugue state with amnesia is multiple alternating personality. Stevenson's *Dr. Jekyll and Mr. Hyde* is the literary fictional model of this type of severe dissociation. The rare actual cases, when reported, often achieve a fame comparable to that of the novel. William James, in his *Principles of Psychology*,

Downloaded from www.pdfbooksfree.org.in

has given an account of double personality which has become famous.

The Reverend Ansell Bourne disappeared from a town in Rhode Island. Two months later a man calling himself A. J. Brown woke up in a fright asking where he was. This was in Pennsylvania, where six weeks earlier he had rented a confectionery shop. A. J. Brown the confectioner then started to claim that his name was Bourne, that he was a clergyman, and that he knew nothing of the shop or Brown. Subsequently, he was identified as the Reverend Ansell Bourne by his relatives. He remained unable to explain this episode in his life which seemed to him uncanny.

Morton Prince, who introduced into medical literature the concept of multiple alternating personality, investigated such a case in the person of Miss Beauchamp.[38] This lady exhibited at various times three separate fragmentary personalities. A self-righteous moralistic and masochistic personality was usually dominant but alternated with a strongly ambitious, aggressive, distinctive character, creating a perplexing cleavage in the life and personality of Miss Beauchamp. In working with this patient, Prince used hypnotherapy. Under hypnosis, a third personality fragment, calling herself "Sally," came to occupy the field of consciousness. Sally was aware of the saintly personality, though the saintly Miss Beauchamp was unaware of Sally, the impish child. Prince, over a period of six years' work, was able to achieve an integration in the character of Miss Beauchamp.

A recent example, presenting the problem of a housewife reminiscent of Prince's Miss Beauchamp, is provided by the study of Thigpen and Cleckley.[50] Masserman[41] has also recently reported a case of alternating personality.

## *Convulsive Hysteria*

Charcot categorized hysteria into two types —convulsive and nonconvulsive.[9] This is an indication of the high incidence of hysterical convulsions in the patients who came to his notice in Paris in the last decades of the nineteenth century. Briquet,[8] in his statistics, showed that nearly three quarters of his patients suffered convulsive attacks. Nowadays, in Western Europe and the United States, convulsive attacks are relatively infrequent manifestations of hysteria. Convulsive attacks were found by the present writer, from 1942 to 1945, to be a frequent manifestation of conversion hysteria in Indian soldiers, in contrast to their occasional incidence as a manifestation of hysteria in British soldiers during the same time.[1] Janet traced the connection between convulsive attacks and somnambulisms, showing that convulsive attacks were merely degraded forms of somnambulism where the outer expression of the somnambulic idea in physiognomy, attitude, and act was no longer clear. He showed, too, in his case studies that hysterical convulsive attacks have the same "moral causes" as somnambulisms or other expressions of hysteria, and that these hysterical accidents, like others, "begin on the occasion of particularly affecting events, genital perturbations, sorrows, fears, etc."

Convulsive hysteria may simulate idiopathic or symptomatic epilepsy. Sometimes, hysteria may be suspected on the following grounds: during the attack, the patient is not completely unconscious; the attack occurs only in the presence of onlookers; the patient does not fall in a dangerous situation; the corneal, pupillary, and deep reflexes are present; the patient does not bite his tongue nor micturate; he becomes red in the face rather than blue or white; attempts to open the eyes are resisted; pressure on the supraorbital notch causes withdrawal of the head. However, it must be stated that hysteria is manifest in so many forms, some of which so closely imitate organic disease of the nervous and other systems, that, without the distinctive marks of its etiology and psychopathology (see later), symptomatology alone can be misleading. Where epilepsy is associated with the development of abnormal rhythms in the cerebral cortex, the electroencephalograph can be helpful in making a differentiation.

It is often clear, on investigation, that the hysterical fit partly represents a rage reaction or temper tantrum due to frustration or fear of genital sexual wishes. Often, too, one can

Downloaded from www.brainlibrary.org.in

find evidence of erotic discharge in the form that the attack takes (*attitudes passionelles*, ecstatic poses, etc.). The case of a young woman of nineteen years who suffered frequent "fits" provides an illustration:

The fits occurred about 6:30 P.M. every evening when she was listening to the radio. The attacks had commenced following the dissolution of a love affair. The young man, it was ascertained, had formerly appeared at her house regularly at this time and had listened in with her. The fit was preceded by painful sensations in the right side of her body. Here she had formerly experienced pleasurable sensation, for her boy friend had sat closely at her side. In conversation, this patient at first expressed the view that she did not care at all about her friend's defection. This defense against her affective disturbance had proved adequate during the day when she was at work. Returning home in the evening, she was assailed by her memories of the young man, and the convulsive attack provided the outlet she required for her outraged feelings.

Kretschmer[37] points out that in living beings the "tantrum violent-motor-reaction" is a typical reaction to situations which menace or impede the course of life. He sees its purpose as enabling the organism to make a rapid selection of that motion, among the many at its disposal, which will meet the situation. Should one of the many irregular motions by chance separate the animal from the zone of danger, this single motion will be continued, with a speedy resumption of quietness. Being an instinctive reaction which expires quite schematically, it may either aimlessly disappear or become directly harmful. In the course of evolution, the violent-motor-reaction as a biological defense reaction retires more and more into the background. More recent and more expedient formations cover the older reaction type. In adult human beings, selective voluntary action is the chief reaction type to new situations. In panic, shocking experiences momentarily paralyze the higher psychic functions, and, being a phylogenetically older adaptive mechanism, the violent-motor-reaction comes once more into activity by stepping automatically into their place. In an earthquake or other catastrophe, a crowd will display "headless" hyperkinesias—screaming, trembling, convulsions, twitchings, running this way and that. If among the many motions initiated there is one which by chance takes the person away from the sphere of tumbling houses or the zone of danger, quiet ensues; the violent-motor-reaction has attained its regulative aim. In children's response to painful stimuli, the violent-motor-reaction—pushing, screaming, sprawling, striking—is often evident instead of the deliberative speech and deportment of adults.

Between these two groups, panic and childish behavior, are inserted the hysterical hyperkinesias—the twilightlike running away, the tremors, and the convulsive paroxysms. The hysterical attack, Kretschmer insists, represents an atavistic violent-motor-reaction. He points out that, in general, such psychogenic reaction forms are hysterical where psychic aims in man avail themselves of reflex, instinctive, or otherwise biologically preformed mechanisms.

## *Paralysis, Involuntary Movements*

Many varieties of hysterical paralysis occur. In some varieties the paralysis is more or less complete. Sometimes it is associated with tremor of the affected limbs; sometimes contractures may be present. Often, paralysis takes the form of astasia-abasia. In this condition, movements may be carried out when lying down or even when sitting down, though standing and walking cannot be performed. Such a symptom as astasia-abasia provides clear evidence of a dissociation characteristic of hysteria. In other cases a number of signs which occur in organic paralysis are absent in conversion reactions; of these signs, those elicited by testing the tendon reflexes may be mentioned. Often, dyskinesias such as tremor, as mentioned above, may accompany paralysis or paresis, and there may be an accompanying bizarre gait. Tics and muscular spasms may accompany a paresis or may occur alone. Another common type of hysterical motor disturbance consists in disturbance of speech. Sometimes this is limited to one language, whereas another language (usually the mother

Downloaded from www.dpabooks.in

tongue) is spoken without difficulty. In such a case a dissociation characteristic of hysteria is already evident on the basis of symptom observation. Usually, however, the certain diagnosis of hysteria requires closer investigation than is afforded by the mere observation of symptoms. On the one hand, most symptoms are readily confused with the manifestations of other diseases; on the other hand, hysteria frequently occurs in concert with other diseases and its contribution to the manifestations of disease has to be determined.

Kretschmer points out how widely spread in nature is the immobilization, or sham-death-reflex—the occurrence in animals, that is, of motor rigidity in response to threatening danger. As previously stated, he groups convulsive hysteria around the biological radical of the primitive violent-motor-reaction. Immobilization, in one form or another, he groups around the biological radical of the phylogenetically important sham-death-reflex. Hysterical paralysis is often accompanied by an obvious restriction of the field of consciousness. Sometimes this reaches the degree of stupor. These hypnoid-stuporose hysterical states, together with paralytic conversion reactions, Kretschmer thinks are anchored in the old, general, animalistic reflex mechanism of sham death. Thus he considers that hysterical reactions group themselves around these two fundamental animal reactions to danger. He considers, too, that in human beings the danger may be external and/or may be bound up with the emotions and conflicts which accompany the sexual life. He states: "Wishes, struggles and disappointments of an erotic nature form the large main group of experiences which produce hysteria in ordinary civil life, especially in women; the war neuroses, and a part of the accident neuroses, contribute the other very large half of hysterical reactions."

In order to illustrate characteristic findings in a case of conversion paralysis, the following summary shows how the diagnosis may be established on positive grounds from the point of view of symptom observation and etiology as well as psychopathology (for which see later).

The patient, a married man, aged fifty-nine years, complained of paralysis of the left leg and weakness of the left arm. On examination, the left upper and lower limbs were slightly spastic. When the patient was encouraged to flex the left thigh at the hip joint, the antagonistic muscles went into increased spasm. The patient was next required to raise himself into the sitting position in bed, his arms being folded and his legs separated. Under these conditions the paralyzed left leg remained firmly on the bed. (The paralyzed leg rises higher than the other under these conditions in organic disease of upper motor neurone type—"Babinski's second sign.") The plantar reflex was flexor (Babinski's sign negative), and the tendon reflexes were present and equal on both sides.

In discussion it was ascertained that the patient's illness commenced during the bombing of London, at which time he had become acutely fearful. Moreover, the illness required giving up work just as he was approaching the time for retirement on full pension. The only other noteworthy item of information in this discussion was that his father had died in his eighties, of cerebral thrombosis with left-sided paralysis. This patient was later given Sodium Amytal intravenously for the purpose of further psychological exploration. Under narcosis he prayed for the forgiveness of his sins, giving an account of the use of contraceptives since the birth of his second son (twenty-five years of age). The doctors had then advised against further children on account of his wife's ill-health, and he had since used contraceptive techniques, though this was against his religious convictions and those of his father. He also spoke of his struggles against masturbation prior to marriage, and wept bitterly. He felt he had committed grave errors and was not entitled to enjoy retirement as his father had before him. During the bombing he had felt convinced that retribution was at hand. In further discussions without narcosis, the patient at first denied any sense of having done wrong and defended his conduct during marriage on the grounds that he had to think of his wife's health, and that in any case she was quite satisfied with her two boys, etc. He appeared quite reasonable in his attitude toward his sexual problem, though he admitted he had always spoken in public against any form of contraception, and went on to talk of moral dangers.

Downloaded from www.dbraulibrary.org.in

Interview with his wife disclosed his great dependence upon her in all respects, including an incapacity for decision without her. Moreover, she gave an account of her honeymoon thirty years before which was marred by her husband's worry lest he had cancer.

In this case the signs were characteristic of hysteria. We may also note the following features: There was a temporal connection between the onset of his paralysis and the dangerous situation of bombing. A conflict of a sexual nature evoked by this stress was uncovered, and the meaning of the symptoms became clear. Moreover, his personality background showed evidence of overdependence and neurotic traits, the latter presenting chiefly in the form of hypochondriasis at the time of his marriage, which, incidentally, he had delayed for a considerable time. We will later elucidate the diagnostic importance of the chronological correlation of stress and conflict with the onset of symptoms in the setting of hysterical character background.

## *Further Notes on Involuntary Movements*

As has been emphasized above, observation of symptoms may not in itself be sufficient to diagnose hysteria; for this purpose further investigation along both psychologic and physical lines may be requisite. For example, in a child, the diagnosis between a relapse of Sydenham's Chorea and a hysterical mimesis is sometimes extremely difficult and quite impossible on the basis of symptom observation alone. Not uncommonly, hysteria is responsible for evanescent hyperkinesis definitely choreiform in type in young children. In such children, an impression of choreiform movements may have been previously produced by an attack of rheumatic chorea, or the child may have observed such an attack, usually in hysterical cases in another member of the family. Sensitivity of the physician to the underlying psychodynamics of the neurosis is essential in arriving at such difficult differentiations, and the psychopathology of conversion reactions is discussed below. It should also be mentioned here that nonchoreiform movements, that is, typical movements which might be performed normatively but which are performed excessively and inappropriately, may also of course be part of hysterical disorder. When such movements are circumscribed, single, or few in number and have become stereotyped by repetition, the terms *tic* and *habit spasm* are often synonymously applied. In older children and adults, systematized tics are usually found in the setting of obsessive-compulsive neurosis or of severe obsessive character disorder. It seems in such cases of persistent tics that the original hysterical symptom has become assimilated within the deeper regression of compulsive disorder. Tics frequently involve the head and neck; spasm of some of the facial muscles or rotation of the head are often observed. The latter symptom may present in full flower as *spasmodic torticollis*. Frequently this is a symptom of conversion hysteria as revealed in intensive investigative psychotherapy (see Ref. 1, pp. 25–27, 30, 40). In such cases, however, obsessive-compulsive features are usually also prominent, and one is obliged to use in diagnosis the inelegant term "mixed neurosis," or some synonym. Similar considerations apply frequently to *occupational cramp*. This is a progressively severe disability due to spasm of the muscles employed in finely co-ordinated movements essential to the fundamental skills of the particular occupation of the patient. *Writer's cramp* is but one example. Occupational cramp often yields to psychotherapeutic intervention when the hysterical nature of the symptoms becomes apparent. Sometimes such cramps also yield in response to favorable shifts in the life situation of the patient when the progressive course is dramatically interrupted.

## *Sensory Disturbances*

Somatic conversion symptoms often include subjective and objective sensory disturbances. Pain is the most common and persistent complaint, occurring anywhere in the head, body, or limbs, and described sometimes in quite horrific terms, though the patient may at the same time evince a complacent attitude. At other times, florid histrionic behavior accom-

Downloaded from www.ebrainlibrary.org.in

panies the complaint of pain. Severe pain and hyperesthesia of the scalp may be localized in the temporal or parietal regions and described as a sensation of a nail being driven into the head (clavus). Pain in the back is common, sometimes accompanied by rigidity of the muscles and curvature of the spine as in bent back (camptocormia). This often follows minor trauma to the spine. Abdominal pains may simulate organic disease, leading to erroneous diagnoses and useless surgical interventions. Localized hysterical tenderness gave rise to the concept of hysterogenic zones, formerly utilized alternatively to stimulate or terminate a hysterical attack. These tender spots are sometimes found over the breasts, the inguinal regions (ovarian), the head, or the spine. Allochiria, the perception of sensation on the opposite side of the body corresponding to that stimulated, is sometimes elicited.

Diminution of sensation is common, sometimes amounting to more or less complete anesthesia. These anesthesias do not follow typical neural distributions but involve, for example, a limb or part of it (glove and stocking) or may be sharply limited by the midline to one half of the body.

The so-called "stigmata" sometimes accompany other symptoms of hysteria. These consist mainly of sensory disturbances and so are mentioned here. Localized reduction of cutaneous sensation or pharyngeal anesthesia may be discovered. Hyperesthetic spots over the ovaries and absence of reflex closure of the eye on touching the cornea have often been described. Concentric contraction of the field of vision and the feeling of a lump in the throat (globus hystericus) are other anomalies. Traditionally, these anomalies were held to be characteristic of hysteria and, on this account, were designated stigmata. They came to form the positive grounds for the diagnosis of hysteria. Babinski,[8] however, weakened this base for diagnosis when he showed that they often arose as a result of iatrogenic suggestion (pithiatism). Sometimes one or more of the stigmata do occur independently of the physician's examination, and accompany other symptoms of hysteria. Ferenczi[17] has shown that the body sites where they occur are peculiarly adapted for the representation of unconscious fantasies, and it is for this reason that they may occur, or readily arise, on suggestion.

## *Affective Disturbance*

Patients suffering from conversion reaction are often quite complacent in the presence of gross objective disability, a proverbially puzzling paradox encountered in the early phase of psychotherapy. Usually, if pain is prominent, much anxious concern is focused upon this, though a complacent attitude about the accompanying disability, or the possibilities of organic disease which the patient suggests himself, may remain. *La belle indifférence* simulates, sometimes, the flattened affect of some forms and phases of schizophrenia. Janet noted the disposition to "equivalences" in hysteria; when, for example, by means of suggestion, a somatic conversion symptom was dissipated, anxiety or depression or, in some cases, confusion appeared in its place, shattering the façade of striking indifference which had formerly accompanied the somatic symptom. Seitz[49] has recently investigated the conditions of replacement of one symptom by another. Somatic symptoms may be replaced wholly or in part by the expression of anxiety or depression, or in some cases by feelings of victimization. As will be discussed later, symptom-formation in hysteria represents the unconscious solution, or attempted solution, of emotional conflict. The symptoms serve more or less as a protection against the perception of anxiety and depression associated with this conflict. When the somatic conversion reaction is incompletely protective, anxiety and/or depression are then also apparent. It is to be noted, too, that anxiety which arises on recession of somatic conversion symptoms, or that which accompanies such symptoms, is usually displaced from its source in the conflict and may be displayed in phobic reactions. Freud termed such displaced anxiety, specifically connected with a special situation, anxiety hysteria.

Anxiety may be exhibited as a vague fear of

Downloaded from www.dbraunmd.com

impending disaster, or, more specifically, of death, heart failure, or insanity. In such cases the somatic accompaniments of anxiety, such as dilated pupils, sweating, palpitations, and digital tremor, may be apparent in addition to the conversion symptoms. Other patients exhibit their martyrdom and resignation with a keen sense of the dramatic value of pathos expressing feelings of sadness and self-pity.

## ¶ The Nature of the Symptoms

### *Hysteria and Freud's Discovery of Psychoanalysis*

Psychoanalysis connotes the techniques devised and evolved by Sigmund Freud for investigating the human psyche and the body of theory that has emerged from the data thus collected. Its beginnings can readily be traced to the working association of Breuer and Freud at the close of the nineteenth century when, together, they worked out a method of treating hysterical phenomena. It was found that, if instead of hypnotizing a patient and then making direct suggestions of cure the patient was simply encouraged to talk while under hypnosis, hysterical symptoms were often relieved more effectively. It was found, too, that this talking out under hypnosis was laden with emotional charge, whereas under waking conditions the same patient would be lacking in affective expression. More than this, it was discovered that important events connected with the emotional life of the patient, which were otherwise forgotten, were recalled and expressed under hypnosis. This method of talking out of emotionally charged and otherwise forgotten events was called "mental catharsis," as it operated to eliminate sources of disturbance from the psychic system which would, without this, result in symptoms. The process of affording an outlet for emotion in talking was called "abreaction."

The fact that a patient suffering from hysteria was unable to recall significant and emotionally charged events in the waking state, whereas under hypnosis such material would, with encouragement, make its appearance gave rise to the psychoanalytic concept of resistance which opposed such recall, and which was lessened by the hypnotic procedure. The fact that the patient came to develop an intense emotional relationship to the physician was one component of the concept of transference. Freud found that this development in the patient-physician relationship was due to emotion becoming transferred from earlier objects of the patient's feelings to the personality of the physician. Later, Freud used the technique of "free association" to replace hypnosis as a method of lessening, or attempting to lessen, resistance, and thus psychoanalysis emerged. Though, in general, the method of free association accomplishes less than hypnosis in factual recall of early events and experiences even when the resistances are unveiled, emotional revival is, in the long run, facilitated. This emotional revival involved in transference became the prime means of success in Freud's later psychoanalytic work. The technique of psychoanalysis has encompassed ways and means of developing and utilizing transference, of effecting its dissolution, and of unveiling resistances in resolving emotional difficulties out of the range of the patient's awareness. This technique has emerged from the mental-catharsis method of treating patients suffering from hysteria.

In the foregoing brief genetic account of the formulation of the concepts of resistance and transference as these became apprehended from the clinical findings in working with patients suffering from hysteria, it will be noticed that these same findings have additional implications. Thus, the fact that certain events of the past were recalled, under hypnosis or as a result of analytical work, indicates that such events were somehow and somewhere recorded and stored within the psyche, though not immediately available to consciousness. Access to consciousness was at first barred by resistance. Such exclusion from consciousness as a result of the operation of an inner resistance is known as repression and is an important manifestation of resistance.

With Freud's theory of dreams,[27] psychoanalysis was enlarged from a psychotherapeutic

Downloaded from www.dbraulibrary.org.in

method to a psychology of the depth of human nature. Freud showed that dreams were meaningful, that each one represented the disguised expression of an attempted wish-fulfillment. He contrasted the manifest content, that is, the dream as related directly, with the latent dream thoughts, reached by the techniques he devised to deal with resistance. In the young child the manifest and latent content may be identical, the dream plainly representing the imaginary fulfillment of an ungratified wish. Usually, in adults, the wish is a repressed one, disguised in the manifest dream because of resistance. Freud showed that human life was dominated by conflict between conscious appraisal of reality plus ethical values (including the unconscious conscience) and the repressed unconscious. In sleep, a temporary withdrawal from the external world, the energy of repression-resistance is diminished so that the unconscious forces obtain some degree of hallucinatory satisfaction. This is "safer" during sleep, since the avenues to motor expression are then blocked; in any case, some degree of repression-resistance persists, so that even in hallucination the latent thoughts are disguised. In this way, disturbance emanating from ungratified unconscious conative processes is drained off, and sleep is safeguarded. Of course, this function of the dream sometimes fails; the disguise is not sufficiently heavy, and the watcher awakes in anxiety. On the other hand, when the disguises have worn too thin, there can be the comforting thought, in sleep, "After all, this is only a dream." Thus sleep is permitted to continue despite the threat of revelation.

The following is a clinical example to illustrate some of the foregoing points and their connection with the psychopathology of hysteria:

A middle-aged male patient was brought to psychiatric interview on account of total paralysis of his legs. Seated in a wheel chair, he explained calmly that two weeks previously he had awakened in the morning to find himself paralyzed. In view of the prevalence of an epidemic of poliomyelitis, he assumed that he had the disease and summoned his physician. He now understood that the diagnosis was in considerable doubt, and that, following intensive organic investigation, no definite organic basis was discoverable. The patient expressed this situation in his own way, and at the same time expressed his doubt concerning the opinion of the physicians. During the further course of interview, the patient explained that he had had considerable difficulty in getting to sleep since his wife had left him three months previously. He also expressed the view that he did not care very much about this, and spoke with bitterness about the faithlessness of women. The events of the day before the paralysis were recounted as routine, but a dream had occurred during the night. In this dream, the patient went away from his house and found himself struggling with two people in a strange neighborhood; shots were fired, he had a gun in his hands, and then he woke up in anxiety to find himself paralyzed.

During the course of further treatment, this dream was further investigated and was found to represent his wish to pursue his wife and wreak revenge upon her and her lover. Consciously, he was very much against any such course of action. It was, indeed, found that his paralysis was a massive defense against any possibility of his moving to kill his wife and her lover, and the massive nature of the defense was partly a measure of the intensity of his vengeful wishes. The "strange" neighborhood turned out, in fact, to be the old familiar neighborhood of his childhood at a time when the patient thought himself to be an unwanted child because his father had been released from the Army, and his mother had given over all her attention to the soldier on his return.

This fragmentary account illustrates that a forceful repressed wish found hallucinatory satisfaction in his dream, and that, the disguise being too thin, he awakened in anxiety. His inability to get to sleep showed his need for inner vigilance to ward off these dangerous wishes, which were being repressed with increasing difficulty. Later, the repression partially failing, it needed to be supplemented in the waking state by the conversion reaction of paralysis. There was much self-punishment in this paralysis, too, as became apparent from the patient's associations in the process of

Downloaded from www.dbraibrary.org.in

psychotherapy. Notice here that the dream is the first member of a series that includes among its members the hysterical symptom, the obsession, and the delusion. As Freud states, it is differentiated from the others by its transitory nature and by the fact that it occurs under conditions that are part of normal life. In this pathological case, the connecting link with a hysterical conversion symptom is clear.

It is also clear in this case that the dream was related not only to current events in the life of the patient but also to childhood experience. The patient in his childhood had found his passionate wish for exclusive possession of his mother's love threatened by the return of his father from a lengthy absence in the Army, and this threat turned out to be wellgrounded in reality. In later years this experience led to his very reserved attitude toward women, and it was only in middle life that he had found his way to marriage with a much younger woman who later deserted him for a younger man. This had revived all the emotions constellated around his childhood oedipal-phase experiences, the murderous wishes being transferred from his "faithless" mother and his father to his wife and her lover. Sleep became difficult because he was afraid to relax lest these ego-alien wishes should succeed in breaking through from repression. In the dream the disguise was not sufficiently heavy to safeguard his sleep adequately, and he woke in anxiety. The succeeding hysterical symptom was a compromise formation compounded of the repressed wishes and the repressive forces, including those of unconscious conscience. In this case some of the repressed wishes are more obvious in the dream, and the defense against them and the self-punishment in the symptom of conversion paralysis. It is also to be noted, in this particular case, that the symptoms of paralysis defend against the expression of hostile wishes which result from the frustration contingent upon the disruption of his marital life. In many cases the symptom has a more clearly evident sexual-symbolic reference. In this case too, however, the paralysis symbolically represents castration—loss of the power to satisfy genital-sexual needs through their unconscious acquisition of a forbidden character by association with earlier incestuous wishes.

## *Psychopathology of Hysteria*

It will be apparent from the above discussion that in conversion reaction the symptomatic changes in physical function unconsciously give distorted expression to the instinctual strivings that previously had been more fully repressed. The symptoms are substitutes for ideational representation of these strivings and can be translated into word language from their body-language with accompanying affective expression. At the same time, the symptoms indirectly represent the defensive force in conflict with the derivatives of instinctual impulses and the retribution or punishment for forbidden wishes.

When traced to its roots, hysteria in all its forms is predominantly related to the climax of infantile sexuality, the oedipus situation, with its struggle to surmount incestuous genital-sexual and hostile strivings.[25] Some conversion symptoms represent a materialization of unconscious fantasies concerned with forbidden genital-sexual wishes. Genitalization may consist in tissue changes including hyperemia and swelling, representing erection, or of muscle spasms, representing the movements of coitus, or of sensations resembling genital sensations, although these are often complicated by the perception of pain. On the other hand, as in the case described above, the symptoms may represent the reactive hostility to frustration of genital-sexual wishes, and in such cases anal-sadistic fantasies may find expression. Sometimes, pregenital expression of predominantly genital wishes may also occur; bed-wetting, a frequent masturbation equivalent in children, is a common example of this. Often interpolated between the original oedipal experiences and fantasies and the symptoms of the adult are daydreams connected with masturbatory activities.

The symptoms consist of an autoplastic attempt to discharge the tension created by

Downloaded from www.pbookshop.com

intrapsychic conflict, and express drive and defense simultaneously, short-circuiting conscious perception of conflict related to the oedipus complex. This last statement covers the primary gain. Secondary gain is involved in the alloplastic ego-endeavor to utilize the symptoms for manipulating other people and the current life situation. Often the attention-attracting function is conspicuous: by physical symbolic exhibition of conflict, the patient indirectly attracts sympathy for his plight. The flight into illness may provide escape from an intolerable job or family situation or from military service. In other words, some gain is attempted from the suffering in which the patient is caught up, and this gain might sometimes be related to a precipitating factor. In the latter event, a passive mastery might ensue, with later recession of the symptoms. Following injury, hysterical perpetuation or exaggeration of symptoms may have a conspicuous secondary gain factor motivated by the wish for compensation. In some cases the secondary gain persists only as long as the symptoms persist, and in such a situation the disease may become chronic, presenting an additional important resistance in treatment, as will be shown later.

Further elucidation of the psychopathology of hysteria follows.

## *Recent Concepts*

### ORALITY AND HYSTERIA

As indicated earlier, in the study and treatment of hysterical phenomena, Freud invented the method of psychoanalysis and developed the basic concepts of this science. The concepts of fixation and regression also grew out of these early studies, and the formulation arose that the personality of those liable to exhibit hysterical symptoms when frustrated was one with fixation at the phallic or early genital phase. In the onset of neurosis, regression took place to this point of fixation with its infantile object-relationships and its attendant castration anxiety. The anxiety motivated repression, which, however, failed to be effective, and symptom-formation ensued. Marmor[40] has recently emphasized that, in many cases of hysteria, fixations in the oedipal phase of development are themselves the outgrowth of pre-oedipal fixations, chiefly of an oral nature. He writes:

> The kind of parent whose behavior keeps a child at an "oral" level is apt to be the kind of parent whose behavior favors the development of a strong oedipus complex. The pre-oedipal history of most of the hysterias I have seen has revealed one of two things—either intense frustration of their oral-receptive needs as a consequence of early defection or rejection by one or both parent figures, or excessive gratification of these needs by one or both parent figures.

Similarly, Fitzgerald emphasizes early "love deprivation" and consequent "love craving" as a basic character trait of the hysterical personality.

The concept of multiple points of fixation, and, in particular, in hysteria, of the importance of oral fixation, serves to explain psychodynamically the clinical associations noted in many cases between hysteria and schizophrenia,[42] hysteria and depressive disorder, and hysteria and addiction, especially alcoholism. There is often a narrow margin between hysterical introversion or dissociative reactions and schizophrenic autism, or between hysterical materialization and schizophrenic hallucination; under certain circumstances, as already noted, the transition from classical conversion hysteria to florid schizophrenic psychosis takes place. Where the oral fixation factor is of greater importance, the egointegrative capacity is weaker, and psychotic regression occurs more easily.

It is to be noted too, in the opinion of this writer, that secondary gain factors are often underestimated as to their importance in the psycho-economy of the patient on account of inadequate realization of the quantitative loading of pregenital fixation. For attention-attracting and sympathy-gaining, the compensation-managing and the acquisition of dominance are related, in the complex stratification of psychic life, to the frustrated oral-dependency and anal-manipulative needs for narcissistic supplies and mastery.

Downloaded from www.drnaulibrary.org.in

## Hysterical Personality

In 1892 Charcot wrote of hysteria:[10]

> The dominant idea for us in the etiology is, in the widest sense, its hereditary predisposition. The greater number of those suffering from this affection are simply born "hystérisables," and on them the occasional cause acts directly, either through autosuggestion, or by causing derangement of general nutrition, and more particularly of the nutrition of the nervous system.

He demonstrated that morbid ideas could act as the "occasional cause," and that symptoms could be influenced by suggestion under hypnosis. Emphasizing as he did heredoconstitutional factors, however, he was more interested in the classification of symptoms and the differentiation of hysteria from other neurological disease than in the personality characteristics of the patients. At this time the known etiological field consisted of constitutional factors and of environmental factors largely unrelated to the early emotional transactions within the parent-infant relationship. The important role of the early personal environment was largely hidden from view before Freud's investigations. Without depreciating the importance of heredoconstitutional factors, Freud, in unraveling the meaning of symptoms in terms of the patient's experience, penetrated the amnesia for events in the early infantile period of life, and recognized its crucial formative importance in personality development. More attention thus came to be paid to the personality characteristics of patients suffering from symptom neuroses.

The first psychoanalytic contribution to characterology was Freud's paper in 1908 on the anal character.[21] As it became apparent that the optimal goal of therapy went beyond the relief of symptoms to resolving the need for symptom-formation, increasingly psychoanalytic characterology assumed clinical importance. Reich,[45] in his book on character analysis, attempted to depict the character structures in symptom neuroses, including hysteria. He described the behavior of the hysterical character as obviously sexualized, including coquetry in women and softness and effeminacy in men. Even locomotion, he considered, was sexualized so that movements are soft, graceful, and sensually provocative. As the sexual behavior came closer to attaining its apparent goal, apprehensiveness became evident. Reich also described unpredictability, strong suggestibility, sharp disappointment reactions, imaginativeness, lack of conviction, compliance readily giving way to depreciation and disparagement, compulsive need to be loved, overdependency on others for approval, powerful capacity for dramatization, and somatic compliance. Wittels[52] had already stressed the infantile and feminine, and the liability to confuse fantasy and reality. Reich attempted to explain these features as being determined by fixation in the early genital phase of infantile development with incestuous attachment, but as we have seen, Marmor has, with more cogency, related some of these features to pronounced orality in the hysterical personality. Abse[1] also stressed the dependence aspects of the personality background, especially in peacetime neurosis when the emphasis is on unsettled infantile situations; in war neurosis, in general, the emphasis is on the role of the actual or current conflict induced by stress.

Chodoff and Lyons,[12] in a recent paper, challenge the close relationship adduced by others between conversion phenomena and the hysterical personality. Of 17 patients with unequivocal conversion reactions, only 5 satisfied the criteria (similar to those of Reich's description above) they laid down for the diagnosis of the hysterical personality. They therefore concur with Kretschmer[37] and Bowlby[6] in the opinion that conversion reactions do not occur solely, by any means, in patients who present the characteristics of the hysterical personality.

Two comments seem appropriate: In the first place, as already stated, some of the features of the hysterical personality belong to derivatives of pregenital points of fixation, and, where these are absent, it might be expected that the etiological role of the actual conflict would be more emphatic. Secondly, while the predisposition to acquire hysteria is built up very largely from undue emotional attachment

Downloaded from www.pharmabrary.com

to one or both parents with difficulty of later displacement of this attachment, the dependent and other correlative patterns of personality are often not so simple and obvious. To understand deviations from such a pattern, it is necessary to study the total repertoire of unconscious defenses and to take into account that the evident achievements in external adjustments and independence may show the character of overcompensation. Basically, such patients remain unconsciously dependently fixated on the infantile object (in fact or in fantasy) and are vigorously defending themselves against this state of affairs. An example from military psychiatric experience is briefly outlined below.

Following enlistment in the Army, the patient, aged thirty, developed pains in the stomach. Later he began to suffer trouble with his eyes, especially when riding his motorcycle. He could not keep them open and complained they kept "screwing up," which, indeed, they did. He was of a very aggressive character type. Prior to enlistment he often performed in fairgrounds on the "wall of death," demonstrating his skill and daring on a motorcycle, and was proud to be earning much more money than his father. He had always been a daredevil, amateur motorcycling being his hobby from an early age. His usual employment was that of a butcher, and he was the mainstay of the home. He had never taken up a sustained relationship with any woman other than his mother, to whom he remained very attached. In discussions he made it clear that he was ready for anything in the Army and could perform wonders on his motorcycle—were it not for the spasms of his eyes.

In this case both the unconscious underlying overdependency and passive homosexual strivings were vigorously countermanded by character defenses. These gave an appearance of remarkable and heroic virility and independence, with others depending upon him, prior to his separation from his mother and the onset of symptoms, including conversion reaction.

### THE DECREASED INCIDENCE OF CLASSICAL HYSTERIA IN URBAN WESTERN SOCIETY

Chodoff[11] writes, of the decreased psychiatric interest in conversion hysteria in recent decades, "This is undoubtedly partly the result of an actual diminution in the occurrence of conversion hysteria due to such changes in the cultural climate as a wider dissemination of education with an increase in sophistication, a less authoritarian social structure, and a decrease in sexual prudery and inhibition." He mentions, too, that Freud's work was itself a very significant influence in bringing about cultural changes, such as decrease in secrecy and prudery about sex and an increase in understanding of the fact that physical symptoms can result from emotional disturbance. Laughlin[39] adds that decreased social acceptability of classical forms of neurosis might account for somatic and physiological expressions of emotional conflict seeking deeper and more disguised avenues of discharge. Where the attempted symbolic resolution of an emotional conflict in body-language begins to communicate as much, or nearly as much, as word language to the patient and to those in his particular life space, the attempt may immediately become abortive, for repression is signaled to increased efficacy.* The unresolved tension may then result in discharge through the autonomic nervous system, with excessive stimulation of innervated visceral structures. A vegetative neurosis[2] may yet again acquire a psychoneurotic superstructure of hysterical type, but in any case, the form of the neurosis departs from the classical forms prevalent in the time of Charcot and Freud.

In this connection, it must be emphasized that conversion symptoms are not limited to the voluntary muscular system but also occur in the vegetative system. Fenichel[16] states: "The urge to express unconscious sexual wishes in a distorted physical way has at its disposal a far more extensive area than has conscious will." It can similarly be shown that commands given to a patient under hypnosis can influence many more physical functions than can conscious will in the same individual. Vegetative functions are also utilized in conversion defense, especially if a condition of somatic com-

* Instead of more effective repression, further defense may be engaged against the symptoms themselves. In some cases, denial may occur, with an intensified form of *la belle indifférence* as the ensuing clinical manifestation, or manifest anxiety may paradoxically be used defensively.

Downloaded from www.PsychiatryOnline.org

pliance has already been established by unresolved tension resulting in autonomic discharge. However, the regression in hysteria may also include a change in ego-state analogous to that obtaining in early childhood. The archaic ego has access to more of the body functions than occurs later after the repressive barrier is established.

It is evident that, for the reasons advanced by Chodoff, there may be an actual decrease in the incidence of hysteria in some centers of modern civilization. On the other hand, this decrease may not be so substantial as it at first sight appears, because the ancient Proteus may take many shapes and thus elude even some of the refinements in modern diagnosis.

Classical forms of hysteria are common in the more outlying rural areas in this country, as is evident, for example, in some regions of North Carolina. Examination of such instances of classical hysteria, in the experience of this writer, reveals that the familial style of life, including sleeping arrangements, results in the relatively frequent early observation by the children of sexual scenes between the adults. This "primal scene" exposure may be of more direct significance than other elements in the cultural mode in lending a special coloring to the oedipus complex with a later increased incidence of major classical hysterical attacks.

### Identification in Hysteria

Hysteria is a great imitator, and this depends largely upon the fact that the sensations or movements evinced in the conversion symptoms may relate to the observations the patient has made of others. For example, Freud's patient Dora[22] developed a cough which was found to be traceable to her observations of Mrs. K's coughing attacks. She unconsciously wished to put herself in Mrs. K's position as the wife of Mr. K, but felt guilty about her rivalry. She selected Mrs. K's affliction as the point of identification, thus caricaturing her envy in the service of self-punishment. Oedipal wishes may, however, result also in an identification with the significant person of opposite sex. Forced to relinquish the forbidden and desired object, a partial identification with the object may ensue. Identification frequently occurs with some aspect of another person with whom the patient has little relationship. Freud used a hysterical epidemic in a girl's school as an example.[26] One girl who received a love letter fainted, whereupon other girls fainted too. The purpose of the identification in this instance was that the girls wished for the same experience and thus dramatized their forbidden wishes, accepting the punishment too. Anyone who, as a prototype, offers some libido-economic advantage at a time of heightened inner conflict and tension may thus be imitated. Multiple identifications often occur, the classical example of which is Freud's patient who tried to take her clothes off with one hand while trying to keep them on with the other.[23] She identified herself as a woman being sexually assaulted at the same time as she identified herself with the sexual aggressor. Bonnard,[5] in a recent paper, described children who had witnessed the quarreling of their parents, and she interpreted their gestures as an identification with both the aggressor and the victim. Multiple identifications may assume dimensions of partial personality systems in more severe dissociative reactions, as described previously in the section on amnesia and multiple personality.

The important role of identification in the sociology of the body-image is discussed by Schilder.[48] He has emphasized that the postural model of the body is not static but in constant flux, changing according to reactions to circumstances. There is a continuous process, underlying the evident changes, of construction, dissolution, and reconstruction of the body-image. Processes of identification and projection are of considerable importance in bringing about such changes. In hysteria the mechanism of identification expresses the close relation of the patient to different postural models of different persons. Innumerable condensations of object-relations may be expressed in a hysterical change in one organ of the body. Schilder also draws attention to Freud's patient Dora (see above). Her coughing attacks also expressed genital wishes to be infected and to take the place of her mother who had vaginal catarrh.

Fenichel[16] states that "identification is the very first type of reaction to an object. All

Downloaded from www.dbraulibrary.org.in

later object relationships may under certain circumstances regress to identification. The hysterical identification is characterized by the fact that it does not involve the full amount of cathexis available." A recent important discussion by Jacobson[21] attempts to show the relation between less and more regressive forms of identification. Foulkes[19] also attempted to show these relations. In the opinion of this writer, it is often by study of the type of identifications the patient has made and the correlative fate of the object-relationships involved that it is possible to obtain a better notion of how far from psychosis is a particular case of hysteria. Identifications may, however, elude understanding, especially in short-contact work with a patient or when psychotherapy is of a "repressive-inspirational" type, utilizing, perhaps unwittingly, primitive forms of identification in the suppression of symptoms.

## ¶ Diagnosis

Glover[28] sums up the pathogenesis of symptom-formation in hysteria by citing, roughly in sequence, the major factors usually involved. These are: (1) somatic compliance; (2) frustration; (3) introversion; (4) regression; (5) reactivation of oedipus strivings; (6) failure of repression; (7) displacement, symbolization, and/or identification with the incestuous object; (8) breakthrough of innervations; (9) inhibition or exaggeration of somatic function, giving rise to crippling or painful symptoms; and (10) somatic dramatization of unconscious fantasy formations, including repetition of some elements actually associated with oedipus-phase development.

Examples of somatic compliance are the localization of symptoms in accordance with fixation of body-libido (erotogenic zones) and localization due to libido-disturbance, the result of organic disease. Thus conversion symptoms of an oral kind may readily occur in a patient of constitutionally strong oral libido with oral fixation. On the other hand, an organ affected by organic disorder is readily chosen to express symbolically a reactivated oedipal conflict. This last is an important warning to the clinician not to adopt an "either-or" frame of reference in the differential diagnosis of hysteria from organic disease.

Conflict induced by frustration results in the reactivation of an oedipus complex which has been held in faulty repression and of which the negative (homosexual aspects) are strongly emphasized.

With these major points in mind, it can be stated that the positive grounds upon which a diagnosis of hysteria is established consist in the distinctive marks of its etiology and psychopathology which psychiatric investigation of the patient and his symptoms affords. The disorder is the result of mental conflict, and there are connections between the conflict and the symptoms. Hysteria is manifest in so many forms, some of which closely imitate organic disease of the nervous and other systems, that, without the distinctive marks of its etiology and psychopathology, symptoms may be misleading. It often happens that the symptoms themselves are no more characteristic of hysteria than of other diseases. In some cases, however, where there are characteristic symptoms such as astasia-abasia, anesthesia *en manchon*, clavus, globus hystericus, or the changing of one to another symptom, it is necessary to consider the extent to which hysteria is responsible for the illness of the patient. The stigmata only occasionally accompany other symptoms of hysteria. Rarely, pharyngeal anesthesia may be discovered, and cutaneous anesthesia is sometimes demonstrable, for example, in cases of hysterical convulsive attacks.

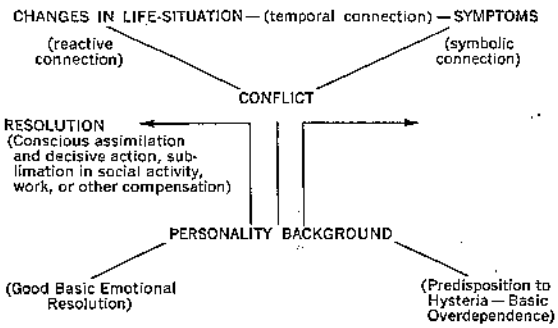
The occurrence of mental conflict prior to the manifestations of the disease, or of its exacerbation, may be revealed by a painstaking history of the present illness. Such conflict is provoked by changes in the life situation of the patient. It is necessary to determine the temporal connections of periods of stress with the conflicts and symptoms. Following this chronological correlation, which is positive in cases of hysteria, the nature of the conflict and its possible symbolic relation to the symptoms needs to be more closely studied. In hysteria the meaning of the symptoms thus becomes evident, for they express regressively (and often in a body-language) both the repressing forces and the repressed oedipus strivings in the field

Downloaded from www.dbraibrary.org.in

of conflict. Next, the personality characteristics of the patient need to be evaluated. Dependence aspects may disclose attitudes derived from the persisting, albeit unconscious, strong emotional attachments to the parents or their surrogates. The repressed oedipus complex of early childhood may express itself in the record of events of later life which the patient is able to recall. Overdependence in the spheres of occupational, social, and sexual adjustment is often clear. In some cases this is masked by a reactive insistence upon independence, which, however, betrays the character of overcompensation and shows the marks of unresolved aggression toward the parent (or parent-figures).

It is also possible in diagnostic interviews to increase understanding of the patient and his illness by a consideration of the neurotic traits which he has evinced during the process of growth and development. These are prominent and, in cases of hysteria, often persist into adult life. In some instances, too, there is a history of previous frank neurosis which can be correlated with the life situation and the conflicts evoked at that time. Table 1 summarizes the requirements in history-taking for the diagnosis of hysteria. No scheme should be rigidly followed, but the data are all required. It may be necessary to have more than one distributive discussion, in which the patient is helped to talk freely in his own way and at his own pace, in order to elicit the information.

As repeatedly stated above, hysteria and organic disease may be contemporaneously present. Organic disease may follow hysteria, as for example, when refusal of food proceeds to anorexia nervosa and subsequent physiological derangement. In other cases, physical disease is primary, with disturbances of the body-image and an induced regressive ego-orientation—a state of affairs conducive to conflict in many people with symptoms comprising, perhaps, an overlay of hysteria.



It is sometimes difficult to differentiate hysteria from organic nervous disorder. In general, an organic lesion of lower-motor-neurone type is one of individual muscle elements, whereas hysterical paralysis is usually a paralysis en masse.[24] An upper-motor-neurone lesion, however, often results in a paralysis which superficially resembles that which occurs in conversion reaction, but there usually are important symptomatic differences. Thus, lower-face paresis, hemianopsia, and circumduction of the leg at the hip are common in an upper-motor-neurone lesion. Pronounced changes in the tendon reflexes, sustained ankle clonus, and the sign of Babinski usually point toward organic involvement of the nervous system. Hysteria has to be diagnosed, however, on its own characteristics and not merely by the exclusion of organic disease, which, at times, it may accompany.

TABLE 1. **Directive Scheme for History Taking in Diagnostic Interview***

1. *Present Illness:*
   a. Consideration of chronological correlations of onset and exacerbation of symptoms with changes in life-situation (or traumatic experiences).
   b. Consideration of conflicts evoked by such changes in life-situation. The connections of these conflicts with particular symptoms as far as can be consciously disclosed in discussions by the patient when his attention is directed thereto.
2. *Personality Background:*
   a. Dependence aspects:
      i. Nature of current interpersonal relationships, especially family and affiance.
      ii. Current occupational, social, and sexual adjustment, including recreational and cultural interests.
      iii. Employment and school record and achievement.
   b. Neurotic traits:
      Predominant type, time of appearance, disappearance, or persistence.
   c. Previous nervous breakdown: type, correlation with life-situation at that time.
3. *Family and Hereditary History*, and the patient's view of it.

* Reproduced from Abse, D. W., *The Diagnosis of Hysteria*, 1950, by permission of the publishers, John Wright & Sons, Ltd., Bristol, England.

Downloaded from www.drsulibrary.org.in

In certain forms and phases of schizophrenia, with delusions, hallucinations, disfigurements of speech, and the generalization of automatization, the disease is readily distinguished from hysteria. Incipient schizophrenia may occasion difficulty in differentiation, especially because the resemblances depend upon an initial similarity of psychological mechanism.[34] The difficulty is enhanced by the fact that, occasionally, hysteria ushers in a schizophrenic psychosis; that hysterical phenomena may cover, or occur with, schizophrenic disease; and by certain forms of hysteria including dissociative reactions such as fugue, Ganser's syndrome, pseudodementia, pueriliism, and stupor. These last are sometimes part of a transient psychotic disturbance, but there is usually no march to fixed schizophrenic disorganization. Hypochondriasis in schizophrenia is usually of a bizarre nature, which may be accompanied by a subjective experience of a change or duality of sex, perplexity, and a peculiar overidcation. If any of these symptoms accompany somatic conversion symptoms, schizophrenia should be suspected.

Depressive or paranoid episodes may punctuate the course of a predominantly hysterical illness. In this case the diagnosis may more properly be designated as "borderline state," and the treatment may be modified accordingly.[36]

## ¶ Prognosis and Treatment

Conversion hysteria is often best treated by psychoanalysis, and the prognosis is generally favorable. Psychoanalytic psychotherapy imparts the potential for the treatment to reach beyond the goal of relieving symptoms to that of minimizing the need for symptom-formation in response to frustrational life situations. Various conditions however, may indicate the suggestive methods of psychotherapy for relief of symptoms, and others may contraindicate psychoanalysis. Immediate help may be mandatory, as, for example, in such acute conditions as anorexia with bodily emaciation, or when anxiety and confusion dominate the clinical picture. Consideration of such cases for psychoanalysis must wait until symptoms have been relieved and the patient is calmer. Advanced age, exceptionally great secondary gain, or feeble-mindedness are contraindications to analysis. In instances of conversion reaction or dissociative reaction which follow a severely stressful precipitating situation, the simpler supportive methods of psychotherapy may suffice for recovery to the *status quo ante*. The question of psychoanalysis may, in such cases, be raised by the patient himself and may be best left to his own consideration and decision.

In cases complicated by the exhibition of psychotic mechanisms, psychoanalytically oriented psychotherapy, with modification of the usual techniques of psychoanalysis, may be indicated.[36] This is frequently the case in the more severe dissociative reactions. In selected instances of conversion hysteria, following adequate investigation, hypnotherapy continues to find a place, and some therapists utilize hypnosis for "uncovering" types of psychotherapy.[52]

There are some cases of conversion reaction with an unfavorable prognosis, no matter what treatment is attempted. The conversion reaction may be the only possible emotional solution for the patient because of the real-life situation which excludes healthier possibilities of gratification. Such cases may not ever recover from valetudinarianism attended by a "favorite" physician who is apt to be changed from time to time. Other cases, which used to be designated "chronic degenerative hysteria," deteriorate into a massive form of emotional dependence, even parasitism, upon others. When the victim or victims separate or are separated, institutionalization may be-

Downloaded from www.dbraulibrary.org.in

come necessary, sometimes because of a supervening psychotic disorder of depressive or paranoid type.

CHAPTER 15

# THE PHOBIAS

Paul Friedman

Downloaded from www.ubraulibrary.org.in

THE TERM "PHOBIA" is derived from the Greek word *phobos*, meaning flight, dread, panic, or fear. When a fear becomes attached to objects or situations which objectively are not a source of danger—or, more precisely, are known by the individual not to be a source of danger—we designate it as a phobia. The patient, as a rule, realizes the irrationality of his behavior but feels compelled to avoid those specific situations which expose him to overpowering anxiety.

The concomitant physiological symptoms usually present in anxiety states and reactions of fear and panic, such as tachycardia, rapid breathing, tremor, sweating, etc., may likewise accompany acute phobic reactions.

## ¶ Historical Remarks

The earliest case history of a phobic patient is recorded in one of the books attributed to Hippocrates.[37] One of the first attempts to deal systematically with the origin of phobic reactions was made by John Locke.[55] * "Antipathies" and fears, Locke reasoned, often arise from an association of ideas, and, if such "antipathies" were acquired in childhood, their causes may later be forgotten:

> The ideas of goblins and sprites have really no more to do with darkness than light; yet let but a foolish maid inculcate these often on the mind of a child, and raise them there together, possibly he shall never be able to separate them again so long as he lives; but darkness shall ever afterwards bring with it those frightful ideas, and they shall be so joined, that he can no more bear the one than the other.

Locke recognized that it is not within the power of reason to relieve the "antipathies" thus acquired, but added that they could sometimes be cured by time. (Incidentally, he was quite explicit in stating that besides the acquired "antipathies," there are some which depend on constitution.)

More than two hundred years later, Watson[75] formulated a view of acquired fears similar in its essentials to Locke's, although stated in terms of conditioned responses. A more sophisticated theory was recently formulated by Dollard and Miller;[16] they describe phobias as learned responses to painful experiences.

* In the chapter "Of the Association of Ideas," included for the first time in the fourth edition of *An Essay Concerning Human Understanding*, 1700.

Within the field of psychiatry proper, phobic phenomena began to receive increasing attention during the second half of the nineteenth century. One of the historically important papers was published in 1871 by Westphal[78] who first introduced the use of the term "agoraphobia" to describe fear of wide streets, squares, or open spaces, and presented data on three agoraphobic patients.* Westphal described the agoraphobic reaction as determined by a fear that is "psychologically unmotivated"; that is, by an idea of danger which appears irrational and strange to the individual, but which dominates his behavior as he approaches the feared area. He also argued against some earlier theories that ascribed such fears to attacks of dizziness or to epilepsy.

The phenomenological similarity between phobias and obsessions led the descriptive psychiatry of the late nineteenth and early twentieth century, as represented in the writings of Oppenheim,[60] of Kraepelin,[49] and (to a lesser extent) of Pitres and Régis,[62] to lump them together, a tendency already implicit in Westphal's discussion of agoraphobia. The phobias as well as obsessions and "impulsions" were regarded as being, to a large extent, constitutionally determined, although Pitres and Régis placed considerable stress on the importance of the precipitating incident and on the emotional aspects of both the phobic and the obsessive reactions. In the early editions of Kraepelin's *Lehrbuch*, these conditions were classified under the neurasthenias; later they were reclassified under "compulsive insanity" which, in its turn, was designated as a psychopathic state. Although he considered these states to be a form of degeneration of the nervous system, Kraepelin admitted that such "degenerative" symptoms could occur in persons of superior intelligence whose intellectual capacity appeared otherwise unimpaired. Kraepelin, as well as Oppenheim, regarded the prognosis of phobias as unfavorable, although both mentioned that recoveries occasionally took place. The therapeutic measures recommended by Oppenheim included exercises aiming to accustom the patient to the phobic situation; in the case of agoraphobia, he suggested that the physician accompany the patient in walking across the feared open places. However, he also advised various somatic measures, such as washing the head in cold water and removal of nasal polypi.

A study utilizing the questionnaire method was carried out by G. Stanley Hall[36] and published in 1897. His statistical analysis of fears, based essentially on a classification of the feared objects, led Hall to advance the view that some fears represent vestigial traces of ancestral experiences, perhaps antedating limbs and visual space perception. According to him, the best evidence for the phylogenetic antiquity of the predisposition for fear rests on "the proportional strength of different fear elements and tendencies. Their relative intensity fits past conditions better than it does present ones."

Pierre Janet[39] submitted the phobic reactions to a more thorough psychological examination, relating them closely to hysterical paralyses, since both have the function of preventing the individual from carrying out some task he does not want to perform. In this conception the fear aspect is a secondary phenomenon rather than a cause of the phobia. Janet was the first to present a massive amount of observational data on the phobic and obsessional syndromes which had never before been exhaustively studied.*

However, it was Freud who introduced the truly dynamic conception of phobia. As early as 1895, in his paper "Obsessions and Phobias: Their Psychical Mechanisms and Their Actiology,"[32] he sharply delimited these two conditions from one another, designating the phobia at that time as a part of anxiety neurosis. But the fundamental psychoanalytic formulation of the mechanisms underlying the phobias is contained in his clinical study "Analysis of a Phobia in a Five-Year-Old Boy,"[27] published in 1909, which remains a classic exposition of the subject. It will serve as a basis here for the detailed discussion of these mechanisms.

* The term "claustrophobia" was introduced in the same year by Raggi.[64]

* Limitation of space prevents a more detailed exposition of Janet's hypotheses which originated in Charcot's theory of the hypnoid states of hysterical patients.

Downloaded from www.pdfbooksfree.pk

## Differential Considerations

First, however, it is necessary to introduce some distinctions whereby the phobias can be more carefully delimited from other types of fear reactions.*

Today we distinguish sharply between anxiety neurosis and anxiety hysteria (phobia). The clinical forms of anxiety neurosis may range all the way from acute kakon-crisis,† characterized by sudden onset and by violent excitation, to milder states of generalized anxiety. The anxiety neurotic suffers from a general fear of dying rather than from fear of a specific object. His anxieties are of a floating form, whereas the phobic's thoughts center on a specific object and subside when this object is removed. This is why phobic patients carefully avoid the anxiety-arousing object or situation.

Moreover, phobic fears must be differentiated not only from fears based upon realistic danger but also from those primarily involving an intellectual belief in the dangerous character of certain objects or situations. For example, a person is not necessarily manifesting a phobic reaction if he hesitates to travel by air because of his knowledge that plane accidents do sometimes happen. It is true that this rational consideration, which is based on statistical facts, may occasionally be overdetermined by a genuine phobia of flying. But then, the phobic component is precisely that part of the fear reaction which is independent of the intellectual estimate of danger and whose intensity is disproportionate to such intellectual judgment. An excellent description of these relationships can be found in *The Love and Fear of Flying* by Bond.[6]

On the other hand, a distinction must be drawn between the true phobias and the so-called panophobic reactions. The latter are usually pseudophobias, in which the fear is not attached to a particular object, although the patients seem to be afraid of many objects and situations. Indeed, such individuals fear anything and everything, especially any change. The phobias proper may be broadly grouped, according to their content, into those relating to objects and those relating to situations. Among the former we may cite the animal phobias; among the latter, stage fright, the fears of blushing in public (erythrophobia), of going out into the street, etc.

Another important distinction among the phobic reactions, which has proved the most practical of all classifications, was originally formulated by Freud[32] when he divided them into "(1) common phobias, an exaggerated fear of all those things that everyone detests or fears to some extent: such as night, solitude, death, illness, dangers in general, snakes, etc.; and (2) specific phobias, the fear of special circumstances that inspire no fear in the normal man; for example, agoraphobia and the other phobias of locomotion." The common—or, as Freud later designated them, universal—phobias thus are fears inherent in all human beings, but which have become intensified and have assumed neurotic proportions. Any normal person might experience fear at the sight of a snake, for instance, or when caught unprotected in a thunderstorm.

There is a wide range of variation with respect to the objects of phobic fears. Some of the more frequently encountered phobias involve fear of animals, of open or closed spaces (agoraphobia or claustrophobia), or of heights. But virtually any object may become the object of a phobia. Hence Hall's[36] idea simply to classify phobias according to the feared objects or situations, endowing each one with a special Greek name (gynophobia, peccatiphobia, botophobia, photophobia, etc.), is no longer considered useful, as one would have to add an infinite number of names to the list.

While cultural factors appear to have some influence on the choice of specific phobic objects, the incidence of some phobic fears seems to be much less subject to fluctuations.*

* Problems of differential diagnosis of phobias by means of the Rorschach test are discussed by Schafer[67] and by Klopfer and Spiegelman.[48]

† von Monakow[57] derived the appellation of this acute anxiety state from the Greek *kakon* = evil.

* Laughlin[50] aptly notes that syphilophobia, common in the 1920's, has become increasingly rare and in recent years was encountered only in association with schizophrenia; by contrast, the frequency of phobic fears of cancer appears to have risen. These changes, as he points out, seem to parallel changes in the rea-

Downloaded from www.pdfchm.com

These are essentially the ones that correspond to the more universal experiences of space, darkness, water, etc., experiences which, in large measure, extend to early infancy. Indeed, as Freud[28] observed, such phobias are rooted in childhood, whereas others most often are acquired later in life.

## ¶ Pathogenesis

The processes involved in the formation of phobic symptoms are especially well illustrated in Freud's "Analysis of a Phobia in a Five-Year-Old Boy,"[27] commonly known as the case of "Little Hans." Usually, the origin of a neurosis can be traced only through a reconstruction of remote events, but in this instance the phobia came under study almost as soon as its manifestations appeared, and the boy's father, who conducted the treatment under Freud's guidance, was in a much better position than are most therapists to supplement the patient's statements with his own knowledge of certain relevant events.

Freud's classic case study deals with a child who refused to go out into the street for fear that a horse might bite him. At the root of the phobia, as the analysis revealed, was a conflict between the boy's instinctual strivings and his ego demands. His oedipal conflict and strong hostility toward his father gave rise to intense fears of punishment, that is, to castration fears, which became transformed into the phobic fear of being bitten by a horse. In other words, the horse was substituted for the father; an internal danger was changed into an external one, and the fear was displaced onto the substitute. It is easier to avoid an external danger than to cope with an inner danger that cannot be avoided.

These processes are characteristic of the phobic structure in general.

listic danger from the two diseases and also to reflect the greater publicity recently given to cancer. On the other hand, according to Laughlin, the popularity of some phobic objects—water, height, closed spaces, open spaces—apparently remained unchanged during the same period. In this connection, however, it should be noted that any intensified fear of disease is more likely to be hypochondriacal-narcissistic than phobic.

## ¶ Repression and Displacement

In phobia the original object of the fear is typically replaced by some other object, and the original source of the fear reaction becomes repressed. In the case of "Little Hans," death wishes against the father and fear of punishment for such wishes were repressed, because consciously they were unacceptable to the boy who also had strong positive feelings toward his father. However, his death wishes and fear of punishment (as well as still other psychic components) re-emerged in the form of a phobia consisting of fears that a horse would fall down and that a horse would bite him. The choice of a horse as object of the phobia appeared to have been overdetermined by various factors, including the fact that prior to the onset of the phobia Hans once had actually seen a horse fall.

The child was unaware of the symbolic meaning of his fear, thus the displacement provided a double advantage: he could go on loving his father, while the fear could be concentrated on an object more easily avoided.

As already indicated, his choice of the horse as the phobic object was by no means accidental. Before the outbreak of the phobia, Hans had shown a lively interest in horses. He had observed that they (and other large animals) had large "widdlers" (penises). This item of information led him to conclude that his father likewise had a large "widdler," and, as yet unfamiliar with the facts of sexual differentiation, he reached a similar conclusion about his mother. Such observations, moreover, served to reassure the little boy that his own "widdler" would grow larger as he grew older. But it is noteworthy that, after the phobic symptom had emerged, the work of repression extended also to the recollection of his observations of the "widdlers" of large animals, that is, of observations that undoubtedly had played a role in the choice of the horse as the substitute object in his phobic symptom.

In fact, the repression not only caused this substitution to be made but also encompassed the original affects. As Freud points out, the

Downloaded from www.orauthority.com

child's *hostile feelings* toward the father were replaced by a *fear* of the horse, so that the aggression was displaced (projected) to the outside. Nor were his sexual feelings toward the mother manifestly present in the phobic symptom, although the castration fear, symbolized by the fear of the horse, was in part derived from a fear of punishment for these feelings.

Even though a transformation of affect takes place in phobia, it is not as pronounced as in conversion hysteria where the original affect is more thoroughly repressed.

The degree of displacement in phobia may vary. Fenichel[21] mentions several categories, such as "sex phobia," eating phobias, fighting phobias, which primarily involve fear of temptation and where relatively little displacement occurs. In other types the degree of displacement is much greater, so that the symbolic meaning of the phobia is more effectively concealed and can be discovered only through prolonged analytic work. Thus the agoraphobic symptom may have a variety of remote meanings, including: (1) the idea of an open street as an opportunity for sexual adventure; (2) the idea of leaving home; (3) the idea that on an open street one may be seen and caught;[21] (4) the idea that some other person (usually a parent or sibling) may die while one is away from home; or (5) the idea of being born. In a less symbolic sense, agoraphobia also may represent a reaction to "equilibrium eroticism," that is, to a sexualized pleasure in the sensations of equilibrium while walking.[1]

Displacement is likewise conspicuous in claustrophobia, a symptom often traceable to intrauterine fantasies. According to Ferenczi,[23,24] there is a close association between claustrophobia and the idea of being inside the mother; the fear of being buried alive is often a transformation of the wish to return to the womb. He cites a case where claustrophobia and fear of being alone in any enclosed space acted as a defense against masturbatory temptation. Observing that skin and chest sensations are particularly prominent in claustrophobic anxiety, Lewin[51] attributes this fact to the fantasy of being inside the mother and to ideas concerning the tactile sensations and breathing of the fetus. This fantasy is also described by him as one of partial identification through oral incorporation.

These are but a few examples where displacement is prominent. It is actually a characteristic feature of most phobias. The assumption that the choice of the phobic object is determined by displacement is consistent with the theory that fears of early infancy affect the subsequent choice of the phobic object.

## ¶ Projection

Concomitantly with displacement, projection plays an important role in the phobic symptom formation. "Little Hans," as already indicated, harbored aggressive impulses against his father. These impulses he projected onto the object of his hostility, the father, thence displacing them onto the horse by which he feared to be bitten.

One might say that the general human tendency to create the outer world in the image of the inner world is especially intensified in the phobic's defense against anxiety. According to Fenichel,[21] even "the physical state of sexual or aggressive excitement" may be projected and experienced in sensations of equilibrium and space. (Whether this kind of projection can still be characterized as anxiety hysteria seems doubtful.) However, although in phobia the ego structure is more severely impaired than in conversion hysteria, the projection here is far less extensive than it is in psychosis. Unlike the paranoiac, the phobic remains capable of reality testing; most usually he is aware that his anxiety is subjective rather than based on objective danger.[59]

## ¶ Identification and Regression

The role of identification in phobia has been described by many authors. Deutsch[14] showed that the phobic fear of going out alone in the street is closely bound up with ambivalences which frequently can be traced back to the oedipal situation. In some instances of animal

Downloaded from www.dbraulibrary.org.in

phobia (for example, the case of hen phobia described by Deutsch), analysis revealed the existence of an earlier identification with the animal which subsequently became the phobic object.[56]

In the case of "Little Hans," the realization that large animals had large "widdlers" became fused with his own wish for a larger "widdler." This occurred by way of identification, thus paving the way for the replacement of the father by the horse in the phobic symptom.

The process of identification may take a more primitive form. Thus the idea of being devoured by animals, a common phobic fear in childhood, is based upon a regression to the oral stage of development. The classical illustration is the fear of being eaten by the wolf, described in Freud's paper "From the History of an Infantile Neurosis."[29] Moreover, oral incorporation also characterizes many phobias of adults. For instance, a male patient related his phobic fear of bridges to a fantasy of crossing into a dangerous country where he might be devoured by prehistoric animals. Since phobic reactions are indicative of regressive processes in the same measure as they place the person in a situation of infantile dependency, this regression is especially marked in phobic syndromes which restrict the patient's locomotion and make him continuously dependent upon a companion.[3, 14, 21]* But to some extent it is inherent in all phobias; they all impose some restriction of action not caused by objective reality. Viewed from this standpoint alone, regression would seem to be minimal where the phobic object is quite remote and easily avoidable, as in a phobia of some rare or exotic animal. This general consideration, however, is not the only criterion for the existence of regression in phobic reactions.

* It may be relevant, in this connection, to note Abraham's[2] comment that the fear of walking in the street usually occurs in persons who are also afraid of being left alone indoors. The common feature of the two feared situations is seen in the fact that "the unconscious of such patients does not permit them to be away from those on whom their libido is fixated," and that "any attempt by the sufferer to defy the prohibitions set up by his unconscious is visited by an anxiety state." Thus, in the cases covered by Abraham's generalization, the term "agoraphobia" describes only one aspect of the manifest phobic picture.

Evidence of regressive features is frequently found in the symbolism utilized by the phobia. For example, in the case of "Little Hans," the repressed impulses themselves—sexual wishes toward the mother, death wishes toward the father—were predominantly of an oedipal kind, in keeping with the child's developmental stage. But his idea of being bitten by a horse contained, along with the castration symbolism, a strong oral-sadistic component characteristic of an earlier age.

## ◧ Symbolism in Phobias

To understand the meaning of a phobic symptom, we must delve into the complex and multifaceted structure of its symbolic content. Only thus can we uncover the real source of the patient's fear.

Coming back to the case of "Little Hans," we find that his fear was a result of a combination of many elements. He was not simply afraid of horses as such or of the street as such. He was afraid, on the one hand, that a specific kind of horse would bite him and that a horse would fall down on the street. But, on the other hand, his phobia also included heavily loaded furniture vans and other vehicles that might cause the horse to fall; and at one point he was afraid, moreover, that a horse would come into the room and bite him.

Freud showed that this diffuseness of the boy's phobia was "derived from the circumstance that the anxiety had originally no reference at all to horses but was transposed onto them secondarily and had now become fixed upon those elements of the horse-complex which showed themselves well adapted for certain transferences." The idea of the falling horse represented a death wish against his father, while the idea of being bitten by a horse having some specified characteristics represented a punishment for this wish. On another level, which emerged only later, the heavy furniture vans represented pregnancy and the falling horse represented his mother having a baby.

These ideas found their clear formulation in Freud's *Introductory Lectures*,[28] where he

Downloaded from www.dbraulibrary.org.in

compared the content of the phobia to the manifest part of the dream: "it is a façade." Lewin, using this as a point of departure for his illuminating study on "Phobic Symptoms and Dream Interpretation,"[32] showed that the overdetermination of the phobic symptom is the work of the primary process, as is also true of the dream fabric. He treats the façade of the phobia as we are used to treat the manifest content of the dream. Indeed, as the case of "Little Hans" exemplifies, true phobias frequently consist of a condensation of various symbols which seem to be interrelated in a meaningful way. Moreover, as I have shown elsewhere,[33] and as Jones[42] had previously observed in his paper on symbolism, in the phobia—as in the dream—there is a certain affinity between the person and the symbols he chooses to express his unconscious imagery.

The following example is an illustration of phobic symbolism. An unmarried woman of twenty-six sought psychoanalytic treatment because of a fear of walking down a flight of stairs, an affliction from which she had suffered since adolescence. The clinical picture could be described as follows. When approaching the first step on her way downstairs she became frightened, and her legs stiffened as though paralyzed. She could not move her feet. Clinging to the bannister, she would move her left leg with great effort by lifting it first to the left, then to the right, before she could finally put her foot down on the step. Exactly the same procedure was then performed by the right foot, etc. Throughout her descent the patient's eyes were centered on her movements, as though she were a child learning to walk.

Her phobia had first appeared at about sixteen, in high school, when a teacher had warned the class to be careful in walking downstairs, as the stairs were rickety and had caused some minor accidents. Since then the phobia had persisted continuously for more than ten years.

The patient had an only brother three years her junior, who apparently was favored by the mother. When he was very small, the patient had hated him, teased him, and often threatened to leave him in the woods at night. She also used to frighten him by telling him that he was not the real child of their parents, but a foundling, and she felt gratified when the little boy would run crying and complaining to the mother about it. She remembered being scolded and punished by her mother, whom she had feared and disliked since early childhood.

Nevertheless, she felt pity for the mother, who, she believed, was being cruelly attacked by the father. When she was about eight or nine she used to overhear conversations between her parents and would not fall asleep until all noise had stopped completely. Many times she became frightened, felt anxious, wanted to scream, and wished her father would die.

At about six she had once walked into the bathroom and surprised the piano tuner while urinating. The man then showed his erect penis to her, and she told him that she had seen the same thing before on her father. It is significant that, in the early stages of her analysis, the patient found it difficult to remember having seen her father nude or having observed him in the bathroom; nor could she remember having indulged in masturbation before the age of ten or eleven, when she had started to masturbate regularly. However, she remembered an incident at the age of about nine. She had been playing with some other girls and boys in an empty carriage that stood abandoned in the back yard of their house. A boy slightly older than she tried to put his hand under her skirt. She became frightened, wanted to jump down from the carriage, and for some reason felt unable to do so. However, in her state of fright she somehow did leave her companions and went to complain to her mother.

When she was eighteen she worked as a secretary for a much older man who once attacked her from behind while she was standing near the files. She became frightened and left the office.

From that time on, there were several unsuccessful love affairs. One, with a young intern in medicine, lasted about two years. She hoped to marry him, but when he suggested a separation she accepted it without any protest or ill feeling; she understood, she said, that he could not afford to marry a poor

Downloaded from www.dreamlibrary.org.in

girl because he needed money to establish himself in practice. She then had an affair with a much older man who likewise left her with some rationalization, which again she accepted. A third affair followed, with precisely the same pattern and the same outcome. In all these relationships she was completely frigid. As she put it, most of the time she would comply with the man's insistent desire to have intercourse and then consent to go on with the affair only because she was very much afraid of being blackmailed.

The patient's early jealousy of her brother persisted during adolescence; it became further increased when he was allowed to go to engineering school, whereas she had to renounce her own aspirations to study medicine. When he enlisted in the Air Force at the outbreak of World War II, she wanted to join the WAAC's or some other military women's auxiliary, but she was forced to give up this project because of a sudden increase of phobic symptoms.

The conflict about her femininity and her identification with the brother was brought out in many revealing dreams during the analysis. Very often she dreamed of being pursued by men who threatened to kill her; she would flee from the man in fright, then gloat as he ran into a mortal danger, but she would finally rescue him from this plight.

At a certain phase of the transference situation, the patient had a dream in which she stood on a small, round platform at the top of a long, narrow, endless flight of stairs. The entire structure was suspended in mid-air in a vast, arenalike space. As she stood on top, she became frightened, nervous, heard a voice telling her to go down the stairs. She felt unable to move and, looking down, thought that nobody could walk down these stairs. But the voice was telling her to go down, to move. Finally, she figured out that by sitting down she would gain more security: "If I were closer to the stairs, I would feel surer of myself." She then imagined that there were railings, and very cautiously somehow she began to descend. She kept her eyes closed until she had moved down some distance. Opening them, she saw that the stairs were beginning to close up at the bottom and were growing nearer and nearer to her. Then she heard another voice, telling her to turn around and go back. She felt paralyzed and unable to release her hold on the rails. With great effort she managed to take her right hand off the rail and to grasp the other rail with both hands, attempting to turn around. She did not remember going up, but thought that somehow she had done so, for she remembered then lying on the platform at the top of the stairs and sobbing. At the same moment the stairs seemed to twist like a snake, but they were stationary the rest of the time.

This dream, in which the patient's phobic experience was minutely enacted, became fully understandable only through the analysis of another anxiety dream soon thereafter. This time no stairs appeared in her dream; the dilemma consisted in having to cross a bridge, but of being threatened with death if she did so.* Her associations to this dream led to hitherto inaccessible childhood memories, including the recall of two decisive experiences at the age of five or six:

1. The patient remembered that she had slept in the same bed with her parents. Half awake, she had witnessed intercourse between them. She remembered exactly how her mother had pushed her father away, saying to him: "Turn your back, it's enough." The father then had turned toward herself, put his arms around her, and touched her with his wet penis. She had been frightened, as if paralyzed, wanting to jump out of bed, to scream and holler at her parents, but unable to do so. This was all she could remember about this incident. But she immediately related the words spoken by her mother, "Turn your back," to the dream in which an invisible voice told her to "turn around and go back." She was as paralyzed in the dream as she had been when lying in bed with her parents. It became clear that the movement of the stairs and the trembling of the platform represented the shaking of the bed during the parents' intercourse.

* This dream and its interpretation were previously reported by the author in a paper on bridge symbolism.[35]

Downloaded from www.libtool.com.cn

2. The second memory concerned an incestuous game with her brother, which had taken place on several occasions near a window overlooking a bridge. While engaged in this forbidden sexual activity, the little girl had guiltily looked through the window, watching lest someone should come.

Thus the analysis of these two dreams showed that the bridge and the stairs were really interchangeable. Both were symbols crystallizing the conflict at the base of the phobia: desire and punishment for incestuous sexual pleasure.

This brief fragment from the patient's history and analysis has served to demonstrate the sadistic and self-punitive trends underlying the structure of her phobia. From a tender age she had harbored hostile and aggressive impulses, and the analysis revealed intense murderous wishes toward the brother whom she had used in her incestuous play. Her guilt feelings and self-punishment were at the basis of her masochistic behavior. It is not intended to elaborate further on this case, which was reported mainly as an illustration of the interrelation between symbol and phobic symptom.

The symbolism of the stairs, so often used by Freud, is especially transparent in the staircase dream supplied by Rank (and included only in the latest edition of *The Interpretation of Dreams*).[30] It is interesting to note that the connotation of this symbol here is not static but kinetic, a concept described in my aforementioned paper.[35] There, too, the bridge symbolism represents a dynamic process of crossing.*

Stairways and bridges seem to be closely connected and often used interchangeably. Both represent links (one vertical, one horizontal) between one place or condition and another.

There are other sets of symbols presenting similar affinities; for example, all vehicles or all animals, respectively, are interchangeable. By the same token, an original monophobia may progressively spread to other objects belonging to the same associative constellation.

* Gerhart Hauptmann, in his book *Griselda*, makes use of the symbolism of stairs, giving it also a sexual meaning. This was cited by Reik in *The Secret Self*.[66]

If we noted before that virtually any object can become the object of a phobia, we may now add that any symbol can be used to express a variety of meanings. Taking the phobia of the elevator as an example, it may stand for a fear of the *claustrum*; it may stand for a fear of height; or it may, like any phobias involving vehicles of locomotion, stand for a fear of sexualized sensations of equilibrium and space.[21]

The foregoing considerations are of importance because they shed light on the obscurities behind the façade of the phobic symptom.

While the psychoanalytic theory places considerable emphasis on symbolic substitution in phobic symptom formation, some authors, notably Rado[63] and Lief,[53] stress the role of the "sensory context" in the acquisition of phobias. Indeed, phobic reactions may become attached to the "sensory context" of a traumatic experience, but upon closer scrutiny the latter may prove to be a precipitating rather than a causative factor. Phobic reactions which are largely a result of sensory conditioning, and in which symbolic substitution plays a less prominent role, might correspond roughly to the processes described by Dollard and Miller.[16] In their view, phobias are essentially avoidance responses acquired as a result of painful experiences.*

## ¶ Phobia in Children

Phobias "are *par excellence* the neuroses of childhood."[27] Indeed, there is scarcely a human being who has not, at some time in early life, experienced fear of a phobic nature.

The classical case history of "Little Hans" is especially illuminating also because it demonstrates a typical causative factor which often

* In a recent paper, Dixon *et al.*[15] maintain that it is "both incorrect and misleading" to consider phobias as isolated symptoms and that "any apparent specificity of the complaint may in fact be due to an unconscious displacement." While the statistical analysis presented by these authors is highly interesting and instructive, exception must be taken to their conclusion that the phobia is not a distinct entity. The fears dealt with in this study seem to be symptoms of various clinical conditions.

Downloaded from www.pbookshop.com

gives rise to infantile phobias—the little boy's castration fear. In girls we may find a corresponding factor in fantasies of previous injury to the genitals. Bornstein[8] reports a case of this kind, where the child's belief that her genital had been injured produced a phobia as early as the third year of life.

Castration anxiety and its feminine counterpart, however, are by no means the only major source of childhood phobias. Symbolic threat of sexual attack plays an important pathogenic role in girls[70] and in boys with passive homosexual tendencies. Moreover, phobic reactions in both sexes frequently originate in separation anxiety. Thus, Abraham[2] reported a case of childhood agoraphobia that could easily be traced to the child's desire to be with the mother, an observation which is corroborated by interpretations of agoraphobia by Weiss,[76] Deutsch,[14] and other psychoanalytic authors.*

Separation anxiety seems to be responsible for a variety of phobic reactions which in recent years have received a great deal of attention under the general description of "school phobia." As suggested by Johnson *et al.*[41] and corroborated by more recent studies, school phobia is a syndrome occurring under very definite circumstances which include: (1) "a history of a poorly resolved dependency relationship between a child and its mother"; (2) an acute anxiety in the child "produced either by organic disease or some external situation . . . and manifested in hysterical or compulsive symptoms"; and (3) a recent frustration or threat suffered by the mother, increasing her need to exploit the child's dependency relationship, with the result that separation from her when going to school becomes a traumatic experience.[41] However, separation anxiety is certainly not the only causal factor in school phobia.†

Because of the young child's identification with the important persons of his environment, we often find a predisposition to phobia in children of phobic parents. Hence the child psychiatrist may find it necessary to recommend treatment for his patient's parents in order to remove such pathogenic influences. A more exhaustive discussion of childhood phobias would exceed the frame of this chapter.

A childhood phobia may be a transitory disturbance or may continue into adult life. However, not all phobias start in childhood. In treating adult patients, we are often confronted with the question whether the development of a phobic symptom actually represents a new disturbance or a reactivation of an earlier neurosis, a point that may be important in the choice of therapeutic procedures.

## ¶ Some Remarks on Therapy

In dealing with phobic disturbances the therapist will be guided by the same general principles as in the treatment of other psychoneuroses. As we know, however, there is always some fluctuation and haziness in the manifest content of a phobia, and considerable probing may be needed before this manifest content can be accurately described. Sometimes, symptoms can be eliminated by supportive measures alone. In childhood phobias, for instance, this will essentially consist in accustoming the child to the feared situation. Thus it has been found that a child's fear of school* often can

Downloaded from www.dbraulibrary.org.in

* Katan[45] has suggested that a mild form of agoraphobia may be considered a normal phenomenon in the development of the adolescent girl.

† An interesting manifestation which at one level might be regarded as a school phobia, but which in reality was merely a reactivation of an earlier and more idiosyncratic phobic structure, is reported in Freud's case history of the "Wolf Man."[29] This patient, while in school, developed a fear of a teacher who was quite critical of him and whose name happened to be Wolf. As the patient had had a wolf phobia (or, more precisely, a fear of a picture of a wolf drawn in a particular position) in early childhood, the teacher's name apparently reactivated some of those early fears. (Even much later in life the patient reacted with panic when he consulted a dentist named Wolf. Reported in R. Mack-Brunswick's "A Supplement to Freud's 'History of an Infantile Neurosis,'" in *The Psychoanalytic Reader* [R. Fliess, Ed.], Vol. 1, pp. 86–126. Published by International Universities Press, New York, 1948.)

* It may be interesting to cite here the following passage by Locke:[55] "Many children, imputing the pain they endured at school to their books they were corrected for, so join these ideas together, that a book becomes their aversion, and they are never reconciled to the study and use of them all their lives after; and thus reading becomes a torment to them which otherwise possibly they might have made the great pleasure of their lives."

be gradually overcome if he is brought to the school every day but not forced to attend classes or to participate in any prescribed activities.[46] Under these conditions, "going to school," as such, becomes less threatening, and this decrease of the child's fear may then be extended to the specific object or situation (teacher, classroom, etc.) on which the phobia really centers.

In some cases of early childhood phobia, it may be necessary for the therapist to include certain educational measures, such as explanation of the anatomical differences between the sexes, reassurance to the little girl that her sexual organ is intact, to the young boy that he is in no real danger of being castrated. In dealing with such infantile anxieties, the educational and analytical part of the work cannot be rigidly separated. The cases reported by Bornstein[7,8] and by Sterba[70] illustrate that some initial analytic work is indispensable to determine precisely what the child fears or to establish the pattern of communication best designed to convey the needed reassurance.

In children, as well as in adult patients, genuine phobias marked by a high degree of symbolic displacement require systematic psychoanalytic treatment. This method aims to uncover the symbolic meanings of the symptom and to interpret changes of these meanings in terms of the changing transference situation.

In his paper "Turnings in the Ways of Psycho-Analytic Therapy," Freud[34] stressed the necessity of exposing the phobic patient to the dreaded situation or object, and he warned that "one can hardly ever master a phobia if one waits till the patient lets the analysis influence him to give it up. He will never in that case bring for the analysis the material indispensable for a convincing solution of the phobia."

Hence it is very often necessary for the analyst to intervene more actively and to insist that the patient brave the phobic situation. In this way the full strength of the underlying conflict can be evoked in the associative material. Evidently, the analyst will await a propitious phase when the patient's positive transference may help to reduce the phobic fear. This more active intervention in the analysis of phobias constitutes an exception to the standard psychoanalytic procedure.

To give an example: An agoraphobic patient was referred to me after having been treated by several other therapists over a period of seven years. She had always been accompanied to their offices by her husband, and for a short time I permitted this arrangement to continue. But as soon as the transference situation appeared propitious, the patient was requested to come alone. She complied readily, but had to telephone me before each session in order to assure herself that I was expecting her. After a few months she became able even to go unaccompanied to her place of work, although she still had to call me very frequently to feel secure.* Her evident dependency needs and defensive devices, as well as the strong hostility underlying her dependency, could then be analyzed in the light of the transference situation. It thus transpired that the phone calls served to reassure the patient that her death wishes against the analyst as a transference object had not materialized. Her transference manifestations revealed the characteristic ambivalence toward identification figures which has been described by Deutsch,[14] Katan,[45] and other authors as among the basic factors in agoraphobia. I may add that this patient's feelings of dependence displayed, in rather transparent form, a "linkage fantasy"[61] whereby an identity between herself and the analyst (as a symbolic parent figure) was asserted by magical means.

To repeat, psychoanalysis is the treatment of choice; it is the method best designed to yield insight into the meaning of the phobic symptom and the underlying psychic conflicts. However, the psychiatrist, in his daily work, is called upon to deal with situations where regular analytic treatment is not feasible and where early relief of the symptomatology seems imperative. There are, of course, numerous methods by which such relief may be achieved.

* In a somewhat similar vein, Deutsch[14] mentions an agoraphobic patient who, in a state of positive transference, was able to go unaccompanied to the analyst's office, and whose fear of walking alone was considerably attenuated with respect to the analyst's neighborhood.

Downloaded from www.pbookshop.com

Unfortunately, limitations of space make a detailed discussion impossible here. A psychotherapy based on dynamic principles is certainly the most appropriate method, especially in cases where deep repression and symbolic substitution are not too marked.

Hypnosis has been used with some success in the treatment of phobic disturbances. But however spectacular and immediate the results may appear, they by no means reach the goal of a truly dynamic therapy. As long as the underlying conflicts remain untouched and unconscious, the patient is prone to develop a new phobic symptom in place of the one removed.

Since phobic patients realize the irrationality of their fears, direct suggestive therapy is not effective. Sometimes it may even strengthen the patient's guilt feelings or intensify his hostility toward the therapist and resistance to the treatment. And when such attempts at rational persuasion seem successful, it is usually due to rapport rather than to logical reasoning.

The phobic patient, more than any other neurotic, can become a faithful ally of his therapist in the struggle against his ego-alien and tormenting symptom. His need for dependency and protection and his will to recover offer excellent chances for successful treatment, if it is undertaken in the early stages of the illness. But only the therapist's skill and understanding of the dynamics will enable the patient to overcome his resistance and to give up his neurotic defenses.

The ambivalent struggle of an agoraphobic patient, as she anticipated her first unaccompanied visit to her therapist's office, was expressed in the following verses:

*Which Epitaph Shall Be Mine?*

She couldn't try
For fear she'd die;
She never tried
And so she died.

or

She couldn't try
For fear she'd die;
But once she tried
Her fears—they died.

CHAPTER 16

# THE ANXIETY STATES

Isidore Portnoy

Downloaded from www.dbraulibrary.org.in

IT IS CLEARLY EVIDENT that awareness of anxiety as a painful affect is increasing in the Western world. Rennie *et al.*,[47] in a study of a compact central residential area in New York City, found anxiety in 75.5 per cent of the study population. While such a finding no doubt depends on the criteria used, it gives some idea of the extent of the problem. The movement toward ataractic philosophies and drugs, sharply accelerated in recent years, supports the statistical studies. It is clear that anxiety and this movement toward peace of mind must have the most far-reaching consequences for the growth of the individual and the development of the social structure.

Anxiety-producing factors in our culture grow progressively more numerous and intense, while anxiety-relieving agencies have become sharply and increasingly less effective. The cold war and the threat of atomic annihilation are recent additions to the long list of factors that make this the age of anxiety. Perhaps more fundamental are the increasing strains and pressures experienced by individuals living in a period characterized by great complexity, cultural disunity and instability, rapid change, and the mingling of varied and differing cultures. Group identifications, including those of family and community, are weak. In an atmosphere of hostile tension, deriving largely from the competitive character of our society, man's isolation has increased. The particular character of "the search for glory" (Horney,[20] p. 17) in our culture, with its emphasis on status, success, superiority, and perfectionism, has shaped man's view of himself, so that his sense of identity depends on the degree to which he can fulfill the requirements of this particular religion. This is a period characterized further by the undermining of many of the basic values, definitions, standards, beliefs, and illusions which previously provided the foundation for man's orientation to himself, to others, and to life. The passing of the age of the powerful "fathers" has left the "sons" free to make their own way. As the period of angry rebellion subsides, man increasingly faces the difficulties involved in responsibility, choice, and freedom, as he moves with doubt and uncertainty on a road on which the directional signs are at best unclear, at worst, conflicting. Kelman[26] (p. 140) has noted that disintegration can lead to healthier as well as to sicker reintegration.

This is the possibility and the challenge that man faces. His anxiety is an expression of the cultural disintegration in our time.

## ¶ Basis of Definition and Classification

Although considerable progress has been made toward a deeper understanding of the psychodynamics of healthy and sick personality, psychiatric nosology continues to be based on presenting symptomatology. The various schools of psychiatric thought have dealt with the problem of diagnosis and classification in terms of their own particular theory of human motivation, but none of these classifications has gained widespread acceptance. Retaining the descriptive diagnostic category of anxiety states has value for the psychiatrist because it does not fix his thinking in any rigid mold of theory. It has the further advantage of keeping open avenues of communication by providing a language that all can use, however limited its symbols may be in conveying the essence of the underlying pathology. Furthermore, anxiety is more than a symptom complex. It has its own dynamisms, so that the term "anxiety states" has psychodynamic as well as descriptive value.

The anxiety states are defined as neurotic syndromes characterized by more or less chronic apprehensiveness with recurring episodes of acute anxiety. These states are to be distinguished from the condition of pervasive anxious concern which may be considered normal for our times. Not included in this classification are the transitory episodes of acute anxiety occurring in more or less healthy individuals under overwhelming stress. Phobic, conversion, dissociative, obsessive-compulsive, depressive, and psychosomatic phenomena are invariably present to some degree. Where they dominate the picture, the appropriate diagnosis is made. The difference between these conditions may be viewed as expressions of the particular ways in which the individual deals with his anxiety and conflicts. As Martin[84] has indicated, awareness of imminent total involvement in conflict is what threatens in anxiety. In this view, it is the anxiety state which the phobic, compulsive, etc., individual is attempting to avoid. The particular psychosomatic, conversion, or phobic symptom is a symbolic expression of the underlying anxiety and conflict.

While clinical anxiety may be manifested in a great variety of symptoms,[2] each person has his own characteristic way of feeling anxious. The most typical picture is that of subjectively experienced uneasiness, apprehension, anticipation of danger, doom, disintegration, and going to pieces, the source of which is unknown by the individual and toward which he feels helpless, with a characteristic somatic pattern. This somatic pattern shows evidence of increased tension in the skeletal muscles (stiffness, tremors, weakness, unsteadiness of voice, etc.); the cardiovascular system (palpitation, flushing or pallor, faintness, rapid pulse, increased blood pressure, etc.); and the gastrointestinal system (nausea, vomiting, diarrhea, etc.). There may also be other manifestations such as cold wet extremities, rapid or irregular breathing, frequency of urination, and sleep disturbances. Subjective awareness of anxiety may be slight or absent, though physiologic evidence may be readily noted by the observer. The many devices for lessening awareness of anxiety include rationalization, denial, narcotization by alcohol, drugs, sleep, sex, work, activity, and avoidance of any feelings, thoughts, and experiences which could evoke the anxiety response (Horney,[21] p. 49). The question of unconscious anxiety is an important theoretical and practical one (Reid,[46] discussion by Kelman).

## ¶ The Nature and Meaning of Anxiety

Comprehension of the phenomenon of anxiety is essential to an understanding of healthy growth as well as neurotic development. Our present understanding is the product of theoretical concepts and experimental research to which many have contributed. Which contributions are given the greater weight will be determined by one's particular frame of reference. For me, the works of Kierkegaard,[28, 29] Freud,[5, 6, 7] Goldstein,[15, 16, 17] Cannon,[3] Sulli-

Downloaded from www.dbraulibrary.org.in

van,[54,55] Simpson,[52] Kelman,[25,26,27] and above all Horney[20,21,22,23] have constituted essential elements in understanding for the following reasons: Kierkegaard saw "the sickness unto death" as the despair resulting from the loss of self and laid the groundwork for the view that anxiety is an inevitable aspect of being alive and neurotic anxiety the experience of dissolution of the self, nonbeing, and meaninglessness. Freud pioneered explorations into man's inner life, discovered the role of unconscious phenomena (most particularly inner conflicts) in determining the sources of neurotic anxiety, and recognized the crucial significance of anxiety for the development of the individual and the elaboration of his neurotic and psychotic states. Goldstein brought the holistic view of the organism into the field and recognized that "anxiety may be produced by a variety of events, which have one common element—there is always a discrepancy between the individual's capacities and the demands made on him which makes self-realization impossible"[15] (p. 90). Cannon did pioneering work in the field of homeostasis, so that the phenomena in anxiety may be viewed biologically as expressions of threats to, temporary failure of, and attempts to restore homeostatic equilibrium on a new level. Sullivan viewed the human being as an integral part of culture, so that anxiety is seen as arising from a threat to the individual's security in interpersonal relationships. Simpson, with his view of human evolution, provides a biologic base for thinking about man's values which are threatened in anxiety. Kelman brings unitary-process thinking into the field of psychiatry, his basic premise being that "organism-environment is a single, integral reality" and ". . . the patterns of this reality can better be formulated in a language of process. Tension manifested in physical and psychological patterns is one attribute of this hierarchical system. When the mean level of tension in this unitary system is exceeded, anxiety becomes manifest"[26] (p. 151). "Anxiety is cued off when tension develops beyond the mean due to the organism's attempts to integrate in an environment for which it is not adequate and which is not adequate for it. Anxiety appears in the phase of disintegration of the natural cycle, disintegrating-reintegrating as aspects of integrating"[26] (p. 143). Horney's concept of self-realization, anxiety as the dynamic core of neurosis, and acquired conflict and solutions to conflict as the body of the neurotic structure will be elaborated in later sections of this chapter and in Chap. 71, Vol. II ("The Holistic Approach," Kelman).

May[41] has provided a definitive summary and synthesis of the dominant anxiety theories, in addition to contributing his own important emphasis on the crucial role of man's valuating capacity in the phenomenon of anxiety. In the field of present experimental research, the works of Funkenstein,[10] Grinker,[18] Liddell,[31] Masserman,[37,38] Rioch,[48] Selye,[49] Wolff,[57] and others have contributed to the movement in the direction of a holistic biologic approach to the phenomenon of anxiety.

Any attempt to define the nature and meaning of anxiety must begin with the statement that anxiety is a natural phenomenon which the individual experiences when values essential to his existence, his sense of being, and his identity are threatened. It is to be distinguished from fear in which the threat is peripheral, the intactness of the sense of being is not being threatened, the danger is objective, and the individual can evaluate it and can act either in terms of fight or flight in coping with it. Goldstein[17] (p. 296) believes that fear is the experience we have when we anticipate the possibility of the onset of anxiety. Sheiner,[51] stressing the significance of the individual's fear of anxiety, feels that the essential difference between fear and anxiety is that in fear the individual is able to act, ". . . is conscious of himself, his resources, and his surroundings. He is still an integrated personality."

Even more essential is it to distinguish normal anxiety and healthy involvement in anxiety from neurotic anxiety and neurotic involvement in anxiety. When we speak of normal anxiety, what we mean, essentially, is that it is man's nature to have anxiety in the face of certain kinds and degrees of threat. In brief, it is the ultimate expression of our being human rather than gods. (This constitutes one

Downloaded from www.dbraylibrary.org

of the reasons why anxiety is so unbearable, particularly for the neurotic individual who has the need to feel omnipotent.) In normal anxiety we face the limitation of our powers, the degree of our vulnerability—limitations and vulnerability which are not expressions of illness but are inherent in the nature of man. What gives human anxiety its particular quality is man's ability to be *aware* of his finiteness. We experience normal anxiety in the face of such realities as death, old age, and illness, as we recognize our factual helplessness. The anxiety of an infant is similarly based. We experience normal anxiety whenever we move from the old, the sheltered, the known, the tested, and the certain into the new, the unknown, untested, and uncertain; that is, whenever we "stretch," expand, move forward. In this view, normal anxiety is an inevitable accompaniment of healthy growth and change in the direction of greater freedom, autonomy, and creativity as we move toward increasing fulfillment of our innate constructive potentialities. We may assume that no individual's striving toward self-realization is ever so completely crushed that he does not experience such anxiety to some degree. We experience normal anxiety in the uniquely human endeavor to find a meaning in existence. We experience it when we are involved in healthy conflict or the clash between opposing convictions and genuine values. In our culture, love, freedom, equality, respect, prestige, and success, when not compulsive, may constitute more or less normal values, any threat to which may evoke anxiety.

We can speak of healthy involvement in anxiety in terms of the individual's response to these threats and challenges. To the extent that the individual is able to respond with courage, that is, to call on still more of his resources to meet, master, or, at least, endure the threat, we may speak of a healthy involvement in anxiety. Here the individual responds to the anticipation of impending self-disintegration by asserting, at the decisive moment, "I am." In this process of owning, facing, and meeting the experience of anxiety in its anticipatory phase is involved an assertion of selfhood of such significance that the experience of psychic annihilation, which is such an inevitable component of neurotic anxiety, is greatly diminished or is absent. Instead of the characteristic neurotic response in anxiety, which is neither to fight nor to flee but rather to shrink, to vanish as a self, in healthy anxiety, when the threat to selfhood has been perceived, consciously or unconsciously, and the possibility of ultimate disintegration accepted, the human being responds with an affirmative assertion of his being. It must be emphasized that this is not a response *to* anxiety but is actually an aspect of healthy involvement *in* anxiety. Two of the main results of such healthy involvement are an increment of growth and a significant change in the quantity and quality of the anxiety experienced, symbolized in flushing and body heat, as contrasted with blanching and body coldness in neurotic anxiety.

What makes it possible for an individual to have this courage to be, so that the anxiety experienced is a constructive spur to healthy growth rather than a paralyzing, disintegrating block? What, in other words, are the dynamics of courage? It is not within the scope of this chapter to explore at length this most fundamental question. Briefly, courage is an expression of the healthy state, the process of self-realization which is the unfolding and developing of the constructive potentialities of the real self (Horney,[20] p. 364). To the extent that the human organism is genetically and physically intact, and providing that his personal milieu, particularly in infancy and childhood, is favorable, self-realization will naturally occur. In this process, the following conditions evolve: (1) healthy character structure, manifested chiefly by wholeness—the owning by the individual of all aspects of his being, more or less; (2) spontaneity, the capacity for genuine, as differing from compulsive- and anxiety-dictated feeling and behavior; (3) inner unity, which gives the individual stability and a sense of his own identity; (4) good relationship to other human beings and to the community, expressed in the ability to move flexibly toward them in cooperation and love, against them in differing, opposing, and fighting, and away from them in the ability to

Downloaded from www.orgonelab.org

stand alone, separate but not isolated from others, accepting the interdependence which is an aspect of man's being in community; (5) a good relationship to himself, which includes a realistic respect for his assets and limitations, the capacity to take responsibility for and be critical of moral and other shortcomings (healthy guilt, that is, with compassion), and the incentive to reach and extend his capacities without unreasonable demands for perfection; (6) a hierarchy of values arising out of genuine conviction rather than compulsive conformity or defiance; and (7) an affirmative attitude toward life, with a zestful interest in availing himself of opportunities for fulfillment and the acceptance of struggle as an invariable component of living. To the degree to which the individual can move in this direction, he will be able to have a sense of his own "I" and be able to affirm "I am" in healthy anxiety.

The phenomenon of neurotic anxiety differs from this picture in the nature of what threatens the individual and what is being endangered, but most of all in the nature of his involvement in anxiety. In neurosis, not only does the individual experience *Urangst* and the challenge of growth, but he also faces a host of threats, which endanger aspects of the neurotic character structure which he must maintain out of a stringent inner necessity to protect his feeling of safety and unity, and which have acquired enormous subjective value for him, so that he also must protect them in order to maintain his sense of identity and his feeling of worth. At the core of neurotic anxiety is a feeling of utter helplessness which pervades his being, stemming most particularly from his lack of a feeling of wholeness, derived from his dissociation from, denial, repression, externalization of, and active alienation from major aspects of his being, particularly the perceptual, sexual, and organic. The individual's feelings and behavior are dictated by compulsiveness, so that he is driven rather than moved, and cannot feel that he is an active force in his own life. Disunity pervades his whole being and is an expression of unresolved inner conflicts, so that he is unable to have a firm sense of his own identity. His relationships to others and to the community are impaired and are expressed in compulsive needs for dependency and symbiosis, aggression and domination, detachment and isolation. His relationship to himself is also impaired, involving both an extreme undervaluation of his own actual assets and possibilities and an equally extreme illusion of his own perfection, superiority, and invulnerability. This leads to intense self-hate when he cannot fulfill fantastic demands on himself (neurotic guilt), so that, to a large extent, he is both a stranger and an enemy to himself. His system of values derives from his need for safety and his search for glory. He has a negative attitude toward life, focused largely on avoiding struggle and pain. To the degree to which the individual has moved in this direction, he responds to threats to his being with feelings of intense helplessness and the previously noted attempts to shrink, to vanish, to curtail and restrict awareness, experience, feeling, and living. What causes this state will become clearer when I discuss the psychodynamics of the anxiety states.

## ¶ Anxiety as a Multidimensional Phenomenon

When we say that anxiety is a multidimensional phenomenon, we mean that the total organism is involved in every aspect of it—the individual's perception of the threat, his interpretation of it which involves his uniquely human capacity to symbolize and abstract, the role of the past in the present as well as the capacity to evaluate future possibilities, conscious and unconscious decisions concerning his way of coping with the threat, all within the context of his interpersonal and cultural milieu. I wish to make some reference at this point to the somatic dimension of this phenomenon.

The inseparability of the somatic, psychological, and interpersonal aspects of anxiety has been widely noted in recent experimental work. The varied responses of Masserman's[87] monkeys to tranquilizing drugs led him to conclude that "it is impossible to state the effects of

Downloaded from www.brainlibrary.org.in

any drug on any organism without considering the latter's genetic characteristics, past experiences, biologic status, and perceptions about, motivations toward and evaluations of its current and social milieu." Funkenstein's[10] Harvard students showed specific cardiovascular responses related to the emotional response in acute emergency. Individuals who responded to the experimental stresses with "anger out" showed a cardiovascular pattern characteristic of that produced by the excessive secretion of a substance similar to norepinephrine, while individuals who responded with "anger in" or severe anxiety showed a cardiovascular pattern characteristic of that produced by the excessive secretion of a substance similar to epinephrine. These studies demonstrated that the "anger-out," "anger-in," and severe-anxiety responses were determined by a host of factors, including the individual's personality, his cultural status, the nature of the threatening experience, and the relationship to the examiner. The individual's response in acute emergency was felt by Funkenstein to be determined by the individual's basic disposition, in which are combined innate biological factors and psychological factors involving his very early childhood experiences. Aspects of personality which Funkenstein found to be correlated to these acute emergency responses are the individual's perception of his parents, his internal concept of self, his fantasies, social attitudes, and social stratification. On the other hand, Funkenstein found no significant relationship between the individual's response in emergency and his ability to handle stress as time passes. He felt that the latter was an expression of ego-function related to the entire life experience of the individual. He found that the ability to master stress was correlated with the nature of the individual's interpersonal relationships, ability to assess reality, and the integration of his personality. One result, pertinent to our understanding of the interpersonal character of anxiety and having important implications for therapy, occurred when one examiner's doubts and anxieties about the experiments resulted in a response of severe anxiety in *every man* tested by him, results quite opposite to those obtained by other experimenters where anger was the subjects' most common response. Equally significant was the finding that the major conflicts evoked in these subjects centered around hostility—either fear of their own hostile and aggressive feelings or a fear of hostile retaliation. In brief, the subjects did not react, they responded.

While Cannon's formulations concerning the physiology of emotion, the fight-flight response, and homeostasis continue to constitute focal points for much of our present thinking, there is a definite trend toward thinking in more holistic terms about the physical aspects as well as the other major aspects of the anxiety process. Recent work[33] has focused on the role of the reticular activating system in the brain stem in the phenomenon of anxiety as well as in the processes of consciousness and arousal. Beginning with the thesis that the cortex exercises an inhibitory action on the lower centers, Malmo[33] (p. 45) suggests that "pathological anxiety is most probably a state characterized by reduced central inhibition," and, following Eccles, suggests that there is a chemical transmitter for inhibition, the effectiveness of which has been significantly decreased, perhaps as a result of attrition, "possibly produced by mechanisms described by Selye" (p. 47).

Although Gellhorn[12] (p. 359) finds that Cannon's thalamic theory of emotion has in the main been corroborated, Spiegel,[53] in a review of fifty-eight cases of individuals treated by various psychosurgical procedures, noted that "it is not possible to refer emotional reactions to a single circumscribed nucleus within the diencephalon or its connections with the frontal lobes, but that there exists a multiple representation of this function." Gerard,[13] (p. 431), commenting on these findings, stated: "If, as I suspect, the patterns of activity of great numbers of neurones proves more crucial than whether or not any particular neurones participate in the pattern, the final answer will come more from functional than from localization studies." Here, too, we note the trend toward pattern thinking, with emphasis on integration rather than on localization of function.

Similarly, there is increasing evidence that

Downloaded from www.dbraulibrary.org.in

the homeostatic mechanisms involve the organism far more extensively and in a far more complex manner than had previously been recognized. The pattern of organismic response in acute stress appears to involve the hypothalamic-thalamic-cortical tracts as well as the reticulo-thalamic-cortical connections in its upward discharge, and the hypothalamic-sympathetic-adrenal medullary system in its downward discharge, with the familiar peripheral effects of sympathetic excitation—raised blood pressure and pulse rate, inhibited peristalsis, palmar sweating, dryness in the mouth, etc. At the same time, involvement of the parasympathetic branch of the autonomic system, expressed peripherally in increased frequency of urination, emptying of the rectum, slowing of the heart rate, and lowered blood pressure, etc., are frequent aspects of the anxiety picture, particularly when stress is prolonged. These parasympathetic expressions may dominate the anxiety picture, as may also expressions of the participation of the somatic nervous system in the downward discharge. While the synergistic action of the sympathetic-adrenalin and the vago-insulin mechanisms appears to be a physiological necessity for the organism's capacity to fight or flee in the face of danger, the precise factors which account for the dominance of sympathetic or parasympathetic response in anxiety remain rooted in deeper aspects of personality functioning, the dynamics being as yet unclear.

Investigations into the electrical and chemical aspects of the anxiety phenomenon promise to shed further light on the physical dimension of this process. Recently Garb, Tiwari, and Chapman[11] found that a third amine, isuprel, differing in structure from epinephrine and norepinephrine and normally present in the adrenal medulla, was far more potent in its ability to evoke anxiety experimentally, and they suggested that it might be the chemical mediator in anxiety.

Selye's[49] important work in the field of stress has drawn attention to the fact that the endocrines, in particular the pituitary, play a far more significant role than had previously been realized. In his concept of the general adaptation syndrome, he has opened the way to further progress in the direction of a holistic biology. A hypothalamic-pituitary-adrenal-cortical mechanism is called into play in the organism's response particularly to prolonged stress, the stress syndrome being seen as developing in three stages—the alarm reaction, the stage of resistance, and the stage of exhaustion. While all of the body organs are involved in this process, integration of the endocrine and nervous systems is the central phenomenon. Many mechanisms have been suggested for this integration and for the integration of the acute emergency pattern and the pituitary pattern, particularly revolving around the role of adrenalin and its mode of action in this process. Gellhorn[12] (pp. 326, 328) concludes that various forms of stress lead to sympathetic adrenal discharge, with resulting consumption of the adrenal cortical hormones in the tissues. He believes that the lowered concentration of these hormones stimulates the pituitary toward increased ACTH secretion. ACTH, in turn, stimulates the secretion of adrenal cortical hormones, both gluco-corticoids and mineral corticoids, with widespread effects on tissue metabolism, including the cortex.

## ¶ Major Factors in the Etiology of the Anxiety States

### *Hereditary and Constitutional Factors*

Progress in determining factors significant for the genesis of the anxiety states has been impeded by emphasis on monistic etiology. It is now recognized that many factors are involved in a complex interaction, and, as less energy is wasted on the nature versus nurture polemic, there is increasing interest in determining how the many elements subsumed under these headings unite in the process of healthy and neurotic growth.

Kallmann[24] notes that "current information about verified inheritance factors is least complete in the vast area of psychoneurotic traits, where representative twin data are most difficult to secure and few genetic questions have been fully answered." Gerard's[14] view that neurosis may result "more from unfortunate

Downloaded from www.dbraulibrary.org.in

relations of the individual to his environment than to his ancestors" remains widely held. Hoch[19] notes the paucity of references to constitutional factors in the studies of the anxiety states and adds that "those engaged in constitutional research have failed to translate the term 'constitution' into reality." Matte-Blanco[39] has attempted to do so in an extension of Sheldon's theories concerning basic temperament and the somatotypes, while recognizing the importance of cultural factors. Fries[8] has suggested a classification of congenital-activity types with reference to the excitability of the newborn's neuromuscular system in response to certain stimuli. This "biological mode of adjustment" she feels to be determined in varying degrees by inheritance, factors related to intrauterine life, "body changes due to the birth process, illness, growth, stage of myelinization, emotional state and especially parents' emotional attitudes." She particularly notes the effect of this congenital-activity pattern on the parent-child relationship, the child's psychosexual and ego development, its defense mechanisms, and predisposition to pathology.

## *Cultural Factors*

The position of the cultural anthropologists and the social psychiatrists in regard to this dimension of the human being is summarized by Opler.[42]

> "Mind" is of course in one sense mental functioning, but it is also an organization of beliefs, attitudes, and mental patterns derived from social experience in a particular culture. . . . culture . . . is a concrete and ever-active set of realities in the individual. . . . If culture influences types of family organization and the social experience and role position of its carriers, its deepest reflection will occur on any and all biosocial levels as evidenced in norms of behavior and in types of psychopathology.

Reference has already been made to general factors prevailing in our culture conducive to the increase of overtly felt anxiety. They may be considered to constitute the cultural atmosphere of our time. More pertinent to our study is a consideration of factors in the culture and subculture of the individual who develops the specific syndrome of the anxiety state. It is not within the province of this chapter to deal with this problem at length, but I wish to note some of the factors which have been emphasized and which have frequently appeared in my own practice.

Redlich *et al.*[45] noted the relatively higher incidence of neurosis in the higher social levels. Seward,[50] making similar observations, particularly stressed the significance of ambivalence and status strivings in the family environment of middle-class individuals. Here there tends to be great emphasis on parental love of the child, with overprotection and smothering, often actually a considerable pretense of love behind which lurk feelings of rejection and hostility, and undermining attitudes toward the child. In such an environment the child has difficulty adopting a consistent way of coping, particularly since friction with parents and siblings is taboo, and open expression of hostility is viewed as evidence of ingratitude, unlovableness, and defect in the child. Similarly, authoritarianism, with the mother often playing the dominant role as the focus of both authority and affection, tends to be rigidly, but covertly, maintained, so that rebellion is difficult. When it does occur, the usual response on the part of the parents is emotional isolation of the child, withdrawal of affection, and preference for other siblings as subtle punitive measures. Acceptance and approval are thus experienced by the child as being contingent on conformity and submission, though the verbal teachings in such an environment tend to stress independence and individualism. Striving toward higher social status tends to be powerful in this environment, and the child is viewed as an instrument for such upward movement, with acceptance and rejection the reward and penalty for the child's success or failure in this process. The attention given such children is very close but is motivated not so much by a genuine feeling for the child's needs but rather by the role he plays in the parents' striving toward superior status. Toward this

Downloaded from www.dbraum.org

end, unconscious molding of the child goes on from the moment of birth. It often includes particular ways of handling the child's body functions and body pleasures, these ways being *rigidly* adhered to in terms of the particular dominant theory for "perfect" child rearing. In this environment, whatever the surface pattern, there is considerable rejection of the child's sensual, organic, perceptual being, with great emphasis on the intellectual and conceptual aspects of being. Finally, conflicting values are an invariable component of this environment. Success is paramount at the same time that unselfishness is highly valued. Love, equality, and the brotherhood of man are stressed, and, at the same time, equal stress is placed on the importance of getting ahead, triumphing, and excelling over others. "Conspicuous consumption" clashes with a deep strain of Puritanism. The underlying hostile attitude and anticipation of hostility are often evidenced in the emphasis on living up to standards and being beyond criticism, not only for the sake of status advancement but also for the purpose of safety from the hostility of others.

### *The Traumatic Incident as an Etiologic Factor*

It has frequently been noted that the first evidence of overt anxiety may follow a particular traumatic incident in the life of the infant and child. Levy[30] found accidents and operations to be particularly frequent "first situations" precipitating anxiety reactions. He also noted the frequency of "frights, separations, sudden privations, births of siblings, and sudden environmental changes." While there is ample evidence that such events may be traumatic to the child and can produce anxiety, a simple cause-and-effect relationship between such specific events and the development of anxiety states, as defined in this chapter, cannot be established. As Levy noted, these events are part of a total constellation which includes predisposing factors related to special susceptibility in the child, constitutional and organic factors, factors related to rearing practices and home environment, and factors concerning the parent-child relationship. In my own experience it is the last factor that is most decisive in the total gestalt.

## ¶ Psychodynamics of the Neurotic Development

The basis of this presentation is the work of Karen Horney, outlined by Kelman in Chapter 71, Vol. II. In this view, evidence amply indicates that the child's main requirement for healthy personality growth is a human environment which offers him genuine love, consistent acceptance of his actual being, respect for his child status and the needs deriving from it, and a recognition that the process of growth takes the child through the various stages of healthy dependency, healthy differing from and opposing, and healthy separation from the parents as he gains a sense of his own identity in his togetherness with them and as he begins to take his place in the broader-than-family community. The neurotic development does not begin as a consequence of the frustration of a particular pregenital sexual impulse but rather as a consequence of the frustration of the child's innate striving to be itself and to grow in the ways that are natural to it, that is, the striving toward self-realization. If the child experiences his human environment predominantly in terms of overt or covert rejection, approval contingent on rigid conformity to standards; if he is loved only when he is a particular kind of child; if he is exploited, treated inconsistently, glorified in terms of his possibilities, and belittled in terms of his actual resources and needs; if dependency and submission are unconsciously fostered by overprotection; if hostility and friction are inhibited, then, self-realization is hindered. The child develops a conflicting pattern of submission and defiance, the anlage of his future neurotic conflicts. He comes to feel helpless, isolated, and afraid in a potentially hostile world. Horney has called this group of feelings the "basic anxiety" and

Downloaded from www.dbpublishers.co.in

views this deep insecurity at the core of the person's being as the starting point of the neurotic development.

Much remains to be learned concerning the possible role of constitutional factors in determining the child's vulnerability to this inimical environment and the nature of the particular devices which it adopts to cope with life in the face of its basic anxiety. At present, it appears that it is the impact of the total interpersonal milieu, in particular parental neurosis, that is the major factor determining whether the child seeks safety through compliance, aggression, or detachment. Overprotection and exploitation, as described by Martin,[35] are frequently dominant. Horney[20] (p. 222) noted the frequency with which such children grow up in the shadow of an adored parent, self-sacrificing mother, or preferred sibling. ". . . affection of a kind was attainable at a price: that of a self-subordinating devotion." In contrast to the schizophrenic (Arieti,[1] p. 59), these children do not feel hopeless about the possibility of obtaining parental love and approval.

The histories of individuals with anxiety states contain brief periods in childhood and early adolescence in which the aggressive pattern appeared, with evidence of defiance, rebellion, and attempts to control and dominate others, usually in episodic outbursts of "moving against" others. Similarly, compulsive movements away from others, detachment, with emphasis on self-sufficiency, may also briefly dominate the picture. However, these individuals soon adopt as their basic safety pattern a compulsively compliant attitude toward their human environment. Their dominant needs focus on being loved and lovable, being protected and taken care of, being inoffensive, pleasing others, avoiding all friction and conflict with others. Here the groundwork is laid for the dependent pattern and the need to repress assertive and aggressive as well as autonomous strivings. The major possibilities of anxiety come to be rejection or disapproval by others and hostile impulses from within the self. The need to be loved, particularly by the parent who is viewed as the greater threat, may come to have sexual undertones as expressions of the child's search for safety through closeness and intimacy. It must be emphasized that this pattern of rigid, compulsive, anxiety-motivated compliance is quite different from the biological dependency of the child, just as its repressed aggressive needs and detachment are equally compulsive and not to be confused with the healthy self-assertiveness and independence which are natural expressions of growth.

What is particularly significant is the extension of the child's basic anxiety which comes to pervade all of its human relationships. In the basic anxiety and in these neurotic trends, we see the first steps in the evolution of the neurotic process, the beginnings of compulsiveness, the adoption of neurotic patterns of interpersonal relationships, and, above all, a beginning alienation from the real self. As Maslow[36] (p. 42) stated, "if the only way to maintain the self is to lose others, then the ordinary child will give up the self." Safety becomes a supreme principle of life.

While compliance is the dominant solution, it must be noted that inner conflict represents a constant threat to such individuals, since the repressed patterns of aggression and detachment are themselves powerful drives seeking for expression. The threat to the individual's inner unity, produced by this basic conflict between his neurotic moves toward, against, and away from others, arises from the compulsiveness and irreconcilable nature of these defensive trends. The compliant person's orientation centers around being helpless, submissive, appeasing, lovable, good, unselfish, needing to love and be loved, and to see others as kind, generous, and nice. The aggressive individual's orientation centers around hostility, friction, struggle, and competition; with compulsive needs to control, dominate, exploit, outsmart, and excel; requiring him to be hard, tough, and realistic, and to exclude all softer feelings. The detached individual's orientation centers around his compelling need to keep emotionally distant and isolated, to be independent and self-sufficient. As a result of the disintegrating threat of basic conflict, the individual finds himself faced with the stringent necessity to adopt defensive measures for the restoration of his sense of inner unity. In

Downloaded from www.pbraulibrary.org.in

the evolution of the anxiety states, aggressive and withdrawing trends tend to be repressed, compartmentalized, unconsciously controlled, and passively externalized so that he experiences his disowned hostile and aggressive impulses in others directed against himself. Any tendency toward detachment must also be checked, because his center of gravity has come to reside in others to such a great degree, and his dominant needs require that he be emotionally as well as physically close to others.

The neurotic development up to this point may be visualized as essentially defensive in character. This stage of defensive development corresponds in general to the chronological period of childhood. It is one in which the individual is primarily concerned with finding ways to cope with others, to relieve anxiety, and to escape from conflicting orientations toward others. As the individual develops, he feels increasingly some of the major consequences of his neurotic development. As a result of the neurotic interference with the natural process of self-realization, he has been unable to develop a sense of his own identity. Each step in the neurotic development has moved him further and further from his real self—the potential source of identity, meaning, strength, autonomy, and healthy unity. He requires a solution which will not only help him to avoid experiencing his disruptive inner conflicts but will also give him some basis for existence, some sense of meaning and purpose in life, some feeling of identity and value. In a competitive society he requires also some means for coping with his feelings of inadequacy in relation to others, some means for feeling superior, some substitute for the self-confidence which he lacks. What he must have is a more comprehensive, in a certain sense a more positive and creative, solution than those previously mentioned. This solution he most commonly finds in our culture in "the search for glory" (Horney,[20] p. 17), which, with the search for safety and the search for inner unity, comes to constitute the major dynamic, unconscious motivation in his neurotic way of life. The search for glory begins with the process of self-idealization, the construction in imagination of an idealized image of absolute flawlessness, omnipotence, and omniscience. This image is in part fictional, in part an enormous exaggeration of existing assets, in part a glorification of neurotic needs. Imagination transforms the conflicting aspects of his being so that they can now be seen as harmonious parts of a godlike whole. While we readily perceive the fantastic character of grandiose delusions in schizophrenia, we do not as readily recognize the basically similar mechanism in the process of self-idealization in neurosis. This is perhaps due mainly to the fact that what the neurotic individual allows to appear on the surface so closely resembles the normal approved and admired personality of our time. It is only as we become more aware of the subtle expressions of the search for glory in the individual's dreams and fantasies, in his work, and in his human relationships that we recognize the true nature of this phenomenon and the destructive impact on the individual's life and further development. It is the intensity, the compulsiveness, the frantic quality of the individual's attempts to make this image seem real to himself and to others (that is, to actualize his idealized self) that distinguishes it from the cultural image.

In the drive toward the actualization of the idealized self, compulsive strivings for success, status, prestige as part of neurotic ambition, strivings toward vindictive triumph over others, and strivings toward perfection constitute the major elements. The first two elements are so opposed to the compliant individual's dominant orientation that they need to be kept in the background. What is in the foreground are the strivings for perfection. The compliant individual's image tends to be focused on the particular values of saintliness, unselfishness, helpfulness, goodness, inconspicuousness; on "loving and being lovable," being understanding, forgiving, and undemanding; on helplessness, suffering, and martyrdom. While he has an over-all need for perfection, it is particularly with regard to these values and qualities that he demands of himself absolute perfection, and, externalizing these demands to others, feels this is what they demand of him. To the degree that he is able to fulfill these "shoulds,"

Downloaded from www.cbsdlibrary.org.in

he experiences pride in his pseudo self, an emotion which he must, however, keep hidden. What does emerge openly are the reactions of intense humiliation, guilt, and shame when he fails to live up to these unfulfillable inner dictates. Inevitably, the process of self-glorification leads to hatred and contempt for the actual self, with its existing human limitations, and to further alienation from the real self. The hatred of self is an essential element in the dynamics of neurosis. It constitutes the major source of the individual's deep feelings of guilt and unworthiness; the merciless self-reproaches and self-accusations which constitute his neurotic conscience; his persistent unconscious need to belittle, torment, degrade, disparage, undermine, and crush the hated self. Here, too, is a new source of conflict, the intrapsychic conflict as the individual is driven toward self-aggrandizement and self-extinction. The individual whose predominant interpersonal orientation is aggression tends to "solve" this intrapsychic conflict by the solution of expansiveness, in which he identifies himself with his glorified self, the dominant value being placed on mastery of himself, of others, and of life. The predominantly detached individual will tend to deal with intrapsychic conflict by resignation, the dominant value being freedom from emotional involvement with others and with his own feelings and strivings. The predominantly compliant individual "solves" intrapsychic conflict by identifying with his despised self, the dominant value being love. While individuals whose predominant presenting orientation toward life is either mastery or resignation will be found in the anxiety states, and all three orientations are invariably present to some degree in every neurotic individual, it is my experience that, whatever the surface picture, the underlying constellation most frequently is that of the solution of self-effacement.

The central dynamic motivation in this solution is the individual's unconscious determination to eliminate himself, to vanish. In discussing healthy involvement in anxiety, I particularly emphasized the decisive role of the individual's asserting "I am" in the face of threatened self-disintegration. Here, in the neurotic individual's self-effacing solution, the basic statement is "I am not." There is an enormous taboo not only toward aggression, neurotic pride, and expansiveness, but also toward healthy self-assertion, self-respect, self-direction, spontaneity, and growth. Just as he responds with submission in relation to others, so does the individual respond submissively to his own inner dictates and to the judgment of his self-hate, which tells him he is not only weak, fragile, helpless, and impotent, but also worthless, unlovable, ridiculous, and guilty. At the same time, we must remember that neurotic pride, though it must be kept from awareness, continues to operate. On the basis of his helplessness, his suffering, and his pretenses of goodness, he feels entitled to be loved by everyone. Hostility of great intensity is frequently being generated when his hidden pride is hurt, when these special claims are not fulfilled, and as a result of his deep envy of the strength and independence of others. The increasing hostility and abused feelings threaten to conflict with his major orientation, and further repression and reinforcement of the self-effacing solution are required. Sooner or later, love may appear as a magical solution to all of his painful dilemmas. Through a symbiotic relationship with a powerful, aggressive, authority figure, he sees the possibility at one and the same time of relieving his anxiety and loneliness; finding some positive purpose and meaning in life; living through and for another individual since he has had to abandon his own being; losing his own identity in love and sex; secretly reuniting with his own consciously disowned pride, now invested through active externalization in the partner; secretly fulfilling repressed aggressive trends to control, possess, enslave, and devour through weakness and love. His orality, expressed in all areas of his being, including the sexual, is thus seen to be an expression of a fusion between passive-dependent and hostile-aggressive acquired neurotic drives. Viewed in this light, homosexual panics and the far more frequent heterosexual panics are seen to be not primarily expressions of sexual pathology but rather expressions in the sexual sphere of conflicting attitudes toward this pervasive drive to lose oneself in a morbid dependency relationship. The dynamics of the masochistic phenomena so frequently

Downloaded from www.dbraulibrary.in

noted in the anxiety states are similarly viewed.

In the light of this theory of neurotic development, the chronic apprehension in the anxiety states is seen to be an expression of the individual's unconscious and pervasive awareness of the precariousness of his equilibrium and pseudo unity, the rigidity of the entire neurotic character structure, the strain of living under impossible standards with the sword of self-contempt constantly overhead, the extreme vulnerability arising from the mythologic nature of the individual's false pride, and the pervasive helplessness at the core of his being deriving from his extreme dependency on others and alienation from himself. The acute attacks of anxiety arise when an actual threat is imminent. The endangering situation is frequently symbolic in character, hence the tendency to think that the anxiety response is inappropriate or disproportionate to the threat. When the symbolic meaning of the endangering situation for the individual is known, when we perceive the vital nature of what is at stake and what is endangered, and above all when we realize the sources and depth of the individual's feeling of weakness, the anxiety response is seen to be an entirely appropriate and proportionate one.

What is endangered in neurotic anxiety is any aspect of the infinitely complex neurotic character structure whose every element is clung to out of stringent inner necessity and has acquired great subjective value for the individual; that is, all the defenses against anxiety, the means for avoiding involvement in and awareness of conflict, and the various components of the major solutions to conflict, particularly those relating to the pride system. While this holds true for all neuroses, in the anxiety states all the aspects of the passive-compliant-dependent-self-effacing solution, which has come to be the individual's main way of coping with and orienting to life, are especially threatened. The threat may originate outside himself from anything which he perceives as disapproval, rejection, abandonment, hostility, contempt, failure, or disgrace, but it also may arise from anything which emphasizes his individuality, his value, his worth, anything which threatens his need to be anonymous, including conspicuousness, praise, recognition, and success. From within, the threat may be any impulse, healthy or neurotic, which threatens the individual's safety and moves him in the direction of conflict. Most particularly, acute anxiety appears when the individual is thrown into conflict by emerging feelings of hostility, envy, competitiveness, and the unconscious arrogance which underlie his façade; when he is caught between equally compulsive conflicting inner demands; when failure to fulfill dependent needs or inner dictates produces a massive increase of self-hate and self-contempt with a surge toward self-destructiveness; when he is vindictively "going to pieces" (Horney,[20] p. 236); when he is threatened with exposure of his pretenses of goodness and lovingness; when he is thrown back on himself and experiences his inner emptiness and deep unrelatedness. To the degree that his pride condemns it, and to the degree that our culture rejects such dependent attitudes in men and, increasingly, in women, the intensity, the irrational compulsive nature of his neurotic needs must be hidden from others as well as from himself. Acute anxiety is thus experienced not only when neurotic defenses and values are threatened but also when the real nature of these trends is exposed, whether by general life experiences or in the particular life experience of therapy. It must also be remembered that repressed drives toward mastery and resignation remain active, so that anything which threatens these solutions will, in turn, evoke anxiety.

At the center of these neurotic anxiety responses is the individual's deep and intense feeling of helplessness. Originating in the basic anxiety and constituting the center of the individual's orientation to life, this feeling of helplessness is perpetuated and increased by his progressively increasing alienation from his real self during the course of his neurotic development in which he has moved further and further from the dynamic, integrating core of his being. The most important source of this alienation is the process of self-idealization with the substitution of a pseudo self and the rejection of his own reality. A vicious cycle of crucial significance is seen to be operating here. The more alienated the individual becomes, the weaker grows his ability to cope

Downloaded from www.dbraulibrary.org.in

with conflict and the more he must reinforce and rely on neurotic solutions, which, in turn, increases his alienation.

What has been outlined is a particular kind of neurotic character development most frequently seen in the anxiety states in our culture. It is important to add that in the anxiety states, perhaps more than in any other neurotic or psychotic syndrome, healthy growth has taken place. To the picture of an anxious individual apprehensively coping with life in the face of inner and outer dangers must also be added the picture of a human being with courage, able to endure this much anxiety without the more massive defenses and character distortions which characterize the other psychiatric syndromes.

## ¶ Differential Diagnosis

Overt anxiety is not pathognomonic of the anxiety states. Attacks of anxiety occur in phobic, conversion, psychosomatic, and psychopathic disorders, as well as in more or less healthy individuals under overwhelming stress. The schizophrenic and the manic-depressive, as well as the more organically based personality reactions, all have greater or lesser degrees of overt anxiety. Masserman[37] (p. 127) draws attention to a whole host of organic conditions whose symptoms may simulate aspects of the anxiety syndrome. These include cardiac disturbances; hyperthyroidism; hypoglycemia; carotid sinus hyperirritability; diffuse central-nervous-system diseases; lesions involving the cerebellum, semicircular canals, and the vicinity of the diencephalon; Benzedrine and caffeine intoxication; endocrine dyscrasias; and hysterical tetany. Careful examination will establish the diagnosis. It must be remembered, however, that organic conditions and anxiety states may coexist.

## ¶ Prevention and Therapy

Implicit in what has been written about the cultural and familial determinants of the anxiety states are the conditions for its prevention. The evolution of a more stable and consistent social structure, which emphasizes individual growth rather than the "market value" of the individual (Fromm,[9] p. 69), will reduce the number of anxiety states. A human environment in which the individual receives genuine acceptance and respect will further his healthy development and self-realization. As May[40] (p. 89) and others have noted, the goal is not the prevention of anxiety. As defined earlier, the anxiety response is inherent in our being living organisms and arises inevitably as the individual meets the challenges and shocks of existence (Goldstein,[17] p. 306). The endeavor must be to create conditions which will enable the individual to have less neurotic anxiety and to increase his capacity to experience fully, to live creatively, and to grow through the experience of normal anxiety.

Treatment of the anxiety states may be divided into measures aiming primarily at the relief of anxiety and those whose goal is a change in the basic character structure. Measures for the relief of anxiety currently being used are the various drug therapies, physiotherapy, hydrotherapy, occupational therapy, the shock therapies, carbon dioxide inhalation, and the various psychosurgical procedures. While all of these measures have demonstrated effectiveness in lessening the experienced anxiety,[32] the use of the shock therapies and psychosurgical procedures appears to constitute an admission of therapeutic hopelessness and failure. In my opinion, they are not indicated even in the symptomatic therapy of the anxiety states. Acute anxiety and panic reactions will require emergency treatment at times. The indications and drawbacks of the barbiturates are long familiar. More recently, the autonomic suppressants (such as Thorazine, etc.) acting on the hypothalamus, and meprobamate (Miltown, etc.) acting primarily on the thalamus,[44] have been widely used for the relief of anxiety. Complications of the former drugs—agranulocytosis, jaundice, parkinsonism, depression, etc., have led to increasing caution in their use. Meprobamate therapy, while free from these major complications, lends itself to indiscriminate use. As Dickel and Dixon[4] have noted in an extensive study, the danger of indiscriminate use of the tranquilizing drugs includes not only the physical complications but, perhaps more important,

Downloaded from www.jnjaimay.org.in

the effect on physicians and patients alike of the failure to realize that tension and anxiety are important elements in living and in "the shaping of progress."

These various symptomatic measures are used together with a host of psychotherapeutic devices designed to remove the sources of pressure and stress, lessen tension, and restore the patient's equilibrium by strengthening his neurotic defenses, including intellectualization and control. These measures include environmental manipulation; reassurance and education, particularly concerning the fear of insanity and of organic illness produced by the autonomic phenomena; suggestion; emotional catharsis; and desensitization. Here the therapist's role is that of a benevolent authority who serves as an anchor in a world which seems to the patient to be disintegrating. The therapist's ability to convey to the patient, through nonverbal as well as verbal means, his sympathetic acceptance of the reality of the patient's suffering (though he is not caught up in the uses to which the patient puts his compulsive need to suffer); his refusal to view the experience as catastrophic; his ability often to protect the patient from his own self destructiveness—these are among the psychotherapeutic approaches which may help relieve the intensity of the patient's anxiety and suffering.

On a somewhat deeper level are the psychotherapies which Wolberg[58] (p. 8) classifies under the heading "Insight therapy with reeducative goals." Here the primary objectives are "Insight into the more conscious conflicts with deliberate efforts at readjustment, goal modification, and the living up to existing creative potentialities." Here the appeal is chiefly to the patient's rationality, as the therapist helps him recognize some irrational aspects of his unreasonable demands on himself and what he feels others demand of him as the price of his acceptability. The insight gained into some of his gross distortions in perception can be very helpful in lessening anxiety and the intensity of inner conflict.

The deep therapies, of which psychoanalysis is the prototype, have as their primary goal a basic change in character. Where such therapy is available for the individual and where he is available for such therapy, it is the treatment of choice. The specific nature of the depth therapy employed will depend on the particular theory of human motivation and neurotic development with which the therapist is working. In holistic psychoanalysis, based on Horney's work (see Chap. 71, Vol. *II*), the method involves analysis of the total character structure as it finds expression in the dimensions of past, present, and future; in the individual's interpersonal relationships, particularly the analytic relationship; in his relationship to himself and to the world at large; in his unconscious as well as conscious living; in his organic and perceptual as well as intellectual and conceptual being; in his dreams and fantasies as well as in his behavior. The aim is to help the individual become increasingly aware of and able to own, experience, and be involved in his whole being, including his inner conflicts. Through the strength gained in this process of increasing awareness, and particularly as the patient experiences the reality of his neurotic patterns in the analytic relationship, alienation and basic anxiety diminish, neurotic trends weaken, neurotic defenses against anxiety and solutions to conflict —particularly the striving toward self-idealization—can be gradually relinquished to a considerable degree. The goal is a reorientation of values as the individual is increasingly able to take responsibility for himself; increasingly capable of genuine mutuality in his interpersonal relationships; increasingly able to recognize his own individuality, tap his constructive potentialities, and accept his human limitations and his natural interdependency with others. The goal is self-realization (Horney,[20] p. 364).

The outcome of therapy is generally favorable. It depends on the severity of the underlying pathology, the amount of healthy growth which has taken place, and the therapist's belief in and ability to help the patient reach his innate constructiveness.

CHAPTER 17

# OBSESSIVE BEHAVIOR

## So-called Obsessive-Compulsive Neurosis

Sandor Rado

Downloaded from www.dbraulibrary.org.in

THE FIRST PSYCHIATRIC OBSERVATIONS on obsessive behavior date from the 1860's,[24] but it was not until after the turn of the century that Freud opened the way to a deeper understanding of this disorder and its recognition as a well-defined clinical entity.* His classical description of the clinical picture, published in 1917,[12] follows:

The obsessional neurosis takes this form: the patient's mind is occupied with thoughts that do not really interest him, he feels impulses which seem alien to him, and he is impelled to perform actions which not only afford him no pleasure but from which he is powerless to desist. The thoughts (obsessions) may be meaningless in themselves or only of no interest to the patient; they are often absolutely silly; in every case they are the starting-point of a strained concentration of thought which exhausts the patient and to which he yields most unwillingly. Against his will he has to worry and speculate as if it were a matter of life or death to him. The impulses which he perceives within him may seem to be of an equally childish and meaningless character; mostly, however, they consist of something terrifying, such as temptations to commit serious crimes, so that the patient not only repudiates them as alien, but flees from them in horror, and guards himself by prohibitions, precautions, and restrictions against the possibility of carrying them out. As a matter of fact he never literally, not even once, carries these impulses into effect; flight and precautions invariably win. What he does really commit are very harmless, certainly trivial acts—what are termed the obsessive actions—which are mostly repetitions and ceremonial elaborations of ordinary every-day performances, making these common necessary actions—going to bed, washing, dressing, going for walks, etc.—into highly laborious tasks of almost insuperable difficulty. The morbid ideas, impulses and actions are not by any means combined in the same proportions in individual types and cases of the obsessional neurosis; on the

* Freud, like Kraepelin before him, called this entity *Zwangsneurose;* by way of different translations, *Zwang* became "obsession" in London and "compulsion" in New York. Subsequent authors, apparently unaware of this fact and eager to ascertain what is meant by "obsessive" and what by "compulsive," settled for the unhappy designation "obsessive-compulsive." The "standard edition" of Freud's work, published recently in London, abides by rendering *Zwangsneurose* as "obsessional neurosis"; hence my term "obsessive behavior."

contrary, the rule is that one or another of these manifestations dominates the picture and gives the disease its name; but what is common to all forms of it is unmistakable enough.

. . . he [the patient] can displace and he can exchange; instead of one silly idea he can adopt another of a slightly milder character, instead of one ceremonial rite he can perform another. He can displace his sense of compulsion, but he cannot dispel it. This capacity for displacing all the symptoms, involving radical alteration of their original forms, is a main characteristic of the disease; it is, moreover, striking that in this condition the "*opposite-values*" (polarities) pervading mental life appear to be exceptionally sharply differentiated. In addition to compulsions of both positive and negative character, doubt appears in the intellectual sphere, gradually spreading until it gnaws even at what is usually held to be certain. All these things combine to bring about an ever-increasing indecisiveness, loss of energy, and curtailment of freedom; and that although the obsessional neurotic is originally always a person of a very energetic disposition, often highly opinionated, and as a rule intellectually gifted above the average. He has usually attained to an agreeable high standard of ethical development, is overconscientious, and more than usually correct.

## ¶ Clinical Picture

The designation "obsessive behavior" will be applied to patients who have obsessive attacks and obsessive traits. For convenience, I shall subdivide obsessive attacks into spells of doubting and brooding, bouts of ritual making, and fits of horrific temptation. In time, the form of attacks may shift from one to the other. They may be mild or severe, last half an hour, an hour, or longer; may be quiescent for a while or occur many times a day. Obsessive traits, however, once evolved, do not change significantly. I shall describe and illustrate first the three forms of attacks, and then the traits.

Spells of doubting and brooding may be described as a swinging back and forth between the same set of pros and the same set of cons without being able to reach a decision. They are thought activities that tend to defeat the purpose of thinking. Doubt may invade a belief, proposition, observation, or recollection, spreading from one to the other. The patient can trust neither his memory nor the testimony of his own eyes. Upon leaving home, he may feel forced to rush back to make sure that he turned off the light or locked a certain door, eventually repeating this "making sure" trip several times; or, upon sealing an envelope, he may have to open it over and over again to reassure himself that he has signed the enclosed check, etc.

In his bouts of ritual making, the patient repetitively executes a sequence of motor acts. Most often these sequences are ceremonial and distortive elaborations of some routine of daily life, such as going to bed, getting up, taking a bath, dressing and undressing, settling down to work or finishing work. They may, however, also be composed of out-of-place or apparently nonsensical motor acts. Repetition of the sequence tends to be continued until the patient is exhausted.

The term "ritual making" includes obsessive hand washing, washing or cleansing of pieces of wearing apparel or other objects of daily use, as if they had been soiled or somehow contaminated; the obsession to count (for example, the number of parked cars), to touch (for example, every lamppost on the street), or, on the contrary, to avoid touching certain objects (for example, doorknobs), or to step on or avoid stepping on certain spots (for example, the pavement cracks) and the like; ceremonial and stereotyped elaborations of sexual performance, in particular, of its "before" and "after" phases; of the patient's table manners and eating habits; of his toilet habits; of the way he makes and keeps social engagements, parts with money, makes purchases or presents gifts, etc.

In his "fits of horrific temptation" the patient, suddenly beset by the urge or idea to kill someone (characteristically a close and beloved relative), shrinks back in horror from a temptation so alien to his entire being.

Turning to the obsessive traits, we observe that the patient is overconscientious in his own particular way. What he is mostly concerned about are the minutiae, the inconsequential details, the meticulous observance of

Downloaded from www.dbraum.com

minor rules and petty formalities. Specializing as he does in trifles, he is always in danger of missing the essentials. Similarly, his orderliness tends to be excessive and inappropriate, costing valuable time and effort; in his life, the clock is a menace. He may, for instance, keep papers on file that should be discarded and save or record matters of little or no importance. Upon arriving at his office, he may spend hours putting his desk in "order," arranging utensils and papers; turning at last to his job, he is capable of making important decisions hurriedly, without qualms. A scientist, though never noticing that his shoelaces were untied, was so meticulous in his literary documentation that his colleagues dubbed him a footnote fetishist. A patient recorded all his railroad travels from grammar school to high school, listing all the station stops, even when repeating the same trip. Another had his secretary keep a pyramid of indexes to his private files —a regular index, an ever-growing series of cross indexes, and an index of the indexes. Regardless of how rushed he may have been, whenever he consulted the files himself, he had to take time out to see whether the item concerned was indexed to perfection. Another, the product of a Victorian upbringing, from adolescence on kept a meticulous record in secret signs about his orgasms and failures—long before Kinsey and without the latter's point of view. Another, so instructed by his equally obsessive mother who always worried that he might catch cold, kept his supply of socks in the drawer in carefully separated piles marked "heavy," "light heavy," "heavy light," and "light."

A rough sketch of the obsessive patient would depict him as highly opinionated and proud of his superior intelligence, avowed rationality, keen sense of reality, and "unswerving integrity." He may indeed be an honest man, but he may also turn out to be a sanctimonious hypocrite. He is the ultimate perfectionist. While very sensitive to his own hurt, he may, at the same time, be destructively critical, spiteful, vindictive, and given to bitter irony and to bearing grudges in trivial matters. Or, on the contrary, he may be overcautious, bent on avoiding any possibility of conflict. His "common sense" militates against what he views as fancies of the imagination: he is a "man of facts," not of fancies. He smiles condescendingly at people who are fascinated by mysticism, including "the unconscious" and dreams, but let him undergo some psychoanalytic treatment of the classical type, and he will switch to attributing oracular significance to slips of the tongue or the pen. As a "man of reason" he cannot admit even to himself that he is superstitious. His interest in fine arts is slight or pretended; his true admiration is reserved for mathematics, the exact sciences, technology, the new world of electronic computing machines. In contrast to the expressional (so-called hysterical) type, he rarely has artistic gifts and conspicuously lacks genuine charm and grace. His amatory interests are laden with ulterior motivations and pretense. His envy of a successful rival—in work, for example—may carry him to dangerous lengths: if the opportunity arises, he may subtly cut the man's throat—a token of his admiration and respect. This sort of thing is usually termed "ambivalence"—a term itself in need of clarification. Finally, the obsessive patient is almost never completely free from tension and irritability, though in general the degree of these characteristics fluctuates from slight to severe.

## ¶ Pathology

I shall preface this discussion of the pathology of obsessive behavior with brief statements on methodology and adaptational psychodynamics. The latter, a revised system of psychoanalytic thought, is our chief conceptual tool.

### *Methodology*

In all branches of medicine, inquiry into the nature and causes of disorder begins with examination of the clinical picture, continues as a search for the underlying pathological processes (changes in the organism's structure and function), and culminates in the disclosure of that specific constellation of influences which has brought them about. The pathologist, like all human biologists, must,

Downloaded from www.dbraulibrary.org.in

of necessity, use introspective as well as inspective procedures, for these two approaches to the human organism are irreducible yet complementary to each other. He must also realize that it is the hereditary basis of the actual organism which determines, from conception to death, its mode of interaction with its changing environment. The geneticist calls the actual organism the phenotype, its hereditary basis—the cause of its development—the genotype. From womb and nourishing mother, environment gradually widens to include family, school, community, and mankind at large. Psychodynamics, the science dealing chiefly with the part played in behavior by systems of motivation and control, views behavior as the biological organism's interaction with its cultural environment, the society in which it lives. In time, psychodynamics will be flanked with disciplines ranging from physiological to sociological psychodynamics.

In general, the comprehensive pathology of disorder must be visualized as the integrated whole of its psychodynamics, physiodynamics, and genetics. In the pathology of many behavior disorders, we must depend almost exclusively on psychodynamic investigation, for the physiodynamics and genetics of these disorders are undeveloped.

## *Adaptational Psychodynamics*

All true psychodynamics is based on Freud's investigative method, his pioneering clinical findings and points of view. After publication in 1900 of his masterpiece *The Interpretation of Dreams*,[15] however, Freud's theoretical development did not, and could not, keep pace with the growth of his empirical insights. He became increasingly speculative, enamored of explanatory concepts which he himself admitted were "superbly indefinite" and remote.[16] This was the outcome of a drastic decision he had made back in the mid-1880's. At that time, frustrated by the unfriendly reception given his early work by the coriphaei of medicine in Vienna, he retreated into an almost complete scientific isolation from which he never emerged. Out of touch with progress in the biological and cultural sciences, in the twentieth century he was creating nineteenth-century theories—revitalized by a generous infusion of golden Greek philosophy. Despite their captivating artistic beauty, these theories could not, and did not, bear scientific fruit.

Adaptational psychodynamics has evolved a conceptual scheme that remains close to the empirical subject matter of psychoanalysis, meanwhile developing a descriptive language bent on conveying the most information in the fewest words. Here we can sketch only some of its features, contrasting them for the sake of clarity with those of Freud's now-classical system.

The organism seeks to fit its needs to its environment, and its environment to its needs. The first process is called autoplastic adaptation; the second, alloplastic adaptation.[8] Exploration of the adaptive value of the organism's behavior is of overriding importance, since whatever the organism does may work for it or against it. While all behavior may be viewed as the effect of underlying causes, not all behavior can be classified as goal-directed. Our chief concern is goal-directed behavior,* in which, moving from desire to fulfillment, the organism analyzes experience into cause and effect in order to find the means that will lead to the ends it desires.

Freud's elucidation of behavior traced it to instincts, which he thought were composed in varying proportions of the same two conflicting elements: Eros' divine lust to live, and living matter's dark and nostalgic longing to die (revert to the inanimate state). The forces of the former were libidinal; those of the latter self-destructive or, when turned outward, destructive. Despite our sincere admiration of this poetic idea, in our still-young clinical discipline we are obligated to trace behavior to empirically ascertainable motives and motivating systems. Freud attributed irrational thought to the influence of instincts, with emotions implied; we attribute irrational thought

* The properties of so-called goal fields were examined by Kurt Lewin[27] and Thomas M. French[9]; the significance of now so-called feedback in goal-directed behavior was first recognized by Julius Pikler,[29] and, in the last decades, brilliantly explored by Norbert Wiener[52] and his cybernetic school. Chances for establishing physiological correlations in goal-directed behavior have been first opened up through L. von Bertalanffy's "organismic" conception of biology.[2]

Downloaded from www.dtic.mil

to the influence of emotions, with nothing implied but the organism which has them. We place emotions in the forefront of investigative interest.

On grounds of hedonic derivation and motivating action, emotions are divided into two classes: emergency emotions, such as fear, rage, guilty fear, and guilty rage, based on present pain or the anticipation of pain, and welfare emotions, such as pleasurable desire, joy, affection, love, and pride, based on present pleasure or the anticipation of pleasure.

Freud's structural theory envisaged a "mental apparatus" composed of super-ego, described as internalization of the demanding father; id, from the description given, recognizable as unwitting internalization of a seductive mother; and ego, described as mediator between the super-ego, the id, and the outer world.[11] The arrangement recalls the traditional imagery of earth placed between heaven and hell. Super-ego, id, and ego are artistic personifications of conscience, passion, and adaptive common sense.[40]

I have introduced the concept of a "psychodynamic cerebral system" which includes a hierarchically organized "integrative apparatus."[31, 34, 38, 40, 42, 47] This apparatus is composed of four evolutionary levels connected by a common stem. The latter, called the action self, is the supreme unit of the entire apparatus, controlling activity at each of its four levels. It may be described as the organism's systemic picture of itself, derived from the information it receives about its own activities by means of its sensory equipment. If, as Sherrington thought,[51] mind develops as manager of muscle, it is fitting that the action self should arise from kinesthetic (proprioceptive) information. In our mammalian species, presumably it is the infant's sucking at the mother's breast, his most forceful and pleasurable activity, that first engenders in him, in an unfathomable manner, an awareness of self: "I am the one who sucks." This hypothesis, derived from psychoanalytic observation, is splendidly supported by William James's self-observation aimed at discovering the site and quality of the feeling of self. "*When carefully examined,*" he stated, "*the self is found to consist mainly of the collection of these peculiar* [bodily] *motions in the head or between the head and the throat*" [James's italics].[20] Thus, from its kinesthetic reports arises the organism's circular pattern of self-awareness and willed action. This is then complemented by information arriving through haptic, olfactory, acoustic, optic and other sensory channels, including the comments on its performance which the organism receives in its communicative exchange with its human environment. The action self's outward expression is cultural self-realization, fulfillment of the organism's desire to have its own way.

At the phylogenetically oldest level, hedonic self-regulation is established: moving toward the source of pleasure and away from the cause of pain, the organism seeks to repeat pleasurable experiences and to avoid repeating painful ones.[34] During the process of maturation, however, experience forces it to accept delayed reward in lieu of immediate reward.

At the next three levels, behavior is integrated by means of increasingly higher order —preverbal brute emotion, emotional thought, and unemotional (impartial) thought, respectively. Emotional thought is strongly biased, feeding the emotion from which it springs and by which it is controlled. Its ubiquitous conflicts with rational thought make its exploration a major task of psychiatry.

The socially crucial function whose traditional name is conscience develops during childhood in the situation of parental dependence.[31, 34, 35, 40] Its essential mechanisms perform the tasks of self-examination, self-prodding through self-reward (self-respect and moral pride), self-restraint through fear of inescapable punishment, and repair through expiatory self-punishment. These mechanisms develop through anticipation of parental criticism, parental reward (bestowing of pleasure), and parental punishment (inflicting of pain), through the gradual automatization of these anticipatory acts and the use of parental behavior as a model for emulation. True to its adaptive purpose, healthy conscience effects moral self-restraint and promotes peaceful cooperation and cultural achievement by means of self-reward. It is a beautiful example of autoplastic adaptation. The appearance of automatized mechanisms of expiatory self-

Downloaded from www.sahibinden.com

punishment in its organization signifies pathological developments.

The nervous activity of the brain is in part reporting, in part nonreporting.[34,41] Reporting brain activity produces the state and contents of consciousness; hence, we speak of the brain-physiological reporting process, and the corresponding psychodynamic awareness process, or stream of consciousness; we arrive at the former concept when viewing the organism from without (inspection) and at the latter when viewing it from within (introspection). A gross correlation is better than none. Therefore, in the sense of Spinoza we assume that the physiological reporting process and the psychodynamic awareness process are synchronous and congruent; they depict but two aspects of the same reality—one in the language and conceptual scheme of inspection, and the other, of introspection. The terms of the former are reducible to measurement by yardstick and clock; those of the latter are not. In my opinion the overdue construction of a logically consistent and truly complementary theory of the human organism can make no substantial progress without first exploring—in particular, from the linguistic angle—the profound differences between these two conceptual schemes.

Most of the brain's activity is purely physiological; thus, from the psychodynamic point of view, it is nonreporting; yet it profoundly influences behavior, and its motivational significance may, to some extent, be inferred from the contents of consciousness. In making such inferences, we interpret purely physiological brain activity in an extrapolated language of psychodynamics. We thus speak of nonreporting thoughts, feelings, tensions, intentions, and, in general, of nonreporting processes.

The concept of a "psychodynamic cerebral system" thus embraces (1) the reporting range of the brain's nervous activity in both its psychodynamic and physiodynamic aspects, and (2) that range of nonreporting brain activity which is nonetheless accessible to "extrapolative" investigation by psychodynamic methods as well as to ordinary investigation by physiological methods. If (1) is called mind, then (2) may be called the "inferred mind." "The unconscious" was never related to brain activity. Originally the cornerstone of Freud's work, it has since become a phantom, a prolific source of obscurantist thought.

Integrative activity may have both conscious and nonreporting phases and may involve more than one level of the apparatus.

Memories stored in the inferred mind—in nonreporting brain activity—are either on recall or are excluded from recall by the action of precautionary mechanisms constituting the "pain barrier" and the "social pain guard."[38] Working to avoid pain, these mechanisms also prevent unwelcome feelings and intentions from rising into consciousness. The most powerful precautionary mechanism is known as repression.

It was Freud's epochal feat to explore the patient in a controlled emotional situation that enabled him to relax his precautionary mechanisms; in this situation, expecting to be helped by the procedure, the patient could reproduce and express freely an abundance of heretofore repressed feelings and thoughts.[33] This process of communicated introspection is the essence of the psychoanalytic technique of investigation. Adaptational psychodynamics is based chiefly on information gathered with this technique.

## *The Dynamics of Obsessive Behavior*

We are now prepared to turn to the pathology of obsessive behavior. Overreactive disorders arise from the organism's inability to handle danger situations effectively by its available means of emergency control: in this event, instead of acting as signals, its emergency emotions themselves inflict, or threaten to inflict, damage upon the organism. Thus, in the face of an external danger, far from increasing the organism's efficiency, they come to disorder its systemic operations, adding trouble within to the trouble without. We call this development "emergency dyscontrol." It begins in childhood with the parents' prohibitive measures, their punishments and threats of punishment. The disorder so created may continue or may flare up again in later life. It is then complicated by the consequences of the organism's own miscarried repair work which always includes unnecessary

Digitized by Arya Samaj Foundation Chennai and eGangotri www.ubaalibrary.org.in

inhibitions and a reactivation of the long since out-dated adaptive pattern of infantile dependence. Obsessive behavior is a subdivision of the class of overreactive disorders.

In Freud's view, all neuroses originate in childhood, from conflicts between the child and his parents. Dependent upon loving parental care, the child is, at the same time, subject to parental discipline. Though the conflict and its consequences become repressed, they may nonetheless disturb the patient's development and produce his neurosis.[12] These findings, now widely recognized, are embodied in adaptational psychodynamics. As regards the specific etiology of obsessive neurosis, Freud held that the patient's development was to some extent arrested and thrown back to an earlier stage. The patient's "genital level" was weakened by "fixation" at the previous level; his regression to that level, at which the child's life was dominated by "anal-erotic and sado-masochistic impulses," was considered the key to his obsessive neurosis.[11,12,14,17,21]

Freud's theory calls attention to the processes of bowel training. The child must be helped to bring evacuation under voluntary control. However, bowel control presupposes maturation of the requisite neuromuscular apparatus. If the mother is overambitious, demanding, and impatient, and if the child is marked by a particular combination of characteristics, then the stage is set for the battle of the chamber pot.

Irritated by the mother's interference with his bowel clock, the child responds to her entreaties with enraged defiance, to her punishments and threats of punishment with fearful obedience. The battle is a seesaw, and the mother, to fortify her position, makes the disobedient child feel guilty, undergo deserved punishment, and ask forgiveness. This indoctrination transforms the child's fear into guilty fear, and impresses upon him the reparative procedure of expiatory behavior. The mother-child conflict provokes in the child a struggle between his own guilty fear and his own defiant rage. It is a characteristic of the type of child under consideration that his guilty fear is always somewhat stronger; sooner or later, it represses his defiant rage. Henceforth, his relationship to the mother, and soon to the father, will be determined by this motivating system: *guilty fear over defiant rage* or, *obedience* versus *defiance*. The severity of the conflict, sustained by the inordinate and unrelenting strength of fear and rage, perpetuates this outcome. In our view, with the establishment of this motivating system, the child acquires a crucial factor toward a predisposition to obsessive behavior.

Freud's theory of obsessional neurosis features a "sadistic super-ego" and a "masochistic ego,"[11,14] a dramatization unquestionably inspired by observations similar to the ones from which our interpretation derived. Thus, our interpretation is a development of Freud's early insight. On the other hand, his emphasis on the destinies of evacuative pleasure, their significance in the causation of obsessive behavior, is refuted by clinical experience. He assumed that bowel obedience forces the child to relinquish evacuative pleasure by "sublimating" the desire for it or by stemming its tide by "reaction-formations." These developments were then reflected in the shaping of obsessive symptoms. Bowel defiance, he thought, increases the child's evacuative pleasure. The fact is, however, that children forced into bowel obedience enjoy the evacuative act just as heartily as other children, whereas bowel defiance is often enough strengthened by the intent to avoid an act rendered painful by an anal fissure or some other local disturbance. With her insistence on bowel regularity, the mother hurts not the child's evacuative pleasure but his pride in having his own way. Furthermore, one sees obsessive patients whose bowel training has been uneventful, but they are nonetheless marked by the same severe conflict between guilty fear and defiant rage; it originated in other behavior areas. The future obsessive patient's emphatic obedience and stubborn defiance, far from being limited to his bowel responses as a child, are spread over his entire behavior.*

The pathological development of conscience is directly traceable to the unusual strength of two presumably inherited traits, hopelessly at variance with each other. One is the child's

* The manifestations of defiance were meticulously investigated by David Levy who speaks of them as "oppositional behavior."[25]

Downloaded from www.pbookshop.com

craving for autonomous self-realization, a derivative of his primordial belief in his own omnipotence that drives him to reshape the world about him in his own image, which may also be described as a strong bent for alloplastic adaptation. The other trait is his rationalism, his realistic foresight that forces him to take no chances when it comes to preserving the parent's loving care. In adult life this trait is manifested as a strong desire to be treated by one's social environment as an admiring parent treats a favorite child. Since, however, the parents insist on obedience, and later, society on adherence to its laws and mores, the organism so constituted will eventually do its utmost to conform.

That a child is born to stubborn and tenacious self-assertion may be surmised from the inordinate strength of his rage. This provokes the parents into severe retaliatory measures which, in turn, elicit his defiant rage and even stronger fears. He is thus forced to move with undue haste from ordinary fear of punishment contingent upon detection to fear of conscience, that is, fear of inescapable punishment, and then to guilty fear and the reparative pattern of expiatory self-punishment. Automatization at such an early stage makes these mechanisms overstrong as well as rigid. Healthy conscience fulfills its adaptive function smoothly; it has little need for guilty fear and the reparative work of repentance. But with early automatization, conscience grows into an organization dominated not by the healthy mechanisms of self-reward but by the morbid mechanisms of expiatory self-punishment. The latter are morbid because they are automatized operations not of, but in, the patient; he does not initiate them, nor is he or his environment aware of their meaning; he is aware of only the damaging effects these nonreporting processes inflict upon him. A conscience so constituted will diminish rather than increase the organism's capacity for happiness. It is an example not of autoplastic adaptation but of autoplastic maladaptation.

A closer look at these developments is indicated. Endangered by its rage, and forced to control it, the organism does not rely on merely repressing it; through accumulation, repressed rage may, indeed, reach the point of explosive discharge. To forestall this possibility, as its next precautionary move, the organism turns the larger part of its repressed rage against itself, or, more precisely, against the rest of its repressed rage—the strategy of defeating the enemy with the help of its deserters. The retroflexion is achieved by assimilating repressed rage with the now-prevailing mood of repentance. This explains the clinical fact that the child's (and later the adult's) self-reproaches may far exceed in vehemence the reproaches his parents ever leveled against him, and that his self-punishments may be far more severe than were his parents' threats. The strength of these mechanisms of self-control is determined not by the actual attitude taken by the parents but by the strength of the child's own retroflexed rage.

Fear of conscience and its derivative, guilty fear, rest on the belief in inescapable punishment. This belief cannot stem from experience. The child knows he was punished only when caught. Nor can religious indoctrination be its ultimate source, for it flourishes in agnostic patients as well.

The chain of psychodynamic inferences leads us back to the infant. Elated by the success of his early muscular activities, the infant pictures himself as an omnipotent being. The hard facts force this grand illusion to recede slowly into the range of nonreporting processes. Sensing that his beloved omnipotence is about to evaporate, the child fancies that he has merely delegated it to his parents: they exercise *his* magic powers *for* him. He is then terrified to discover that the parents can turn *his* omnipotence *against* him; he has *no* way of telling what they can now do to him. The dread of inescapable punishment, appearing within his fear of conscience and within his guilty fear, is basically a dread of his own omnipotence, which he now feels the parents can cause to work in reverse. It is powerful enough to retroflex the bulk of his repressed rage. We must assume that stronger-than-average residues of primordial omnipotence are a factor in the predisposition to obsessive behavior.

In the healthy individual, the supreme pleasure of genital orgasm gives rise to a host of affectionate desires, which soften rage by their

Downloaded from www.libtool.com.cn

counterbalancing effect. In the obsessive patient, in whom the pleasure of genital orgasm is seen to be comparatively weak, these derivative motivations are enfeebled, without power to soften rage; the job must be done, and is being done, by conscience alone.

One must assume that a shortage of sexual love is genetically determined; in any case, we consider this deficiency a factor in the predisposition to obsessive behavior. It may well be that, genetically, it is linked with the innate strength of rage.

The early rigidity of conscience vitiates its adjustment to the conditions of adult existence. One must qualify the oft-repeated statement that the obsessive patient is overconscientious: he is that chiefly, if not only, in the areas of infantile discipline. His silly excesses in cleanliness, orderliness, regularity, and punctuality show that his conscience still operates in the world of the nursery—ruled most often by an obsessive mother.

Some twenty-five years ago, listening to the jeremiad of a torturous and self-tortured patient, the idea struck me that his obsessive attacks derived from the rage attacks of his childhood.[39] This discovery, abundantly corroborated by subsequent experience, sparked the entire investigation here presented.

In a temper tantrum the discharge of rage is explosive. In an obsessive attack we see the organism struggling with the imperative task of ridding itself of its morbid tensions. Here the discharge of rage, continuously interrupted by counterdischarges of guilty fear, is extremely slow and always incomplete.

The dynamic structure of such attacks is best seen in a simple bout of obsessive ritual making. Here, driven by his tension, the patient performs a sequence of two motor acts and then goes on repeating this same sequence over again. For example, going to bed, he places his shoes on the floor first at right angle, then side by side; then again at right angle, then side by side again, etc. Analysis shows that both acts are symbolic. One expresses the intent of defiant rage to carry out a prohibited desire; the other, the opposite intent of guilty fear. Consequently, one act achieves a fragmentary discharge of morbid rage tension; the other, of morbid fear tension. Repetition of the sequence is continued until tension is somewhat reduced and the patient is exhausted. In its entirety, the process is a mechanism for the alternating discharge of opposite tensions. We call it an interference pattern of discharge;[46] its mode of organization explains why it is so slow and torturous. If the patient tries to stop, his tension becomes so unbearable that he must yield to it and continue. In other forms of obsessive ritual making, the two opposite tensions are discharged by repeating a single act or a stereotyped series of acts; though the motor picture is different, the pattern of discharge is built on the same principle.

The interference pattern of discharge also operates in the brooding spell. Here the discharge is mediated not by seesawing motor acts but by trains of thought traveling in opposite directions. However, doubt and brooding may eventually open the door to mechanisms which are familiar to us from the nonschizophrenic form of paranoid behavior. While, as a rule, their appearance in this context is transient and their form rather rudimentary, such a development is an unwelcome complication of the obsessive picture. In these mechanisms the patient discharges not naked tensions but, in prolonged and separate phases, the full-blooded emergency emotions of guilty fear and guilty rage. Through the quasi delusions of the hypochondriac mechanism, he releases excessive guilty fear at the organismic level; through the quasi-delusional self-preoccupations of the referential mechanism, he likewise releases excessive guilty fear, but this time at the social level; on the other hand, through the quasi delusions of the persecutory mechanism, he vents, in presumed self-defense, his guilty rage.[39]

The problem of discharge in fits of horrific temptation will be considered later.

At this point the relation of full-blooded emotions to their denuded tensions must be clarified by completing our examination of the organism's repressive activities. The patient is just as unaware of his guilty fear as he is of his defiant rage. As stated before, excessive guilty fear prompts the organism to repress its slightly less excessive defiant rage. We must now add: Humiliated by its guilty fear, the organism soon represses its guilty fear as well. The out-

Download from www.brahmanjo.in

come is a tripartite motivating system: restored pride over repressed guilty fear over more strongly repressed defiant rage. In contradistinction to the brute pride that the organism takes in its self-assertive rage, we call this restored pride domesticated or moral pride; now proud of its virtuous conduct, the organism does not choose to remember that it has been forced into morality by its guilty fear of inescapable punishment.

These repressions do not, however, sufficiently control the patient's excessive, if not altogether inappropriate, emergency emotions. Though the repressive mechanism succeeds in inhibiting their characteristic feeling tone and peripheral expression, as well as the thoughts engendered by them, nevertheless the overflowing tensions of the patient's fears and rages penetrate his consciousness. Though his tension fluctuates in degree, he feels tense most of the time, complains about it, and recognizes it when it is brought to his attention. Excessive emergency emotions tax the power of the repressive mechanism. Healthy persons, too, experience naked tensions arising from an imperfectly repressed emotional turmoil, though far less frequently, but in the obsessive patient this failure is chronic and produces far more serious consequences.

Our next task is to trace the multifarious influences that contribute to the shaping of obsessive attacks and traits. The rage that filters through in an obsessive attack is the characteristic reaction to frustration. Some of the patient's present resentments repeat the ones he had experienced in childhood when his parents denied him fulfillment of his most highly valued desires. His rage was then, as it is now, his instrument for making them give in or go away. He wished they were dead. Of course, he took it for granted that when needed they would promptly return—and behave. The child's quick death-wishes, reflecting his ignorance, are not really murderous; they are only coercive, as are so many other expressions of his rage.

At first the child uses rage to force satisfaction of a particular prohibited desire. Later, as a matter of policy, he wishes to keep the parents under permanent control; they should let him have his own way and still love him. While continuing to serve other ends, the desire to dominate becomes a goal in itself. Next, the child wishes to eliminate, or at least dominate, his siblings; they must not be allowed to compete with him for the position of the favorite child. This motive produces the clinical pictures of "sibling rivalry."[26] The obsessive patient is the child who has, despite innumerable defeats, retained these attitudes for life. His ritual making and brooding perpetuate the struggle for dominance, drawing their original dramatic contents from the long-since-repressed conflict situations of his early years. This remarkable fact shows that its repressed rage glues the organism to humiliating experiences of its past. Its thirst for wiping out those humiliations takes precedence over its desire to repeat routine gratifications: triumph is a stronger self-reward than routine pride.

The child's first orgastic experience, made often by chance, awakens his desire for genital self-stimulation. This applies to boys and girls alike. The mother (father) counters the child's practice with a campaign of deterrence, threatening, among other things, punitive removal of his (her) guilty hands and of the boy's penis (Freud's "threat of castration"). He (she) is now caught in the clash between two groups of forces of almost equal strength: *prohibited sexual desire plus defiant rage* versus *fear of conscience plus guilty fear*. This is a precarious situation; to touch or not to touch is now the question. He (she) may find a mode of orgastic arousal that does not depend for its success upon touching the genital organ. He outsmarts the parents by sticking to their words. Later, he will try to circumvent, in the same manner, prohibitions of whatever kind.

If, however, guilty fear prevails and he represses his prohibited genital desire, he may switch his pleasure-seeking tendency and self-stimulatory practices to his anus, or resign and develop a tic, or go into ritual making. It is almost unbelievable to what extent the obsessive ritual may draw its basic conflicts from the now-repressed tragedies of the past. This is particularly true of the struggle, begun in childhood and resumed at puberty, to achieve the genital abstinence demanded of him.

The child may advance his forced precau-

Downloaded from www.dtic.mil/biosys.jsp

tionary moves to an earlier target point. His parents' intimacies, which he witnessed by chance if not surreptitiously, aroused him. Were it not for his parents' example, he would not have to struggle with his temptation. His effort to keep the parents sexually apart may continue under the guise of an obsessive ritual.

In passing, it should be noted that motives of this kind may produce socially valuable results rather than disorder. A brilliant electrical engineer, in his middle twenties, had more than a dozen patents to his credit. His inventions ranged over a wide variety of technologically unrelated problems. Until his treatment, he never realized that, each time, his success hinged upon preventing the formation of an electric spark. He was an only child who, as an adolescent, had managed to break up his parents' marriage; his infantile obsession to prevent them from having another child eventually besieged his scientific imagination.

The organs the obsessive patient most often uses in his ritual making are the four extremities. Their psychodynamic significance dates from the corresponding stages of neuromuscular maturation and derives from the sequence of illusions which the child develops about his newly won powers. Gorged with his success in coordination, he grandiosely overestimates the might of his hands and feet, in particular, of his trampling feet. This illusion persists in the patient's ritual making, whose procedures, as we shall see, are performed not for their physical but for their hoped-for magical effect.

Earlier, the child believes that his mouth, in particular the biting teeth, is his most powerful weapon. He will have fear-ridden dreams —as will later the adult—in which he loses his teeth; this means that he loses the magic power of his coercive rage to secure domination for him and the magic power of his sexual organ to give him orgastic satisfaction. Attempts to control the dangerous power of teeth may eventuate in their compulsive grinding in sleep. The charm may spread to saliva (compulsive spitting) and to speech. Verbal attack knows no limits when words have magic power. This is seen in the obsessive patient's resort to magic words and in the ordinary citizen's use of cursing. As we shall later see, the magic of words is also a significant component in the dynamics of stammering.

To spit, void, or defecate upon someone are the expressions used in the vernacular to signify contempt. This language usage derives from the annihilating magical effect attributed by the child to his excretions and evacuative acts. But, in the contrary emotional context of yearning for help, the same excretions are relied upon to produce a healing effect. The puzzle of their antithetical meaning and significance is solved by the simple fact that they are utilized as tools by love and hate alike. In ritual making, no nonreporting motive occurs more frequently than the fear of having been contaminated by someone's secretions or excretions, or the desire thus to contaminate someone else.

The fact that magic thought appears in the shaping of obsessive behavior was discovered at an early date by Freud and Ferenczi.[7,18] We have shown that magic's deepest root is the infant's belief in his own omnipotence, in his primordial self which we view as the nucleus of the action self. From this source derive the obsessive patient's superstitions which he is reluctant to admit even to himself.

Our theory of primordial self also explains the fact that magic is universal. In our culture its most common manifestations are our wishful or fear-ridden dreams and daydreams, the creative arts, the performing arts, the born leader's charism, etc. In emotional thought—be it lovebound, ragebound, or fearbound—the power of the wish corrects reality. To a degree, all emotional thought is magic thought. In pathology, however, the purpose for which magic is used depends upon the nature of the disorder. The obsessive disorder specializes in coercive magic; the expressional (so-called hysteric), in the performance magic of illusory fulfillment. In the former, unknown to himself, the patient seeks to break his prohibitive parent, intent on turning him into a first-class slave; in the latter, likewise unknown to himself, he materializes his adolescent dreams of drama, romance, and glory.[39]

We shall now revert to the patient's fits of horrific temptation. Though hardly more than a signal of rage below, his temptation shakes

Downloaded from www.dbtauthority.com

the patient's proud morality. His reaction of horror amounts to a voluminous discharge of guilty fear; it may take him hours to regain his composure. His groping for safeguards tends to disrupt the pattern of his routine activities; he is distracted, makes mistakes, loses himself in aimless repetitions, and does not really know where to turn.

It would be a serious mistake to surmise that the patient bursts with repressed rage. On the contrary, closer examination shows that his outward-bound rage has been almost completely retroflexed, turned upon himself; all he can do with it now is to torture himself. To be able to vent it, instead, upon the environment would be his salvation. This inspiration of despair is, indeed, the secret message that his horrific temptation to kill conveys: "I wish I were a murderer."

Extreme retroflexion of rage may be precipitated by opposite errors in education. Too harsh discipline is bound to break the child; oversolicitousness is likely to disarm him: "My parents are so nice to me, I cannot allow myself to get angry at them even when I should." A patient who suffered from the horrific temptation to kill the grandchild she loved most had been overindulged all her life.

Horrific temptation may take the form of obsessive confession, a mechanism first described by Theodor Reik.[50] Learning about a crime from the newspapers, the patient may at once be convinced that it was committed by himself. Nonreporting guilty fears may accumulate from an endless series of nonreporting temptations. To relieve such insupportable guilty fears, to secure deserved punishment and eventual forgiveness, the patient may confess to a crime he never committed. Fëdor Dostoevski, our best pathologist of conscience so far, described memorable examples of this obsession. Police chronicles literally abound with such cases.

If the patient develops a severe depression, his morbid self-accusations not infrequently refer to a beloved person whose actual wrongdoings he blames on himself. Such self-inculpatory fits have, invariably, an ironic intent.[46]

Under the accidental influences of his changing life situation, the patient may shift his doubts and broodings from one favored subject matter to another, and move the seesaw of his symbolic transgressions and repentances further and further away from the original contents of his conflict. But the motivating system responsible for these activities remains the same, showing that the obsessive attack must be understood in terms not of its dramatics but of its function of discharge.

From the model of the patient's obsessive attacks, we can readily understand his obsessive traits, for, in one way or the other, most of these permanent marks derive from the same motivating system—perpetuation of the infantile conflict between the child's overstrong tendency to self-assertive domination versus his still stronger clinging to the security of being loved and cared for. The more environment-directed rage slips through, the stronger the self-assertive aspect of his traits; and, on the contrary, the keener his rational foresight and prudence, the more prevalent will be his traits of cautious avoidance.

The patient's craving for perfection is a direct expression of his primordial almightiness; to the warning that no one can be perfect in an imperfect world, he will respond with a polite smile.

Special mention must be made of the attitude the obsessive patient displays toward the competitive aspects of life. He may be prudent enough to limit his fierce competitive efforts to his major areas of aspiration. He often professes the doctrine of fair play which calls for competitive cooperation, victory through superior performance. At the same time, not always unwittingly, he may quietly employ all the tricks of sibling rivalry, seeking to discourage if not to disqualify his most dangerous competitors from staying in the race, then rush to offer assistance to his victims. When in a slightly elated state, he may be seen competing indiscriminately for almost anything.

In the obsessive patient the manifold and widespread motivations ordinarily sustained by affection and sexual love are diminished in both strength and scope, presumably because his genital orgasm lacks the overwhelming force and pleasure it has in healthy people.

Downloaded from www.pdfbooksfree.pk

We suspect strongly that this is an innate trait. It must not be confused with the patient's capacity for sexual performance, which may be unimpaired. Unwittingly, the patient is prone to make up for his romantic impoverishment by pedantic execution of the act. He is not exactly a lover, but he is a dependable ritual maker. If an impairment of performance is present, however, its pathological mechanisms are the same as elsewhere.[32, 37] The question of sexual pain dependence will be dealt with in another context.

A few words should be added about the obsessive patient's "ambivalence." Bleuler, who coined the term in his work on schizophrenia, distinguished between intellectual, emotional, and volitional ambivalence.[3] We trace these manifestations uniformly to the severity of the underlying obedience-defiance conflict. Bleuler stressed the fact that the schizophrenic patient, like the child, tolerates the coexistence of conflicting thoughts or feelings or impulses in his consciousness. The opposite is true of the obsessive patient. While the schizophrenic patient is, or appears to be, unaware of such conflicts in him, the obsessive patient is, more often than not, only too keenly aware of them. He ponders unendingly: Must he give in, or could he gain the upper hand without giving offense? Facing the same question, the ordinary citizen makes a decision and sticks to it. But to the obsessive patient this question is a dilemma that throws him into endless broodings and keeps him engaged in countless postmortems. Since the two tendencies concerned are almost equally overstrong, he will always believe that he made the wrong decision. He could have won, why didn't he try? If he wins, he is afraid he will have to pay for it. He cannot make up his mind: Does he love his wife or does he hate her? If he loves her, why does he resent almost everything she does? And if he hates her, why does he cling to her so firmly? He is aware that his indecision is both widespread and chronic.

The obsessive patient excels in repeating the component acts of performance. Repetition enters as an organizing principle into his ritual making, brooding, and, to some extent, the entire routine of his daily life. Its origin is unmistakable. Repetition is pre-eminently the technique employed in the learning process. Whatever the child has to or wants to learn must be repeated and practiced. The point is that it is the parents who impose this maxim upon him. The defiantly obedient child, the future obsessive patient, carries it, in utmost seriousness, to absurdity: "All right, all right, if this is how you want me to do it, I shall go on and on until *you* get sick and tired of it." His senseless use of repetition is a travesty of the learning technique. Aside from this, repetition is forced upon him by the prompt interdictions of conscience. Interrupted by them as soon as he starts, he must make a fresh start over and over again. He never gets beyond the first step toward the nonreporting goal of his forced effort. Without loss of ironic intent, repetition thus becomes an integral feature of the interference pattern of discharge.

Stammering is a speech disorder closely related to obsessive behavior. They have two dynamic features in common—motivating system and interference pattern of discharge. The stammerer gives a drastic illustration of the afore-mentioned point: He, too, gets stuck at the start—in the first letter or syllable—and repeats it until he is able to complete the word. In stammering the organism acts upon the early illusion that its most powerful weapon is the mouth; its rage is channeled into speech. Naturally, in the motivational context of rage, the magic of words is coercive or vindictive. To the nonreporting range the letters or syllables in which the patient most often gets stuck signify the beginning of a verbal assault —obscenity, cursing, etc. Without knowing why, he gets scared. Guilty fear promptly stops his speech, as if to warn, "Watch your words." This mechanism explains why stammering disappears in situations which obviate the necessity of precautions. As is generally known, the stammerer's speech is undisturbed when he is alone, or recites the same lines together with an entire group, or when he sings, etc. Otherwise, humiliated by his defect, he tends to withdraw and reduce his speech to a minimum; this phobic avoidance is, of course, a secondary development. Or, if the patient is angered by his defect, he will stubbornly insist on speak-

Downloaded from www.dbraulibrary.org.in

ing and finishing what he wants to say. In this effort, one of my patients pressed his teeth together, blushed, his cheek muscle vibrating restlessly and going into spasm. I should like to close these remarks on stammering with a personal reminiscence. When I was a young psychoanalyst, a dear friend and mentor of mine referred a severe stammerer to me for treatment, explaining the nature of this disorder as follows: "Stammering is a conflict between the urethral-erotic tendency to expulsion and the anal-erotic tendency to retention, displaced upward to the mouth. *Eine Verschiebung von unten nach oben*, that's what it is." In this explanation my friend's romantic enthusiasm for the libido theory eclipsed his native brilliance; he was, in human quality as well as in scientific achievement, the towering figure among Freud's early disciples.

Like all chronic disorders, obsessive behavior imposes unfavorable modifications upon the organism's pattern of interaction with its social environment. It forces the patient to live on an ever-rising obsessive note of tension, lowering his adaptive efficiency, capacity for enjoyment, and active achievement in life.

The onset and further course of the disorder, as well as the measure of its severity, vary widely. In evaluating the degree, we have to consider three pathological factors: the first is the degree to which the self-punitive mechanisms of conscience have become automatized; the second is the degree of the patient's pleasure deficiency, which is indirectly responsible for his severity of conscience; the third, closely linked with the first, is the presence and degree of pain dependence.

Clinically, we can readily appraise degrees of automatization and residual flexibility, by watching, as we do in a laboratory experiment, the influence that stress, absence of stress, and other factors have upon an established response. But about the organization of these highly significant processes we are completely in the dark and will probably remain there until behavior physiology comes to our aid. Unfortunately, as far as mechanisms of conscience are concerned, little help can be expected from animal studies.

Pain dependence is a chronic disturbance imposed upon the organism chiefly by its own retroflexed rage, which, in turn, is an outcome of restrictive upbringing.[31, 32, 37] Its various forms may be observed in the pathological context of any disorder. In the obsessive patient, the form called moral pain dependence is most frequent. Its development may be summed up as follows: His omnipresent and unrelenting fear of conscience—fear of inescapable punishment—and his refusal to take chances with his security force the patient to shy further and further away from activities that could lead him into temptation. From its original area the inhibition thus spreads to include the approaches to this area, thence to include approaches to these aproaches, and so on in ever-widening circles of precautions.

A graphic and typical illustration of this process is supplied by a patient who, as an adolescent, was prohibited from visiting a house of ill repute. He avoided the house as ordered, then he felt compelled to avoid the street in which the house was located, and eventually he avoided the entire section of the city. By coincidence, he subsequently had to move to a town in which there was no house of ill repute; he departed with a sigh of relief. Unfortunately, in this town he discovered a former schoolmate who had since acquired an unsavory reputation; step by step he developed the same series of precautions. Changing circumstances are powerless to terminate obsessive preoccupation; the same idea will force itself upon the patient in another form. In this patient his house-of-ill-repute experience became the hidden content of an obsessive ritual.

Yet no man can stay alive without satisfying, one way or another, the organism's minimal hedonic requirements, and so the patient is forced to find solace and high moral gratification in the fact that he is a "fine man." He discovers more and more opportunities to "fulfill his duty," imposing upon himself burdens and sacrifices which often enough do no good either to him or to anyone else. He becomes a self-styled martyr—without a cause. In moral pain dependence, under the supremacy of retroflexed rage, conscience defeats its purpose.

However, the obsessive patient may also

Downloaded from www.wbahlibrary.org.in

suffer from sexual pain dependence. As a source of pleasure, genital orgasm is unrivaled. If, as they usually do, the parents interfere, the organism puts up a hard fight to protect it. We have already seen that the child may circumvent the parental prohibition by indirect modes of stimulation. But there are other methods. Defeated as a child by the campaign of deterrence, the adolescent may find himself incapacitated for standard sexual performance. By chance, he then discovers that his submission to humiliation or other abuse has a disinhibitory effect upon his performance. Analysis reveals the reason: He has taken the inescapable punishment beforehand; now he is entitled to prove that he deserved it. He develops the practice of inviting abuse (short of serious injury) from the mate, thereby restoring his (her) capacity for performance. We call this practice the fear-ridden or submissive version of sexual pain dependence.

Another patient may discover that coercive rage takes care of his trouble. Assuming the role of the authority, he (she) inflicts the dreaded punishment upon the mate, enjoying vicariously the mate's suffering. The triumph unfreezes and strengthens his (her) sexual potency even more. This practice is called the enraged or triumphant version of sexual pain dependence. The two versions of this disturbance are far less self-destructive than is moral pain dependence.

I shall now sum up the etiologically significant results of this analysis. Obsessive behavior is based on a predisposition which is acquired in childhood and includes five clearly discernible factors: (1) overstrong rage; (2) guilty fear made stronger by retroflexion of the larger part of repressed rage; (3) stronger-than-average residues of primordial omnipotence that make rage strong and its paradoxical retroflexion possible; (4) relative pleasure deficiency in the area of genital orgasm, with its consequent enfeeblement of genital love and affection—a deficiency that makes it imperative to control repressed rage by retroflexion; (5) intelligent foresight leading to realistic fears. Presumably, the acquired predisposition to obsessive behavior is based on a genetic predisposition in which the overstrength of rage may be linked with the pleasure deficiency of sexual orgasm.

Parental punishment initiates a pathological development of conscience—repression of defiant rage, first by fear of punishment contingent upon detection, and, later, by fear of conscience—of inescapable punishment and guilty fear. The child's fear that the parents can make his omnipotence work in reverse increases his fear of conscience and guilty fear to such a degree that they become capable of retroflexing, as an added safety measure, the larger part of his repressed rage. Retroflexed rage makes remorseful self-reproaches and expiatory self-punishments all the more severe.

Accumulation of excessive emergency emotions in the nonreporting range—guilty fear and the rest of outward-bound rage—forces the organism to create an outlet. His denuded tensions filter through the pain barrier of repression and produce the obsessive attacks with their interference pattern of discharge. Horrific temptations arise when the retroflexion of rage is carried to an extreme. They show that, in his despair, the tortured patient would prefer to be a murderer.

Looking once again at the motivating system, we find rage at the bottom, in the key position: restored pride over repressed guilty fear over more strongly repressed defiant rage. Beyond a shadow of a doubt, in the etiology of obsessive behavior the ultimate psychodynamically ascertainable factor is rage.

In 1926 Freud[14] summed up his etiological theory of neurosis in the following beautifully phrased (in the German original) passage that ends on a disarming note:

> These minor rectifications cannot in any way alter the main fact that a great many people remain infantile in their behaviour in regard to danger and do not overcome age-old determinants of fear [*Angst*]. To deny this would be to deny the existence of neurosis, for it is precisely such people whom we call neurotics. But how is this possible? Why are not all neuroses episodes in the development of the individual which come to a close when the next phase is reached? Whence comes the element of persistence in these reactions to danger? Why does the affect

Downloaded from www.freeclinicallibrary.org.in

of *fear* [*Angst*] *alone* seem to enjoy the advantage over all other affects of evoking reactions which are distinguished from the rest in being abnormal and which, through their inexpedience, run counter to the movement of life? In other words, we have once more unexpectedly come upon the riddle which has so often confronted us: whence does neurosis come—what is its ultimate, its own peculiar meaning? After whole tens of years of psychoanalytic work we are as much in the dark about this problem as ever. [Italics supplied.]

In the above paragraph Freud does not so much as mention rage, or even imply it, say, by some reference to his so-called "death instinct," that "instinct of destruction and self-destruction."

I have shown here that persistence and excessive strength of the child's fears are necessary consequences of the fact that the child—and later the adult—is forced to hold his rage in check. My examination of the other psychoneuroses (the overreactive and mood-cyclic disorders of our classification) has led me to the same conclusion. Summing up a series of studies, I wrote in 1955:[31]

Caught in the clash between their own defiant rage (violence from within) and the retaliatory rage of their parents (violence from without), these patients [suffering from overreactive and moodcyclic disorders] have emerged from childhood with an established pattern of adaptation that forces them unawares to damage themselves in order to avoid the dreaded danger of damaging others. Their suffering is increased if they develop pain-dependence.

The primary task of education is to domesticate the infant, to make him fit for social life by taming his rage. If this process miscarries, the child's inadequately controlled rage will cause behavior disorders. Trapped for decades in a labyrinth of misconstructed theories, it may well be that we are at last finding our way back to the obvious.

From the analysis of obsessive behavior, we derive a general insight. Since, in all overreactive and mood-cyclic disorders, the root disturbance is emergency dyscontrol, the principal dynamic function of these disorders is to discharge the insupportable tensions created by emergency dyscontrol. Or, to put it more precisely, these disorders are created by the biological necessity to discharge insupportable tensions; in each of them, formation of the characteristic clinical picture is then influenced by contributory causes.

The physiological pathology and the genetics of obsessive behavior have hardly reached even the preparatory stage of development. To offer clues to such investigations is a psychodynamic task of paramount importance.

## ¶ Differential Diagnosis

A sprinkling of obsessive mechanisms may be found in any person. The diagnosis of obsessive behavior must rest on the evaluation of the total picture. On the other hand, as will presently be shown, obsessive behavior may be complicated by mechanisms known to be characteristic of other disorders; this fact calls for differential diagnosis.

Phobic avoidance, the mechanism of the so-called phobias, is frequently seen in obsessive behavior, but there is no difficulty in telling the two disorders apart. We speak of phobia when the clinical picture is dominated by the avoidance mechanism but other signs of obsessive behavior are absent. Analogous considerations apply to the differential diagnosis between nonschizophrenic paranoid behavior and obsessive behavior.

The presence of sexual pain dependence does not by any means point to obsessive behavior. As mentioned before, this disturbance may occur in a variety of behavior disorders or may constitute one by itself.

I have never seen a true expressional pattern combined with true obsessive behavior in the same patient. In early psychoanalytic literature, statements to the effect that obsessional neurosis always has a "hysteric nucleus" are explained by the fact that Freud called the phobias "fear hysterias" (*Angsthysterien*). We classify them as phobic forms of emergency dyscontrol; psychodynamically, they are quite unrelated to the syndromes of expressional behavior.

Obsessive behavior may appear during the

Downloaded from www.dbraulibrary.org.in

intervals between two phases of mood-cyclic behavior.[1, 46] This fact is revealed by the patient's history.

Though these questions may claim theoretical interest, their practical value is nil. In contradistinction, the diagnostic separation of genuinely obsessive behavior from certain forms of schizophrenia is a task of serious theoretical as well as practical significance. The occurrence in schizophrenic patients of obsessive, hysteric, phobic, and other apparently neurotic symptoms has been established by Bleuler,[4] Freud, and other clinical observers. More recently, Paul H. Hoch and Philip Polatin designated this group of cases as "pseudoneurotic schizophrenia."[19] In retrospect, there can be no doubt that Josef Breuer's famous patient suffered not, as he and Freud believed, from hysteria but from schizophrenia.[5] Freud suspected that his famous "Wolfman" was schizophrenic.[13] With our increasing knowledge of schizophrenia, we are now sure that he was. The analysis of this case became a classic in the psychoanalytic literature of the psychoneuroses. The patient from whose observation Ferenczi abstracted his concept of "pathoneurosis"[6] was subsequently treated by myself in a mental hospital where he spent month after month in a catatonic stupor. One cannot escape the impression that the number of schizophrenic patients erroneously diagnosed and treated as "obsessive-compulsive neurosis," "conversion hysteria," "anxiety hysteria," "mixed psychoneurosis," and so forth has been and continues to be very high.

Help may come from the "theory of schizotypal organization."[34, 49] The genetic origin of schizophrenia was definitely established by the work of Franz Kallmann[22, 23] and others. Taking this fact as a point of departure, my theory of schizotypal organization holds that the organizing causes of schizophrenic differentness reside, more than anywhere else, in the integrative apparatus. The individual called schizotype—schizophrenic phenotype—is marked by two fundamental, genetically determined, impairments:

1. The capacity for pleasure is diminished, pleasure's ordinarily strong motivating action enfeebled; this impairment is designated as integrative pleasure deficiency.

2. The individual's awareness of his own body is, or tends to become, distorted; this clinical fact is interpreted as an impairment of the action self, hence, in the last analysis, of the proprioceptive system.

It must be stressed that the degree of these impairments varies widely from patient to patient. Together, integrative pleasure deficiency and proprioceptive impairment give rise to a compensatory system of adaptation which is peculiar to the schizotype. If properly developed, the system of schizoadaptation may work well and hold the individual in a compensated state for the rest of his life. Otherwise, emergency dyscontrol may precipitate decompensation, producing the clinical pictures of pseudoneurotic schizophrenia. In a gradual breakdown of the system of schizoadaptation, next appears the stage of disintegration, of adaptive incompetence manifested in the clinical pictures of overt schizophrenic psychosis. The last stage, known as deterioration, may, in most instances, be due to lack of proper care. It is marked by a lasting cessation of function, signifying a nearly complete withdrawal from the adaptive task.

The clinical pictures of schizotypal disintegration can hardly be mistaken for obsessive behavior, but there is a large margin for diagnostic error in pseudoneurotic schizophrenia. Here the clinical picture may include a variety of pseudo-obsessive, pseudophobic, pseudo-expressional, and still other mechanisms, all deriving from the obedience-defiance conflict, which, in my view, is the predominant motivating system in schizoadaptive behavior. The differential diagnosis rests on the presence or absence of minute schizophrenic traits and on the experienced psychiatrist's ability to use his own emotional resonance as an exploratory tool.[44, 47] Verification of his findings by subsequent developments may teach him to spot the schizotype "by feel."

Statistics on schizophrenia are misleading, for they deal only with the incidence of overt schizophrenic psychosis; increasing familiarity with pseudoneurotic schizophrenia has opened

Downloaded from www.dbraulibrary.org.in

our eyes to the fact that, in the general population, the number of schizotypes is a multiple of 0.8 per cent.[23] Now the pendulum of privately voiced opinion is in the process of swinging to the other extreme. Looking at the procession of patients in private practice as well as in outpatient clinics, competent observers wonder if they will ever again encounter a case of genuine "obsessive-compulsive neurosis" (obsessive behavior) or "conversion hysteria" (expressional behavior). The implication is that such things do not exist. In my opinion they do, though in the last few decades in the United States their incidence has conspicuously declined. The development of obsessive (and even more so, of expressional) behavior is strongly influenced by the cultural climate, in particular by our shift from "prohibitive" to "permissive" education. In the teens and twenties on the European continent, the incidence of obsessive (and of expressional) behavior was high, and that of juvenile delinquency low; today, in the United States, the picture is exactly reversed.

One can only urge that the differential diagnosis be made as early as possible, since the overreactive (and mood-cyclic) disorders on the one hand, and the schizotypal disorders on the other, require radically different treatment procedures.

In view of the wide distribution of schizogenic heredity, one may speculate that, though in the schizotype the two constitutive impairments are firmly linked, there may be individuals of another type who are what they are because they have inherited only integrative pleasure deficiency. The proprioceptive impairment got lost in the Mendelian shuffle. A hemischizophrenic heredity such as this may contribute a significant component to the presumed genetic basis of obsessive behavior. The patient's integrative pleasure deficiency, even if limited to the pleasure of genital orgasm (and the sexual love derived from it) may give him the appearance of a schizotype, which he is not. In my view, without proprioceptive impairment there is no schizotype; hence no schizophrenia. If we had a method for disclosing a latent proprioceptive impairment, the problem of differential diagnosis would, I strongly believe, be solved.

## ¶ Treatment

Self-control by obsessions is a torturous outgrowth of emergency dyscontrol. The damage it inflicts upon the organism may be measured in terms of suffering, lost time, and wasted effort. Every reduction of these losses is a potential gain for the patient's healthy pursuits. It is only by means of psychotherapy that we can help him extricate himself from the clutches of his obsessions, or, if this is impossible, at least diminish their hold on him.

We distinguish (1) reconstructive, (2) quasi-reconstructive, and (3) reparative methods.[30, 47, 48]

### *Reconstructive Treatment*

Reconstructive therapy is a psychoanalytic procedure which is based on adaptational psychodynamics and employs the adaptational technique.[30, 47, 48] It is the method of choice for the treatment of patients suffering from an overreactive disorder. These patients have remained at, or regressed to, the adaptive level of infantile dependence. By removing their inhibitions, the reconstructive method seeks to enable them to rise to the level of maturity. Toward this end it (1) engenders in them processes of *emotional* learning and un-learning, (2) keeps them, as much as possible, at the level of self-reliant cooperation (adult treatment behavior) throughout the entire course of treatment. The reconstructive method should be used only by psychiatrists who have received special training and acquired full command of its technique. Of special value in the treatment of obsessive patients are its revised conception of the dynamics of obsessive behavior, its strict avoidance of ambiguous terms and theories, its abstention from ritualized proceedings, and its special measures for probing, releasing, and dissipating the patient's repressed rages.

Under the classical "transference" procedure, the patient lavishly used the psychoanalyst as

Downloaded from www.psychiatrylibrary.org.in

a willing scapegoat, thus replenishing his supply of guilty fears. For, regardless of the analyst's interpretations ("You don't mean me, you mean your father") he, in fact, never lost sight of his actual dependence upon this man's therapeutic skill and interest. Unnoticed by either of the parties, the seesaw of the patient's outbursts and repentances tended to become a ritual in itself—neat, interminable, and inconsequential. "My patient," I once heard a colleague exclaim in a conference, "seems to take special delight in reciting to me the entire Freudian theory back and forth, but otherwise nothing whatsoever has changed." I remarked: "Don't you think your patient is teasing you?"

Under the adaptational technique the patient is led to discover the true objects of his repressed rages and to discharge his repressed rages in the memory context of the original cast and experiences that provoked them.[30] As soon as the patient regains his composure, an exploratory analysis follows, conducted in simple terms of motivation, showing him why he behaved in the reported situation the way he did, and, by contrast, how healthy people behave in similar circumstances. The same technique is repeated on every single occasion of this kind—the oftener, the better. Patients with a period of classical treatment to their credit may, at first, resent and resist this technique. The obsessive patient likes nothing better than to make a monkey of the therapist and himself, without having the remotest inkling that this is precisely what he is doing.

The patient must be kept motivated for hopeful and realistic cooperation throughout the entire treatment procedure. If and when such an atmosphere is achieved, then the main task is to modify the tripartite motivating system by breaking up the mechanism of retroflexed rage, thus reducing the patient's guilty fears and expiatory self-punishments. He must learn, first, to face his full rage and then to nip it in the bud with a special technique of complete and instantaneous relaxation. It is a technique of rage abortion; as a control measure, the exact opposite of rage suppression. It requires prolonged and patient practicing until it becomes semiautomatized. It does not replace insight; it makes it effective. Decades of experience have shown that insight by itself is powerless to forestall either renewed repression of rage or its renewed explosions.

Since the mechanisms of conscience are automatized, the technical procedure is difficult. In the average patient the results are from fair to good. Severe and inveterate patients are hopeless, notably if their integrative pleasure deficiency is rather conspicuous. This pathological factor is naturally inaccessible to psychotherapy. To use Linus Pauling's term,[28] we consider it a "molecular disease." We may look forward to the time when the biochemist will give us the means of controlling it by replacement therapy. Sitting before the crystal ball, another biochemical development may also be predicted—drugs of pin-point action and lasting effect designed to reduce the overstrength of rage. Biochemical advances such as these will open up new opportunities for reconstructive treatment of the obsessive patient and of other patients as well.

### *Quasi-Reconstructive Treatment*

Though the therapeutic goal of reconstruction through re-education was first envisaged by Freud, his original (now classical) technique of psychoanalytic therapy can only be classified as quasi-reconstructive: it keeps the patient's treatment-behavior at the level of childlike emotional dependence upon the physician ("transference").[12] Designed more than forty years ago, this technique is becoming increasingly obsolete. The patient's disordered life-performance (his "neurosis") is in direct view and can be dealt with directly. But the patient tends to disorder his treatment-behavior as well, in the image of his disordered life-performance. Freud accepted this tendency and proceeded to treat the patient's disordered life-performance via his "transference-neurosis," which is in fact disordered treatment behavior. It is superfluous, if not self-defeating, to view and treat through a distorted mirror-image what can be seen and dealt with directly. The post-Freudian doctrine of "corrective therapeutic experience" is a rationalization.

Quasi-reconstructive psychoanalytic therapy,

Downloaded from www.dbraulibrary.org.in

usually designated as orthodox or classical, requires special training for the psychiatrist. Its practitioners tend to think that the obsessional patient benefits but little from it.

### *Reparative Methods*

Reparative therapy includes a sizable number of procedures, most of them inadequately described and undefined. One or the other may offer the obsessive patient temporary or even some lasting relief.

Today we have a number of psychoanalytic schools, marked by revised theoretical approaches and therapeutic techniques. As to the merit of each school's treatment of obsessional behavior, one would have first to clarify whether the goal pursued is reconstructive, quasi-reconstructive, or reparative. And one would have to be familiar with each school's technique through practical experience; to my regret, I am not. Unfortunately, every psychoanalytic school speaks its own language. Reduction of this Babel to one tongue has not yet been attempted.

Once the obsessive patient has reached the stage of a chronic and severe tension state, our chances of reaching him with psychotherapy are reduced to nil. Attempts to treat such patients with surgical, electrical, and pharmacological procedures still yield rather discouraging results. This further demonstrates how important it is for the obsessive patient to seek psychotherapy as early as possible.

CHAPTER 18

# REACTIVE DEPRESSIONS

Emil A. Gutheil

Downloaded from www.dbraulibrary.org.in

A REACTIVE DEPRESSION is an acute feeling of despondency and dysphoria of varying intensity and duration. As the name indicates, it is not an illness but a reaction, a response to conditions of loss and disappointment. This response is highly subjective; what depresses one individual may leave another unaffected.

## Etiology

Reactive depression can be physiologic (normal) or neurotic. A physiologic (normal) depression is a reaction to life's acute difficulties. Such difficulties are loss of a job, loss of a sex object, or the like. The dysphoria is transient and ends with a spontaneous remission without causing a deep-rooted change in the patient's life adjustments. The neurotic dysphoria is one of the most frequent neurotic symptoms. It (1) may remain the only presenting symptom (the "essential" or "genuine" form of depression); (2) may be the first noticeable sign of an oncoming or concurrent somatic or psychic disease (symptomatic depression; most physical and mental conditions show a depressive incubation stage in which the patients complain of an unexplainable feeling of foreboding about the future, apathy, and fatigue); or (3) may be hidden behind other somatic and psychic symptoms, in which case we speak of "equivalents of depression."

Reactive depression* usually follows some unpleasant experience which, under ordinary circumstances, might not have caused more than a passing feeling of disappointment, sadness, or lowering of the prevailing mood. What makes this pathologic reaction noteworthy is that it is more marked and prolonged than the usual one, and that the patient, in most cases, cannot overcome it by his own efforts. Among the pathogenic experiences we may find a financial setback, illness or death of a close relative, loss of love, loss of prestige, a professional or occupational disappointment, and the like. The patient's capacity for work is usually more or less severely affected.

Some investigators (Kretschmer,[4] Kallmann,[5] and others) assume that a constitutional predisposition exists even in the psychogenic forms of depression, and that this organic predisposition is responsible for the afore-mentioned pro-

* In order not to complicate the nomenclature, we shall refer to the "neurotic" reactive depression simply as "reactive depression."

longed and more intense reaction. However, we can always find also predisposing psychic factors, among them a conspicuous psychic overcharge (overcathexis) of certain objective values, such as money, prestige, or the like, the loss of which affects the patient in an abnormally strong way. We must assume that, under normal circumstances, the loss of a love object should not have such far-reaching consequences. The same is true with the loss of a job.

The immediate cause for the outbreak of a depressive dysphoria can be explored by obtaining a detailed history of the symptom and by projecting it, as it were, against the backdrop of the patient's total personality. Both the pathogenic situation and the affected individual have to be explored.

In elderly patients, excitements and emotional shocks are more likely to set off a depression than in young individuals. Older people have, as a rule, a lowered threshold for stress, especially in its chronic form. Their depressions have often an added element of anxiety ("apprehensive" forms of depression). It is clear that the older a person gets, the more chance he has to lose his old contacts, his relatives, his friends, and his position, the more likely is it also that his prestige and self-confidence will suffer. In general, we may say that social conditions under which an individual is forced to live contribute some of the influences which make him susceptible to depressive reactions. People who live a life lacking in incentives, who are surrounded by uninspiring company and removed from meaningful associations, people who work hard without too much hope for recognition, these are natural candidates for all sorts of dysphorias, especially under conditions of duress.

In young people it is the adolescent, with his marked lability of mood and temperament, who is particularly susceptible to reactive depressions.

Most patients suffering from reactive depression are able to describe the circumstances which have led to it. Their memory is usually intact, and their relation to reality is undisturbed. Only in exceptional cases is analytic exploration necessary to bring the underlying cause to light. The more pathologic the personality structure of the patient, the more is this procedure indicated. The ego in such patients will probably show lowered defensive strength, which can be seen in concomitant symptoms of denial, projection, depersonalization, undoing, and other immature forms of defense.

The so-called anaclitic depression holds a special place among the depressions and is supposed to be the result of severe emotional neglect of young children, in some cases even proving fatal.[7] According to Spitz, it especially affects children who are brought up in communal homes, hospitals, or in any atmosphere which lacks a mother's love and care. It is, of course, difficult to evaluate the extent of such emotional neglect. The hospital routines, as such, even if they are superficially beyond reproach, do have all sorts of deficiencies other than lack of mother's love.

As stated above, some psychogenic depressions are of symptomatic nature. They may accompany a physical or mental disorder, sometimes completely hiding the underlying condition. This type is found in patients suffering from a malignant or debilitating physical disease such as cancer, tuberculosis, or the like. It may also be present in patients who are victims of mutilating accidents, which represent a severe injury to the patient's narcissism. In early hypoglycemia, depression may be the only presenting symptom.[8] It can be found also among other symptoms of mental diseases, for example, in schizophrenia.

Finally, there are depressions which do not present any noteworthy mood changes but, instead, a number of mental and physical symptoms. Conditions of this kind can rightly be called equivalents of depression.

To the somatic equivalents of depression belong especially fatigue and pain, the latter of varying localization and intensity. Fatigue is the result of internal tensions created by deep-seated emotional conflicts. It is often a consequence of the patient's intensive efforts to neutralize his upsurging antisocial impulses generated by a specific stressful situation. Pain, usually generalized, vague and rheumatoid, or localized—for example, headache—is another

Downloaded from www.dbraulibrary.org.in

type of a successfully neutralized aggressive trend. In such cases we speak of *introjection*; it is a discharge inward of aggression combined with self-punishment, as a concession to the super-ego.

Other equivalents of depression which may be observed are dyspepsia, nausea, a bad taste in the mouth, constipation, and general irritability. Physical examination of the patient may yield no pathologic findings to account for these complaints.

To the psychic equivalents belong all sorts of impulsions, such as phagomania, dipsomania, drug addiction, and others.

As we see, most of these equivalents are of oral character. They represent attempts at self-cure; attempts to counter the depressive trend with an artificially created elation (drugs, alcohol, food, etc.). In most instances such attempts do lead to a temporary relief. There are cases, however, in which self-help fails, and the latent depression breaks through the camouflage of equivalents. We find this especially true with alcoholism. Some patients become overly depressed only *after* they have ingested alcohol.

## ¶ Symptoms

The most conspicuous symptoms of reactive depression are diminished activity, lowered self-assurance, apprehension, constricted interests (including the sexual one), and a general loss of initiative. All these symptoms make the patient's performance of his everyday tasks difficult but not impossible. The difficulty lies in his lack of concentration on his duties. However, most of our depressed patients are able to maintain their jobs, even though they have to work harder to obtain halfway satisfactory results.

The following are the symptoms of Spitz's anaclitic depression in children: loss of appetite (hence also failure to gain weight), apathy, dysphoria, frequent stools, and general progressive marasmus which may end in death. In some of these children, failure to get attention at an early age may lead to exaggerated needs for attention and affection at a later age, and—if the youngsters are rebuffed or frustrated—to the development of antisocial behavior patterns.

## ¶ Diagnosis

The diagnosis of reactive depression may, at times, be difficult. We have to differentiate it from (1) the psychotic depression, (2) the physiologic lowering of the mood level in so-called normal individuals, (3) depression which occurs in another mental disease, and (4) a depression preceding (and sometimes masking) an organic disease (such as general paresis, arteriosclerosis, or others).

The individual who suffers from reactive depression complains of a general loss of capacity to enjoy his social contacts, his work, and his hobbies. However, he is accessible to reassurance and encouragement. Since, as a rule, he is fully able to maintain relations with others and (fortunately) also with the therapist, his mood can be influenced therapeutically and, in most cases, he can be consoled in his grief. Distractions, change of environment, light entertainment, and other measures of this type are of definite help; they can be used not only therapeutically but also diagnostically, for patients suffering from a psychotic depression are completely inaccessible to these types of superficial influences.

A detailed history of the complaints will, in most cases of depression, enable us to obtain a picture of its intrinsic mechanism. Contrary to the organic and psychotic forms of depression, a psychogenic depression has always a logical reason. In order to find the precipitating factor, it is often desirable to establish the so-called "critical area" of the patient's life history, when the traumatic event(s) must have taken place which set off the depression.

The time period toward which we have to flash back may represent hours, days, months, or years. In order to find the approximate demarcation lines of the critical area, we must first ascertain what was the last period of time when the patient had been carefree and not depressed. Let us call that point A. Then we try to find out (with the patient's aid) when

Downloaded from www.dbraulibrary.com

he recalls having been definitely depressed. We can call this point *B*. Somewhere between the points *A* and *B*, lies the critical area in which the pathogenic factor(s) must have assailed the patient, triggering off his depressive reaction.

Having thus established the approximate time of the onset of the depression, we submit this period to an especially careful scrutiny, trying to elicit in the patient as many recollections as possible. The time employed in the clarification of this issue must be considered well spent, for if we come upon recollections which prove to be relevant, a successful attempt can be made toward establishing the so-called basic formula of the given depression. The formula then reveals the specific target for our therapeutic attack. In general, the basic formula of depression is:

$$D = S + P$$

Depression *D* is a combination of sadness *S* and pessimism *P*. The pessimistic component is the essential part of the formula. It is the patient's conscious or unconscious neurotic idea that what happened to him now will always continue happening, or that the condition in which he has recently found himself will never change. This pessimistic attitude, this inept attempt by the patient to forecast his future, is one of the factors responsible for turning sadness into depression.*

Loss of something of value (for example, money) may lead to sadness but not to depression; loss by death of a beloved person may lead to grief and mourning but not to depression. Only thoughts essentially unrelated to the loss but connected with a neurotic attempt to generalize the experience and to prophesy the future can bring about a depressive reaction. They lead to a decrease of self-value, to self-accusations, and to general constriction of the patient's adopted life patterns.

Pessimism is especially easily induced, if the object lost had been subjectively overcathected. The patient's self-esteem depends, to a great extent, on whether or not some of his ego ideals (originating within the super-ego) have been fulfilled. It is in the question of ego ideals that overcathexis usually originates.

As stated above, it is diagnostically significant for the psychogenic depression that the patient is accessible to encouragement, that the explanations can take root in his personality, and that self-reproaches, if at all present, are of logical character. In addition, changes in external conditions are capable of affecting the patient's reactions. The patient himself usually makes every effort to help himself; he knows that he is sick, and he wants to get well, instead of blaming himself for being "bad, lazy, and unworthy," as does the melancholic patient. The reactive depression, as a rule, is also a dysphoria without mental inhibition or agitation.

Especially significant is the absence of physical symptoms which are considered pathognomonic for the endogenous form of depression. Among them are: (1) a significant and progressive loss of weight which terminates only after the deepest point of depression has been passed; (2) precordial anxiety; (3) reduction of bodily secretions (dry mouth, lack of appetite, constipation, dry skin, hypomenorrhea or amenorrhea, and others); and (4) stubborn and often intractable insomnia.

In cases of psychogenic depression, we find none of these and, as a rule, no outspoken diurnal rhythm. If a fluctuation of mood is at all noticeable, the mood level is lower toward the evening hours, when the "day's hopeless struggle" has brought about feelings of mental and physical fatigue. But we must not forget that slight fluctuations in the mood level occur also in so-called normal individuals, especially those of the cyclothymic personality type. We must, therefore, consider the intensity, duration, and character of the mood changes as well as the circumstances which brought them about, if we wish to record them as parts of the patient's pathologic reaction.

In taking the patient's history, we inquire whether a similar condition has existed before. This is an important diagnostic question, as periodicity points toward an endogenous character of the disorder, especially if the depressive attacks show a tendency toward presenting a "photographic likeness" to one another.

A fifty-three-year-old female patient, whose

* Incidentally, it is also one of the weakest logical points in his reasoning and can be easily challenged by the therapist.

Downloaded from www.dbraulibrary.org.in

melancholic depression occurred periodically for twenty-four years, had a peculiar kinesthetic sensation at the onset of every spell of depression. She had the feeling as though a train were passing over her body. The reoccurrence of this "train" was an unmistakable sign that another depressive mood swing was developing.

The nature of reactive depression precludes the appearance of such stereotyped sensations. However, some life histories of depressed patients do show several spells which have occurred at different times, under different conditions of internal or external stress. In cases of this kind, it is diagnostically important to exclude the periodic mood changes of melancholia especially, since many melancholic individuals are also inclined to attribute their recurrent melancholic attacks to some external experiences. The total picture of the illness and the patient's personality must, therefore, be considered in arriving at the correct diagnosis.

The differential diagnosis between psychogenic depression and the physiologic (normal) phenomenon of mourning is often extremely difficult. Both may follow the death of a beloved person. Mourning is needed for the psychic assimilation of the trauma suffered by the loss, and for the dissolution of the emotional ties between the individual and the object he mourns. This process—the "work of mourning"[2] —requires a certain amount of time which varies with the individual case. According to old psychiatric experience,[6] mourning requiring a period of more than six months should be considered pathologic.

Some grief reactions are delayed. The patient, who, at the moment of the loss, appeared to be unaffected, at some later time may suddenly develop feelings of grief which are uncontrollable. We find such delayed grief reactions in people whose attitude toward objects they mourn had always been ambivalent. The delayed reaction is usually the result of a resurgence of guilt feelings, which must be worked out in therapy.

Depressions in schizophrenia have the tendency to last for shorter periods and to occur more frequently, after short intervals. Sometimes such spells occur several times in a single day. However, the schizophrenic depression impresses us, in most cases, as an absence of affect rather than as a lowering of it. Also, the patient's grasp of reality may be deficient and his motivation less logical, and his hypochondriacal self-observation may show signs of autistic self-preoccupation. A thorough exploration of the total personality is, therefore, necessary in such cases to establish the diagnosis.

The prognosis of psychogenic depression is good. The patient may experience spontaneous recovery; that is, his depression may wear itself out. This may be the case when the original pathogenic circumstances have improved. At the depth of depression, the patient may be suicidal but, in most cases, he can be talked out of committing an act of despair, especially if he is under psychiatric care. Once the patient has established a positive transference relationship, the danger of suicide, as a rule, diminishes.

## ¶ Psychodynamics

As stated above, most reactive depressions are caused by some sort of traumatic experience. What has made the experience traumatic is subject to conjecture. In many cases it is the past events which supplied the psychologic matrix for subsequent exaggerated reactions. The analytic exploration must answer this question. These patients have been sensitized to the traumatic event by losses they have sustained in the past, by insecurities, and by unendurable situations of stress to which they were exposed in their childhood. The stronger the ego, the better can the individual absorb the traumas. Persons with weak egos, individuals who, even under normal circumstances, are able to maintain only a precarious emotional equilibrium, do so by taking recourse to all sorts of internal self-reassurances. When the traumatic event occurs, or when the patients are exposed to acute or chronic stress conditions, these internal self-reassurances may be upset, and various old anxieties are remobilized. One of these anxieties is the fear of losing love or of being deprived of other "narcissistic supplies."[2] Foremost among the internal self-reassurances by which the patient succeeds in maintaining his equilibrium are unconscious fictions[1] based on the patient's

Downloaded from www.dbtelibrary.com.tr

belief in omnipotence: that the patient is a favored child of fate; that providence will always protect him in adversity—as his parents did. The traumatic experience of loss of love or prestige may have a shockingly sobering effect on the daydreamer who suddenly finds himself unprotected, unloved, abandoned.

Chronic stress has its biologic and physiologic repercussions.[5] Biologically, it endangers the individual's basic adaptive pattern, while psychologically it represents a condition of prolonged frustration. Some patients adopt a system of ingratiating themselves to their fellow man. They use all sorts of stratagems to create, or to preserve, an atmosphere of friendliness and acceptance as the only medium in which they can live and breathe without a permanent fear of rejection. Often they succeed in this endeavor. However, this fiction—the attempt to prove to themselves that people do love and accept them—cannot be maintained indefinitely. Reverses of fate and other disappointing events of the unpredictable real life make those bubbles burst, and the magic phantoms of security disappear. The patients, deprived of their vital defensive devices, are then inclined to react with all the more severe feelings of despondency and inadequacy.

In some cases we find another maneuver by which the patients try to control their meager adaptations to mature life. Driven by neurotic needs to prove to themselves that they are able to love in a mature way (while in reality they are too infantile to do so), they may not be able to stand the loss of a love object even for a short time. Having lost the object, they are inclined to "fall in love" anew, and often precipitately, or to seek immediate substitute gratification by drinking, gambling, or other neurotic devices.

Still others court sympathy as the next best substitute for love. They demonstrate their misery to their environment by lamentations and other displays of suffering. Sadistic elements often color this attitude. It is as though these patients were proclaiming to the world, "love me, or else. . . ." They try to force the environment into supplying them with the love they are missing, while unconsciously they offer hate for having been disappointed to begin with. Guilt feelings and depressions may be the result of this process.

Under stress, narcissistic and autistic fictions such as, "I must be the best," or "Everybody must love me," constructed as they are to overcompensate the patient's basic insecurity and the weaknesses of his personality and maintained by the patient as pillars of his precarious adaptation, may be obliterated or may swing to their opposites. They then become pessimistic prophecies, such as, "I will always be a failure," or "Nobody will ever love me," or the like, a mechanism to which we referred before as the basic pessimism in the psychodynamics of depression.

Depressions which occur in the initial stages of neurotic disturbances are indications that an instinctual conflict is taking place in the depths of the patient's personality, a conflict which involves the patient's self-esteem. It is usually the super-ego's attack against unruly surgings of the id, a duplication of a strict parental disapproval which is known to create morbid feelings of guilt.

There are certain stress situations which are more traumatic than anything the individual has ever imagined. I am referring here to experiences in concentrations camps, where individuals are subjected to tortures, privations, "brain washing," humiliation, and frustration —and yet do not respond to them with reactive depressions. As a matter of fact, many survivors of the Nazi concentration camps remarked that they were astounded about not having seen more cases of suicide than actually did take place. In most cases it was the intrinsic moral force of the brutalized individual and the secret rebellion against the debauchery of oppression that kept the victim's ego well charged and strong. The prisoner felt himself as a morally victorious victim of inhumanity and hoped that ultimately evil would find its retribution. This explains, in part, why some of the survivors of concentration camps suffered breakdowns and even committed suicide, *after* they had found a haven in a free country and were exposed to the everyday frustrations and unavoidable rejections in their new lives. Suddenly, their egos felt all the privations,

Downloaded from www.dbraulibrary.org.in

anxieties, and narcissistic injuries which were no longer covered up by the all-powerful righteous indignation and by the basic desire to survive.

In some forms of sexual deviation, particularly in homosexuality, we sometimes find a peculiar form of psychogenic depression which may lead the otherwise reluctant patient to the attention of the psychiatrist. A homosexual patient may introduce himself to the psychiatrist with the words, "Please, do not try to change my sexual attitude, with which I feel perfectly satisfied; my depression is the only thing I should like to lose."

Upon closer examination, the psychiatrist may become convinced that at least a part of the patient's personality feels deeply unhappy. The unverbalized feeling in question is that homosexuality keeps the patient out of the great creative process of life; that he is the last link of a chain; that in him his generation finds its termination, and that ultimately he will fall off the tree of life like an empty fruit. It is this melancholy teleologic attitude which is (consciously or unconsciously) perceived by the patient and which thus creates a matrix for a psychogenic depression. Onto this matrix are planted the specific conflicts of the patient, which may be oedipal in character or may originate on a pregenital level and, as such, are replete with their own guilt complexes, capable of leading to despondency. Feelings of the afore-mentioned kind are likely to occur especially in those homosexuals who are unable to sublimate their creative ability—as so many of their fellow deviates do—in art or other outlets, and thus suffer from a latent sense of futility and worthlessness.

## ¶ Therapy

In dealing with patients suffering from reactive depression, an empathetic, sincere attitude of the therapist will soon secure for him the proper friendly relationship with the patient, which is the premise of all therapeutic successes. Since most patients of this type are victims of an overstrict super-ego, the therapist, a super-ego substitute, has an important part to play in the shift of identifications which is to take place in the patient's mind. The therapist must conduct himself with strength, yet also with kindness, which, as a rule, quickly allays the patient's initial anxieties. Too much permissiveness is not desirable. The patient needs guidance and counsel, but above all strength, which he should be able to derive from his therapeutic relationship.

Prolonged, especially orthodox, analysis is hardly ever needed to cope with this condition. Active analysis or brief psychotherapy are, as a rule, the therapies of choice.

The therapist has to confront the individual with the situation which he has recognized as having been traumatic. He proceeds from the supposition that, for example, being jilted by a partner should not be a cause for despair. The therapist must work out with the patient the underlying dynamics of the given situation, which may have been conditioned by early rejections, and will encourage the patient to seek other adjustments. He will point out that it is up to the patient not to accept life as a series of repetitions and stereotypes. He will awaken in the individual his dormant creative forces which will help him to break the repetitive pattern in a healthy search for new experiences.

Loss of a job, as a cause of depression, will offer the therapist ample opportunities for discussing the patient's relation toward employers, his ambitions, his dormant resources and hidden talents, and for directing his thoughts toward the goal of regaining lost territory. Social agencies may be recommended to help the patient in planning his future more realistically.

In all these endeavors, the therapist will point out that "similarity is not identity," that two similar experiences, past and present, must not be permitted to be perceived as though they were the same experience, and that they must be evaluated without bias, on their own specific merits. Usually, the psychiatrist can bring about a better concentration on the present as something to which the patient has brought many potentialities—ready to be applied successfully.

In addition, all sorts of supportive measures

Downloaded from www.dbraylibrary.org.in

can be considered; among them are change of milieu, removal from a noxious family or work environment, and others.

Hospitalization is unnecessary in most cases, unless the hospital in question, in addition to offering effective dynamic psychotherapy, is also equipped for an intensive occupational and recreational psychotherapy. Only serious suicidal tendencies should be considered as an absolute indication for hospitalization. This is also the case if the patient is completely lacking in supervision or company. Under ordinary circumstances, hospital treatments are not without harm. The deficiencies of the patients' personalities make them easy preys for all sorts of autosuggestion. This complicates the problem of isolating the patients from noxious influences in a hospital, in which conversation revolves almost exclusively around illness and suffering. Unless such exchanges can be controlled, or even utilized therapeutically as a part of group psychotherapy, they must be considered undesirable. Work is beneficial; it prevents depressed patients from brooding and spinning gloomy daydreams. It gives them a feeling of achievement and self-worth, an important ego-strengthening influence. However, one should not expect too much from supportive measures alone.

Of great value as a "friend of the lonesome," a source of distraction and consolation for depressed individuals, apart from books, is the movie. (Recently, the television has taken over, in part, this role.) The type of picture is not even of too great an importance. We can safely say that any amount of time the depressed patient is able to spend in the movies (or before the TV set) is a contribution toward his recovery. It is not necessary that the patient be entertained by the picture, if it can only make him forget his worries for a time.

Another great help as a supportive measure is sleep; it can withdraw the patient's mind temporarily from painful thoughts and memories. The psychiatrist will, therefore, have to take an effective sedation of the patient into consideration. Sedatives and/or tranquilizers, taken during the day only, are preferable to hypnotics prescribed for the bedtime. Sufficient sedation during the day offers the relaxation the patient needs for falling asleep "on his own power," as it were. This system does not leave him as much opportunity for developing a dependency on the magic power of the pill. Falling asleep spontaneously can also bolster his morale and make him aware of the progress he is making.

The use of drugs is indicated primarily in the initial phases of the depression. It should be reduced and ultimately discontinued as soon as the patient begins to manage his affairs satisfactorily, and psychotherapy can assert its sovereign rights.

Some authors recommend the use of electric convulsive therapy for the more refractory cases of psychogenic depression, but I have rarely seen the need for it when effective psychotherapy and supportive, manipulative, and chemical measures are available.

CHAPTER 19

# CHARACTER STRUCTURE AND CHARACTER DISORDERS

Joseph J. Michaels

Downloaded from www.dbtculibrary.org.in

THIS CHAPTER* will attempt to deal with the problem of character and character structure; it represents a biased point of view, however, and is only a beginning venture. Character is a complex concept, for it has many meanings. Ordinarily, character means a moral and ethical value judgment of behavior. In this general lay sense character and traits of character are merely descriptive and pertain to such qualities as honesty, sincerity, and integrity. It is common usage to describe the individual character as a "good" or "bad character," with all types of variations, so that there are eccentric characters, conforming characters, and so forth.

## Character in General

The problem of what constitutes character has received attention from the fields of education, psychology, sociology, philosophy, and religion; divergent points of view are reflected in the use of the term "behavior" by the students of personality, and the term "conduct" by the students of ethics. Kilpatrick,[81] the educator, believes that character is the structural basis of conduct, something that is largely built up through training and experience and upon which we can more or less rely for the conduct that is to follow. A more picturesque conception is given by the critic, Chamberlain:[18]

When we speak of character we mean a human being's ability to remain more or less constant despite the corrosiveness of time—a personal insistence upon permanence and stability amid ceaseless change.

The psychologist, Allport,[6] in writing of character, defines it thus:

The aspect of personality that engenders stability and dependability, that is responsible for sustained

* I wish to acknowledge my gratefulness to Dr. Helen H. Tartakoff for her comments and criticism.

effort in the face of obstacles, or works for remote ends rather than those that are nearer in time but of less worth. Character enters the situation only when this personal effort is judged from the standpoint of some code. Character is personality evaluated and personality is character devaluated.

In discussing the problem of the relation of personality to character, Herbert Read,[101] the poet and critic, stated that "character must be placed in opposition to personality, which is the general-common-denominator of our sentiments and emotions." Roback,[109] in a comprehensive, eclectic review of the subject of character which includes about thirty-five hundred references, concluded that character is "an enduring psycho-physical disposition to inhibit impulses in accordance with a regulative principle." The social psychologist, Riesman,[107] speaking of social character, defines character structure "as the more or less permanent, socially and historically conditioned organization of an individual's drives and satisfactions."

Studies of character and character structure within various frames of reference have been made in anthropology—Mead,[90] Gorer,[61] La Barre[84]; in sociology—Adorno *et al.*;[3] in politics—Lasswell,[85] Lindner.[88] Of special interest is the study of literary figures by psychoanalysts—Bonaparte,[15] Greenacre,[62] Hitschmann,[74] the Sterbas, [114] and Weissman.[120]

When character is used in a psychiatric sense, it has a more specific meaning, although the term has been utilized differently in psychiatry and in psychoanalysis. In the field of American psychiatry the term most commonly used to apply to the individual has been "personality." In contrast, in German psychiatry one finds that the word character has been used in a similar sense. Hinsie and Shatzky,[73] in their *Psychiatric Dictionary* state:

> Character as used by psychiatrists today is more or less synonymous with personality. It is made up of patterns of behavior, characteristic for the given individual as physical and mental activities. The character of an individual is the resultant of forces emanating from the inner life of the person and from the environment.

Psychobiologic psychiatry before the influence of psychoanalysis seldom referred to character in discussing personality; in fact, the tendency persists to speak of the total personality when some concept of character seems to be implied. From the standpoint of nosology and psychopathology, the diagnosis of character disorder has been applied to those disturbances in personality which manifest themselves in the social behavior of the individual when his actions lead to difficulties with society. The diagnostic category in psychiatry which embraces character disorders has been psychopathic personality.

A reflection of how a frame of reference affects diagnosis and nosology can be seen in comparing the *Diagnostic and Statistical Manual: Mental Disorders*,[22] utilized by the American Psychiatric Association, and *Nomenclature of Psychiatric Disorders and Reactions*,[88] prepared by the Veterans Administration. In the former, character disorders are not listed as such but would be found under the headings of personality disorders, personality pattern disturbance, personality trait disturbance, and sociopathic personality disturbance. In the latter, a main classification of character and behavior disorders with various subheadings is designated. It is evident that the VA nomenclature is more dynamic in its orientation.

## ¶ Psychoanalytic Concepts of Character

Tartakoff[117] has presented a broad historical perspective of the development of the theoretical aspects pertaining to character structure. To the writer's knowledge, it is the first attempt at an integrated description of the psychoanalytic concept of character in the literature. Bibring[18] has lucidly traced the evolution of the theory of instincts; Hartmann[67] has concentrated on the vicissitudes of ego psychology. Tartakoff mentioned that the function of the ego which has been least studied is that of integration. To this statement might be added that even less is known about the integrative aspects of character structure as a whole within the framework of the total personality.

In reviewing some of the literature on char-

Downloaded from www.dbtindia.org.in

acter neurosis and character disorder, it becomes evident that each writer views the problem of character according to his own character structure, his training, his psychologic orientation, and the discipline within which he has worked. Thus, in some of the typologies which have evolved in regard to character and to personality, these above-mentioned qualifications will become apparent.

The difficulty in constructing a theory of character results from the fact that this must be an integrated concept. In the development of psychoanalysis the theoretical concepts were evolved primarily in so far as they pertained to the explanation of the neuroses. Freud began with elucidating various aspects of the personality, and, although a metapsychology of the personality was evolved, it was not explicitly applied to the total picture of character structure.

Looking back upon Freud's early clinical studies, it is apparent that characterological features were not emphasized. Because neurotic symptomatology was the focus of attention, the main diagnosis was given in terms of a specific neurosis, although characterological overtones were present. Today we recognize that there is an admixture of character problems and neurosis. (Nunberg[99] emphasizes the similarities between a character neurosis and the symptom neurosis and minimizes their differences.) Contemporary analysts are shifting the emphasis from neurotic features to the character structure of the individual, and there is a growing movement to construct a theory of character structure.

In psychoanalysis the psychobiologic concept of the total personality has been dealt with primarily under the heading of character structure. Diagnostically, what the psychiatrists have designated as character disorders the psychoanalysts usually refer to as character neuroses. The use of such terms as the oral and anal character or oral and anal traits of character has been traced back to their dynamic-genetic origins. Because the science of psychoanalysis is uniquely sensitive to the individual aspects of personality and aware of the complexities in human behavior, it has been largely preoccupied with emphasizing these features of particularity and has only recently begun to investigate the more structural problems. In the latter area, psychoanalytic studies have been chiefly focused on "neurotic" characters, with emphasis on their origin. Psychoanalysis has as yet not offered a *weltanschauung* or an evaluation of character as such. Concerning this subject, psychiatry is in the same stage as was medicine when it was almost exclusively preoccupied with disease or pathology rather than health, although certain preliminary steps taken by psychoanalysts constitute a beginning to the solution of the problem.

As psychoanalysis has evolved, the term "character" has been used predominantly, so that we have traits of character, character structure, disorders of character, and character neuroses. Therefore, when we speak of character structure, we are limiting ourselves to viewing this concept from psychoanalytic metapsychology. When we refer to the total personality, we mean something in addition to character structure, such as the degree of intelligence, individual talents, and even perhaps temperament added to, or combined with, the character structure. Brierley, in her attempted integration of psychoanalytic concepts,[17] recommended that, in our consideration of character structure, the term personology be used to include the concept of the total personality. She states, "Concepts of personology refer to experience, whereas the concepts of metapsychology refer to objective mental processes, although they are also inferred from experience."

The problem of character formation interested Freud from the beginning of his work, where one can observe broad references to character in accordance with the metapsychological theory prevailing. One of the first explanations of character occurs in *The Interpretation of Dreams*,[41] in which it is stated that "what we describe as our character is based on the memory—traces of our impressions; and moreover, the impressions which have had the greatest effect on us—those of our earliest youth—are precisely the ones which scarcely ever become conscious." In this instance, the basis of character is ascribed to a functional locus in the brain which later becomes a part of the functions of the ego.

Downloaded from www.dbraulibrary.org.in

As might have been expected, Freud's early conceptions about character were within the frame of reference of the libido theory. Since the first concern was with the unconscious, the conceptions were colored accordingly and traits of character and aspects of character were seen as derivatives, reactions, or sublimations of instinctual forces. In a certain sense, traits of character and the character itself were viewed in a manner similar to symptom formation, i.e., according to the theory of neurosis. Later, when the structural point of view prevailed, a broader perspective toward traits of character and character itself developed.

When Freud, in 1905, discussed character from the libidinal point of view in "Three Essays on the Theory of Sexuality,"[48] he stated:

> A person's "character" is built up to a considerable extent from the material of sexual excitations and is composed of instincts that have been fixed since childhood, of constructions achieved by means of sublimation, and of other constructions, employed for effectively holding in check perverse impulses which have been recognized as being unutilizable.

In 1908, Freud[37] wrote, "The behavior of a human being in sexual matters is often a prototype for the whole of his other modes of reaction to life." Thus the emphasis on instincts and the unconscious (later the id) is observed with the construction of the first character type as the anal character.[36]

It must always be borne in mind how Freud interwove theory and fact, especially as his therapeutic techniques evolved. In 1915, while describing "Some Character-Types Met with in Psychoanalytic Work,"[47] he indicated how the patient's resistances which can be attributed to his character interfere with the treatment. He[47] referred to them as:

> . . . character traits, individual attitudes of the ego, which are thus mobilized to oppose the attempted alterations. One learns then how these character traits have been developed in connection with the conditions of the neurosis and in reaction against the demands, and observes features in this character which would not otherwise appear, at least, not so clearly, i.e., which may be designated latent.

In this early period Freud referred to character in much the same manner as the psychiatrists referred to personality. When he described character in this general sense, he offered explanations paralleling his theory of neurosis existent at the time. An example of this point of view occurs in "Psychopathic Characters on the Stage."[46] Some broad clinical studies of character types such as "the exceptions," "those wrecked by success," and "criminality from a sense of guilt" appeared in 1915, to be followed by the study of Dostoevsky[38] whom Freud classified as an instinctual character.

Reich[103] was a decisive influence in focusing psychoanalytic theory and practice on the problem of character. His basic assumption was that the social order had a repressing and inhibiting effect inherent in the character structure which prevented the attainment of genital sexual gratification. With his firm beliefs in the power of the social order to affect character, he stated that character structure is the crystallization of the sociological process of a given epoch. Character, he postulated, consists in a chronic alteration of the ego, the exposed part of the personality—stemming from the continued influence of the conflict between libidinal need and threatening outer world—which one might describe as a rigidity, an automatically functioning mode of reaction.[103] He believed that the final quality of character was determined qualitatively by the stage of libido development—the specific fixation point of libido—and quantitatively by the libido economy. Some of the character types which he described were the hysterical, compulsive, phallic–narcissistic, masochistic, genital, and neurotic. In describing the impulsive psychopath, he stated that "there is a largely unformed character structure, the opposite of a thorough armoring toward the inside and outside." With this degree of character formation, the impulsive psychopath lacks one of the cardinal functions of character, that of binding "free floating" anxiety, or absorbing dammed up energy. Reich allocated the impulsive psychopath to the phallic-narcissistic level.

In 1939 Kardiner[79] wrote:

> Character is a special differentiation of ego structure arising within the ego. Ego structure is a

Downloaded from www.dbraulibrary.org.in

cultural precipitate; character is a special variation of each individual to this cultural norm. In contrast, by the basic personality structure is meant—the effective adaptive tools of the individual which are common to every individual in this society.

Fromm,[50] minimizing libidinal origins and emphasizing a socioeconomic orientation, delineates five character types: receptive, exploitative, hoarding, marketing, and productive. In criticizing the "orthodox Freudian approach," Fromm[51] indicated that psychoanalysts assumed that social phenomena and cultural patterns are to be explained as direct outcomes of libidinal trends. He contended that capitalism is explained by Freudians as a result of anal eroticism or of the operation of the death instinct. According to this writer such a condensation indicates a distortion of basic psychoanalytical concepts.

Horney[75] developed a simple classification of character according to what she considered the three basic strategies of life: (1) the detached personality—the person who moves away from people; (2) the aggressive personality—the person who moves against people; and (3) the compliant personality—the person who moves toward people.

Relying on the concepts of Fromm, and emphasizing changes in population and technology as the chief correlates of changes in the social character, Riesman,[108] the social psychologist, constructed three types of social character: tradition-directed, inner-directed, and other-directed. Havighurst and Taba,[69] emphasizing the moral aspects of character, delineated the following personality types: the self-directive person, the adaptive, the submissive, the defiant, and the unadjusted.

In the development of psychoanalysis there have been two main trends toward a theory of characterology: the first one appeared during the pre-ego psychology period, when the libidinal point of view (zonal phase) was dominant; the second one appeared following the inclusion of the structural point of view. Thus, the first phase emphasizes the erogenous zones as the main determinants and postulates oral, anal, phallic, and genital traits and the oral, anal, phallic, and genital character. The second phase—with the new orientation of the libidinal-structural concept of the personality; id, ego, and super-ego—provided a much broader perspective. In his further elaboration of the structural aspects of personality, Freud[45] stated:

> Character belongs entirely to the ego and . . . the super-ego was the most important and decisive element; next came identification with the parents of a later date and with persons in authority, and the same identifications as precipitates of abandoned object-relations. Contributions which are never apart, are the reaction-formations, which the ego acquires, first in making its repressions, and later in a more normal way, in repudiating undesirable impulses.

A third classification system may also be considered—ego types such as the inhibited, controlled, impulsive, aggressive, and even delinquent ego.

Where Freud dealt with problems of character, it was usually in relation to the specific traits of character most often related to certain libidinal zones. His discoveries in this area which appeared in the earlier papers,[36] have led to further development of these concepts, e.g., Abraham,[1] Jones,[78] Ferenczi,[27] Coriat,[20] Glover,[57] etc. Freud realized that there were possibilities of constructing other types of character when he said, "One ought to consider whether other types of character do not also show a connection with the excitability of particular erotogenic zones."[36] He was hinting at the urethral zone when he indicated the intense burning ambition of those who formerly suffered from enuresis.

R. Sterba[118] combines a descriptive and psychoanalytic approach in stating:

> Character designates the features of personality which are more or less indelibly engraved upon it, features which express themselves in actions and reactions, features that are "characteristic" of the individual, features by which one ego structure can be differentiated from others.

Anna Freud[32] suggested that character formation is the whole act of adopting habitual attitudes by an individual ego in order to solve the conflicts that arise in choosing which instinctive urges to help toward satisfaction,

Downloaded from www.pdfbooksfree.org.in

which to oppose, and what methods to adopt in the ego's defense against the threats represented by a painful outer world as well as a powerful inner world.

## ¶ Characterology and Typology

There has been an apparent disregard of typology in psychoanalytic theory, paralleling its inattention to psychopathy. Here also there are logical and historical explanations: (1) The word typology may suggest something fixed, static, constitutional, in opposition to dynamic explanations. (2) The concept of typology may seem to run counter to the fact psychoanalysis has demonstrated—that all symptoms are multidetermined and that the character of the individual is a complex composite of many factors. (3) Psychiatric typologic studies, for example, Kretschmer,[82] have not proved fruitful for psychoanalysts because they cannot be integrated or understood within a psychoanalytic frame of reference. (4) There is a tendency in the psychoanalytic literature to try to fit the manifestations of human behavior into the theoretic formulations under which neurosis and psychosis can be subsumed. Some authors go so far as to envisage the explanation of all personality disorders of a nonorganic nature within the orbit of neurotic mechanisms, thus including psychoses as a severe form of neuroses; i.e., similarities are maximized and differences minimized (e.g., Saul,[110] Bowman and Rose[16]). (5) Freud, by broadly dividing the neuroses into transference and narcissistic neuroses, may have inadvertently contributed to this trend, although he indicated that neuroses and psychoses were different qualitative entities.

The absence of a psychoanalytic typology may also be explained by the absence of a complete theory of character structure. Now, however, in view of our present understanding of ego functions, it would seem that the construction of a psychoanalytic theory of character structure is due and that, when it is drawn, it will form an important architectural plan in psychoanalytic theory and practice, furnishing a blueprint for the problems of the choice of the neurosis, psychopathy, psychosis, and psychosomatic disorders and perhaps a closer link to psychiatry and medicine.

The total personality, in a psychoanalytic frame of reference, involves many dynamic aspects. If we are to coordinate the topographical agencies (the id, ego, and super-ego), the libidinal development, mental principles, and object relationships within the single framework of the nature of the total personality another dimension—the structural aspect—proves most useful.

Although Freud indicated that mental activities, in order to be fully understood, should be explained topographically, dynamically, and economically, this conception was applied primarily to the nature of symptoms; it was not expanded to encompass the total personality. The concept of the structure of the total personality would be a broader, inclusive one, integrating all aspects and levels. Such integration seems logical, particularly since the conceptions of structure and process can be complementary rather than antithetical. Furthermore, structural analysis and synthesis will provide a basis for the further development of psychoanalytic typology, which is as yet in its infancy.

The emphasis, in psychoanalysis, on causation—on "why," "when," and "how"—has delayed the development of adequate definitions of "what." A broad nosology of psychobiologic illness has not yet evolved, partly as a result of the neglect of typology and character theory. This fact has hindered comparative studies of the evaluation of psychoanalytic therapy. It is no accident that the statistics of patient-illness treated psychoanalytically are given in terms of discrete symptoms—for example, impotence, frigidity, enuresis, etc. Kubie[83] has emphasized the importance of a more coordinated approach, as did Brierley,[17] who recognized the need for clarification in the area of typology in her attempt to formulate a theory of personality.

Freud laid the groundwork for a beginning typology but confined himself to libidinal considerations in classifying certain purely psychological types. In the sphere of character, however, in which all components of the personality —biological, psychological, and sociological—

Downloaded from www.pdfbooksfree.pk

should be envisaged, one questions whether character types can be viewed only psychologically. Freud implied that biological factors should always be taken into consideration. In *A Psychosexual Study of Leonardo da Vinci*,[42] he stated: "The tendency to repression, as well as the ability to sublimate, must be traced back to the organic bases of the character, upon which alone the psychic structure springs up." In fact, he[43] states: "It will be most valuable of all if we can make our classification on the basis of a regularly occurring combination of physical and mental characteristics." Nevertheless, his approach to typology was colored more by his earlier thinking than by his later conceptions of the total personality, and he dealt largely with libidinal types without encompassing a holistic point of view. An ideal typology would comprise libidinal, aggressive, and ego features with their characteristic defense mechanisms.

Freud distinguished three main libidinal types according to the allocation of the subject's libido mainly to one or another region of the mental apparatus. The three types were (1) the erotic, in whom the relatively largest amount of libido is focused on love, (2) the obsessional, in which the super-ego exercises supremacy, and (3) the narcissistic, in the main negatively described, in which no tension exists between the ego and the super-ego. Usually the three types appear in mixed forms as erotic-obsessional, erotic-narcissistic, and narcissistic-obsessional, with the erotic-narcissistic the most common.

In the sphere of character disorders most attention has been paid to those disorders more closely allied to the neuroses. Thus there has been an extensive psychoanalytic literature on the hysterical, compulsive, and narcissistic character neuroses, with their libidinal relationship respectively to the genital, anal, and oral libidinal zones. As has been mentioned before, a character neurosis is composed of a mixture of these types, and each is designated as a specific neurosis according to the most predominant feature.

I shall describe these types in brief detail (and mention a few others often discussed in the literature) before proceeding to a lengthier description of a suggested fourth type to be included in this system of characterological typology.

## ¶ Genital Character Traits: the Hysterical Character

Genital character, as applied to a "normal" person, is essentially an ideal concept. It implies that ambivalence has been overcome and that instinctual energies are economically regulated. In the genital character, periodic discharge of libidinal tension reduces the instinctual demands on the ego. The ego takes over, without any guilt feelings, the genital libido and certain pregenital tendencies of the id for gratification. It sublimates natural aggression and certain aspects of the pregenital libido in social action. Because the ego has no negative attitude toward the id as far as genitality is concerned, it can all the more easily impose inhibitions on it, since it does not interfere in the main respect wth libidinal gratifications. This seems to be the only condition under which the id can be held in check without recourse to repression.

With the giving up of the wish for incest and the wish to eliminate the father (mother) —in other words, with the achievement of the post-ambivalent genital stage—genital interests become transferred to a heterosexual object which does not, as in the case of the neurotic character, actually represent the incest object but instead has taken its place. The Oedipus complex no longer exists in actuality; it is a moot question whether it is successfully repressed or is free of cathexis. Pregenital tendencies, such as anality, oral eroticism, etc., are anchored partly in cultural sublimations and partly in the forepleasure acts; at any rate, they are subordinated to genitality. Aggression is also sublimated in social achievement to the extent to which it is not a part of normal genitality—it never urges for direct and exclusive gratification. This distribution of instinctual drives satisfies not only the true genital drives but also the pregenital libidinal and aggressive

Downloaded from www.pharmacy.org.in

tendencies. The more the two systems, genitality and pregenitality, communicate with each other, the more complete is the capacity for satisfaction and the less does one find pathogenic stasis of libido.

In the case of hysterical character, one finds that the problem lies in a fixation on the genital phase of infantile development. The Oedipus complex unresolved, there is a strong incestuous wish always in operation; the direct genital aggression of the hysterical character represents both the incest wish—which has retained its full cathexis—and the attempt to escape the anxiety of the incest wish by a form of direct confrontation of the fear, a never-ending and never-successful attempt to feel out, as it were, the nature and magnitude of the infantile dangers.

The hysterical character, more predominant in the female sex, is evidenced by coquetry in walk, expression, and speech, together with a strong apprehensiveness. More hidden traits are those of lability of emotion, unexpected behavior, strong suggestibility, and a tendency toward representing fantasy as fact. Because the incestuous objects have an actual cathexis, or the corresponding libido is warded off by mechanisms which supplement repression, the hysterical character is usually more or less orgastically impotent.

To the extent to which other than genital mechanisms are found in the hysterical character, they no longer belong specifically to this character type. For example, depressive mechanisms are common, and in these cases the genital-incestuous fixation is in part replaced by a regression to oral mechanisms. The hysterical character, then presents itself in pure form if it is agile, nervous, and lively; if it is depressive, autistic, and retiring, it shows mechanisms which are no longer specifically hysterical.

## ¶ Anal Character Traits: the Compulsive Character

Persons whose instinctual life is anally oriented show certain character traits which are partly reaction formations against and partly sublimations of anal-erotic activities. Specifically, orderliness, frugality, and obstinacy are clear indicators of the anal orientation. In the case of compulsion neurosis, one finds an intensification of these trends.

Anal character traits are formed around the training for cleanliness in infancy, when the child must forego an instinctual pleasure in deference to the demands of society. At the same time, the child is acquiring an active mastery of his instinctual drives. Whether or not this period is traumatic for the child is apt to determine the degree to which he develops strong anal traits of character.

Frugality represents a continuation of anal retention; it can be motivated either by a fear of losing or by erogenous pleasure. Orderliness is an elaboration of the obedience to the environmental demand to be clean; obstinacy, on the other hand, represents the rebellion against these environmental demands. Stubbornness, or obstinacy, can also represent getting one's way against superior forces. As the child refuses to produce feces for the adult, he is expressing an active hostility through a passive form of aggression. On the other hand, orderliness, punctuality, propriety, all represent obedience and are revealed as reaction formations. Frequently these reaction formations break down and the orderly person becomes surprisingly disorderly.

Anal orientation implies a high allocation of libido to the super-ego. Speaking of the compulsive type who has achieved successful sublimation of his anal-erotic conflicts, we find a high degree of harmony between id and super-ego. The genital libido, being gratified directly, is not hidden in the ego-ideal strivings. Social achievements, therefore, are not a proof of potency, as in the neurotic character, but are a means of providing a natural narcissistic gratification. Without potency disturbance, there are no feelings of inferiority. The ego-ideal and the real ego do not differ greatly from each other; there is consequently, no appreciable tension between the two.

In the compulsive neurotic character, on the other hand, there is a marked conflict between id and super-ego. A major factor in compulsion neurosis is the existence of the unresolved

Downloaded from www.pharmkiran.org.in

Oedipus complex. As a result, the incest prohibition, which is the core of the super-ego, is also fully maintained, disturbing mature sexual relationships. The sexual and aggressive repressions intensify sadistic impulses, which express themselves, among other ways, in a harsh morality. Since there is often a more or less conscious feeling of impotence, social achievements become primarily compensating proofs of potency. These, however, cannot replace the genital potency feeling, and for this reason the neurotic character is troubled with inner emptiness and feelings of incapacity—a constant sense of inferiority. Thus, in time the positive demands on the ego are increased steadily, while the ego, impotent and doubly paralyzed by inferiority feelings, becomes more and more incapable.

One of the most striking phenomenon in the compulsive character is the blocking of affect. The numerous defense mechanisms have done their work effectively, resulting in a restrained, self-controlled individual, lacking in spontaneity and cautious in his actions. The typical mode of repression in the compulsive character is dissociation of affects from ideas, so that frequently highly censorable ideas can appear in consciousness. Other defense mechanisms following regression are reaction formation, isolation, and undoing used against pregenital strivings. From this, one also arrives at the affective anchorings of the first identifications and the super-ego: The demand for self-control, originally imposed from the outside on a resisting ego, was internally accepted. More than that, it became a rigid, chronic, unalterable mode of reaction; this could be achieved only with the aid of repressed id energies.

We find, then, two layers of repressions in the compulsive character: more superficially, the sadistic and the anal; more deeply, the phallic ones. This corresponds to the reversal of direction in the process of regression. What was more recently invested with affect in the process of regression lies closer to the surface; the object-libidinal genital impulses are most deeply repressed and covered up by layers of pregenital positions. These structural relationships make clear how erroneous it would be to try to make the compulsive understand affectively the weak manifestations of genital object-strivings before having worked through the pregenital layers. If one were to try to do this, everything would be accepted coldly or warded off with doubt and distrust.

## ¶ Oral Character Traits: the Narcissistic Character

Oral character traits are consistently recognizable in emphases on taking or giving which indicate the oral origin. Self-assurance and optimism, for example, would indicate pronounced early oral satisfaction. The not uncommon traits of generosity and altruism, which contain a high element of narcissism, are oral traits reminiscent of the "nursing mother," and represent identification with the object by whom the person wants to be fed. Displacing "hunger" to the mental field, curiosity may become an oral trait.

In the sense of normal or healthy character traits, narcissistic trends refer to the goal and origin of the cathexes—implying that the cathexis is of a libidinal nature and that it is not only turned toward the inner world but has pertained to the ego and emanates from it. In the strict dictionary sense, oral traits and narcissistic trends cannot be used as terms for describing object relationships. For, reverting to the idea of primary narcissism, just as the infant experiences external satisfactions as part of itself, undifferentiated from its own body, orality and narcissism imply the containment of the ego in any act. In actuality, normal narcissism refers to that ego cathexis which enters into relationship with the external world and with object representations. These cathexes are ego libidinal in nature. Normal narcissistic fantasies are in comparative accord with reality and do not involve a high degree of infantile striving for omnipotence. The narcissistic character appears self-confident, often aggressive, impressive, and vain. In contrast to the compulsive character, he can be openly aggressive and sadistic.

Oral neurotics—or narcissistic characters—show the fixation on the oral infantile period. Such persons require a constant source of sup-

Download from www.brautbar.org.il

plies from the external world for the satisfaction of their immediate needs. One finds, in this category, the "independent" personality who has more or less regained the security of primary narcissism and feels that "nothing can happen to me." On the other hand, one finds the dependent neurotics who, fixated in the infantile relationship to objects, must look to the external world for every kind of gratification. The chameleon personality who can do nothing but fulfill the assumed expectations of others indicates multiple and evanescent identifications. Such persons have not progressed from the infantile stage of object relationship which is identification.

Oral deprivation may determine either a pessimistic (depressive) or sadistic (redress-demanding) attitude, each expressing the fixation to the world or oral wishes through the demand that others look after him. As in the two substages of oral eroticism, this demand may be expressed either passively or in an active oral-sadistic manner. Identification with a frustrating mother can produce a fixed unwillingness to give anything to others. In all such cases of narcissism, one finds a high proportion of libido directed to the ego.

## ¶ Some Other Character Disorders, in Brief

As the interest in ego psychology has developed, a variety of character disorders have been delineated in children and adults. I shall mention briefly some of these areas; however, these disorders require further detailed study to align them within a systematic framework of medical psychology.

We find discussed, among the character disorders of children, the autistic child (Kanner), the atypical child (B. Rank), and children with ego variations (Beres). The literature pertaining to adults is quite extensive; however, a few special types are the "as-if" (H. Deutsch), persons with ego-modifications (Freud), pregenital and ego-defect characters (Hendrick), persons with ego distortions (Gitelson), and individuals with borderline conditions (Greenacre).

Among character disorders related to borderline states and psychoses, we would include perversions and drug addictions, which are discussed in Chapters 29 and 30. These conditions are characterized primarily by a disturbance in the ego, which is fragile, vulnerable and shows some impairment in reality-testing. The object relationship of these individuals is unstable and there is an impairment in their capacity for identification. There is a high degree of narcissism and intense oral fixation, and defusion of instincts may occur—giving the impression that their aggressive energy has not been sufficiently neutralized. In these disorders the more primitive mechanisms of defense, introjection, and projection are especially prominent.

Although there are many character disorders related to borderline and psychotic conditions, only a few types will be briefly considered. The cycloid type is extroverted, outgoing, with tenuous ties to many objects in the external world. He is subject to variations in mood, with mechanisms similar to those encountered in the manic-depressive psychosis. Abraham[1] indicated that the basic character structure of these individuals is similar to that found in the obsessional neuroses. Denial is the major mechanism of defense utilized in dealing with their instinctual drives and reality. The schizoid type is autistic, shy, introverted, and withdrawn. He may go through life restricted in his object relationships and emotionally detached without ever developing a psychosis. Under adverse circumstances, e.g., intense emotional traumatic incidents, a psychotic (schizophreniclike) episode may erupt, indicating a fragile ego which is momentarily disrupted. The paranoid type is recognized by his suspiciousness and jealousness and a heightened sensitivity in perceiving the unconscious of others, especially their hostile intentions. These three types give the impression that they harbor a latent psychotic core and that, under certain stressful situations, a transient psychosis may become manifest.

## ¶ The Impulsive Character

The phenomenon of impulsiveness has not been accredited the importance that it deserves in either the theory of character development

Downloaded from www.brainpay.com

or the theory of neurotic formation. If an impulsive type were to be added to the three types suggested by Freud, a much broader area in characterology would be encompassed. With this addition, a greater richness and more precise differentiation in the mixture of types would be possible, with the ideal "norm" probably consisting of an erotic-obsessional-impulsive-narcissistic mixture.

Just as aggressiveness is neutralized by eros, so it may be that impulsiveness is balanced by compulsiveness. There has been much study of the origins of the compulsive neurosis and the compulsive character, but relatively little of impulsiveness and of impulsive character and psychopathic personality (as Freud related types to pathology—for instance, the erotic to hysteria, the impulsive type may correlate with psychopathy). The mixture of impulsive-compulsive-narcissistic types would probably furnish us with the matrix for the large, unwieldly group of individuals who are commonly said to have borderline conditions.

In discussing the above problem elsewhere,[91] I suggested that, if the urethral zone is included in the theory of erogenous zonal phases, it is possible to round out the libidinal series as a developmental sequence; thus, the urethral trait and the urethral character can be envisaged logically in the typologic system that preceded the structural point of view. To reconcile the impulsive type with Freud's three libidinal types within the structural framework presents greater difficulties. Freud's emphasis was on the creation of a normal typology in which there was a harmonious balance between the three agencies. The addition of a fourth type raises the question of the psychic agency to which the libido might be ascribed. This problem is resolved if one assumes a weak super-ego, so that tension arises between the ego and super-ego.

It may be that the concept of the impulsive character could be further divided into two types: (1) the impulsive psychopathic character, which would embrace the psychopathic personality of psychiatry and be consistent with the group designated by Glover[56] as impulsive and with the impulse disorders described by Frosch and Wortis,[52] and (2) the impulsive neurotic character, which has been described within the psychoanalytic theory as the impulsive character by Reich,[104] as the neurotic character by Alexander,[4] and as the reactive group by Glover.[56] The first type would be considered more alloplastic, with ego disturbances less serious in nature than those found in the psychosis but involving more impairment than is present in the neurosis. The second would be much more autoplastic, with neurotic mechanisms of the compulsive form.

The impulsive neurotic character presents dormant psychopathic tendencies which are held in check by the compulsive neurotic components of his character. When these components are predominant, the individual behaves like the severe compulsive neurotic, showing marked inhibition, feelings of guilt, ambivalence, doubts, and suffering. Psychoanalysis finds evidence in such patients of a mixture of the features found in the impulsive psychopathic character and those characteristic of the compulsive neurotic character. It should be kept clearly in mind that persons with impulsive psychopathic character represent an extreme type. There are many individuals with distorted characters, with super-egos which corrupt easily, who perpetrate crimes in a most sophisticated manner but who belong to types quite different from the impulsive psychopathic character. The disturbances in their character structure are probably not as pervasive as in the impulsive psychopathic character nor do they possess a similar psychosomatic substructure.

The relationships between psychopathy, compulsive neurosis, borderline states, and the psychoses become easier to trace, once the typology is expanded to include a classification of impulsive psychopathic character. In general, the compulsive neurosis tends to strengthen the character structure through the capacity to bind anxiety and to furnish defensive reaction-formation mechanisms. In the psychiatric literature there have been numerous studies on the relationship of compulsive neurosis to the psychoses. Some authors stress the belief that when the individual with a severe compulsive neurosis breaks down, there is a tendency to schizophrenia: others see the direction as one toward manic-depressive psychosis. With the

Downloaded from www.cbtaudiolibrary.com

inclusion of the impulsive type of character and the recognition of borderline disorders whose matrix is a mixture of impulsive-compulsive components, decompensation of the compulsive neurosis might be viewed as the breakthrough of impulsive factors also resulting in psychopathic reactions. Thus, the particular form of reaction to the devolution of the compulsive neurosis would be dependent on the type of personality organization with its specific sensitized loci of ego-libidinal fixations.

I shall not, at this point, discuss in detail the impulsive psychopathic character from the standpoint of zonal phases in libidinal theory. In a previous book,[94] however, I discussed certain relationships between the lowest incidence and lowest persistence of enuresis and compulsive neurosis and manic-depressive psychosis. In the same study, I indicated that enuresis may have different meanings according to the basic structure of the persons who suffer from this symptom.

If one examines the psychodynamics of the resolution of emotions in a similar way—from the standpoint of the variability of meaning of a symptom—it becomes possible to see how hate is resolved differently according to character structure. For instance, it has been found that hate and aggressiveness are most freely expressed in the impulsive psychopathic character. When we differentiate the two main types of impulsive character as suggested (impulsive psychopath and impulsive neurotic), a rounded-out picture appears of the different ways in which hate and aggressiveness are resolved in the continuum of character structures.

Here again, it must be emphasized that there are no pure types of character structures. In the admixtures that occur, however, there may be a predominance of one type which gives the main coloring to the total personality. In the individual with a predominant character structure of a psychoneurotic type, for example, with hysteria, the symptoms reflect primarily the vicissitudes of dealing with love and its sexual aspects; when confronted with impulses of hate, such a person wards them off through the mechanism of repression, the typical defense of the ego in hysteria. In the compulsive neurotic, with his many reaction formations, aggression is bound and, together with anxiety, gives rise to the cardinal symptom of ambivalence. When psychosomatic symptom formation is the chief tendency of a personality disorder, the patient has the possibility of binding or neutralizing aggressiveness within an organ or organ system. This capacity is predicated on the presence of compulsive components in the character structure.

In the impulsive psychopathic character, along with impulsiveness there is an enormous quantity of aggressiveness in the form of hate that is freely expressed. Certainly the impulsive psychopathic character is not ambivalent; he does not hesitate to give vent to his feelings, a process which in turn leads to his fight with the outside world. In the impulsive neurotic character, however, aggressiveness is somewhat bound and neutralized by defensive reaction formation mechanisms. Clearly, the difficulties of the impulsive psychopathic character are externalized, whereas the difficulties of the impulsive neurotic character are sufficiently internalized to account for the greater degree of conflict within the latter. Finally, in the psychotic character, the greatest degree of defusion of instincts occurs. Where the problem of dealing with hate is paramount, as in the paranoid individual, aggressiveness and hate are dealt with in a distorted manner through the defensive mechanism of projection. In brief, viewing the typological continuum as a whole, aggressiveness in the form of hate is resolved by being repressed, turned inward, bound, expressed, or projected according to the predominant type of character structure.

By setting up the impulsive type of character we may be opening the road to the inclusion of clinical conditions which previously were not encompassed in the scheme of typology or psychopathology. Thus the syndromes of traumatic neurosis and epilepsy may be envisaged in closer relationship with impulsive types than with any other categories. The three conditions of psychopathic personality, traumatic neurosis, and epilepsy have in common a high degree of narcissism, a fragile ego in which both the ability to bind anxiety and the threshold to external and internal stimuli are low, a marked tendency to respond with action (action-syn-

Downloaded from www.pdfbooksfree.pk

drome-Kardiner[80]), and a lack of inhibition with a high degree of impulsivity. It may be of some significance that Wheelan,[121] in an intensive investigation of a pair of uniovular twin brothers who were extremely different in moral organization and social adjustment, found that one was a serious delinquent and a psychopathic personality, the other was morally stable but subject to attacks of unconsciousness which were considered to be epileptic.

Of neurophysiologic significance is the presence of electroencephalographic abnormalities, specific for epilepsy and nonspecific for psychopathic personality. Evidence for associating electroencephalographic findings in aggressive psychopaths with epileptic cerebral pathophysiology has been presented by Hill.[71] The presence of an abnormal electroencephalogram among psychopathic personalities raises many questions which cannot be answered in this presentation. For example, is such a finding coincidental, is it another discordant manifestation at the cerebro-physiologic level,[95] or does it have more specific implications of organic disease of the brain reflected in a defective ego?

Finally, the continuum of impulsive character would range from the impulsive psychopathic character, traumatic neurosis, and epilepsy at the simplest and most primitive pole, with the impulsive neurotic character at the most complex pole. Thus neurotic and conflictual features would be least evident in the impulsive psychopathic character, greatest in the impulsive neurotic character. The impulsive psychopathic character and the epileptic character would have more neurophysiological elements in common—e.g., electroencephalographic abnormalities—the individual with traumatic neurosis and the impulsive neurotic character more psychodynamic features. From the standpoint of Freud's mental principles, a hierarchy might be structured, with the repetition compulsion more dominant at the pole of impulsive psychopathic character and the reality principle developed to the greatest degree in the impulsive neurotic character. Here again one realizes that mixtures of these two particular types do occur, but for the purposes of emphasis they are presented in this schematic manner.

## The Impulsive Character and Acting Upon Impulse

Atkin[8] and A. Reich[102] have described patients with character problems in an illuminating manner and demonstrated elaborate specific defensive structures. A. Reich's patient, as a matter of fact, was an obsessional character. If one swings to the other extreme, a composite picture of the opposite type of character—the impulsive character with acting-out tendencies—becomes evident. Viewing character types as a continuum, the compulsive character appears at one end and the impulsive character at the other. Within this continuum, I shall attempt to delineate the impulsive character from a typological point of view, although the concepts are elaborated from clinical experience.

In neurosis, the cardinal manifestation is that of conflict. The solution of a conflict usually results in a compromise formation and takes the form of a symptom. Thus, the symptom is ego alien and results in an awareness of illness with suffering. In impulsive character disorders the solution of the conflict is resolved in a different manner and may actually be taken up into the character structure. Whatever difficulties there may be, these are ego syntonic without an awareness of illness and little, if any, suffering. Furthermore, in the neurosis there is a struggle between the id, ego, and super-ego. In the character disorder the struggle exists primarily between the ego, super-ego, and the outside world. This process is similar to what occurs in a psychosis, and yet it has certain differences. In the psychosis, there are distortions of reality such as delusions and hallucinations. Cleckley,[19] interestingly, considers the psychopathic personality closely allied to the psychosis; he sees it as having a semantic nature in which experience as a whole cannot be grasped or utilized in its ordinary significance or meaning. Freud[44] suggested that the illogicalities, eccentricities, and follies which are encountered in the analysis of characterological attitudes have a relationship to the psychoses which is similar to that of the perversions to the neuroses.

Downloaded from www.dbsalibrary.org

In the severe type of character disorder in which acting upon impulse is prevalent, there is a difficulty in control, indicating a disturbance in inhibition, an incapacity to delay action in which tension is expressed freely. These individuals show a pregenital orientation and there is a similar configuration of the ego. The ego characteristics of these individuals are probably related to the type of ego found in borderline conditions. Some of these variations have been described as ego-modifications by Freud,[35] the ego-defect neuroses by Hendrick,[70] and fragmentation of the ego in the atypical child by Rank and Macnaughton[100] and Beres.[10] The ego of persons who act upon impulse is not equipped to bind anxieties. This accounts for the low threshold to stimuli. One finds in them a high degree of uninhibited aggressiveness with a lack of fusion of the libidinal and aggressive instincts. The main mechanisms of defense available to this type of ego are those of introjection and projection.

Consideration of the super-ego in relation to the impulsive character disorder indicates that the super-ego may be malformed, implying an incomplete formation. According to Johnson,[76] the condition of super-ego lacunae is a type of variation of the super-ego. The capacity to become neurotic, to develop feelings of guilt and shame are dependent upon the full evolution of the super-ego.

Of equal importance in considering the impulsive character disorder is the disturbance in object relations. Individuals with such disturbances have difficulty in establishing good basic object relations; the object is sought primarily for need satisfaction.

Impulsive character disorders are specially characterized by action tendencies which include the living out of impulses, acting upon impulses, and "acting out." The phenomenon of "acting out" was first recognized as resistance in the course of psychoanalytic therapy and was used in a very specific sense by Freud:[39] namely, that, although the patient does not remember what is forgotten and repressed, he expresses it in action, he reproduces it in behavior, and he repeats without knowing that he is repeating. The term "acting out" later came to be used generally to apply to almost any overt behavior that had social implications, usually of a derogatory nature.

The tendency to action is least marked in the individual with a compulsive obsessive character structure and most evident in the individual with an impulsive psychopathic character. The word behavior implies action, but our concern here is that type of action which is unrestrained, impulsive, and detrimental to either the individual or society.

In individuals who act upon impulse,[91] there seems to be a primary orientation to senses and things, so that perception and concreteness take precedence over conception and abstraction. Furthermore, retardation in the development of language is reflected in a high incidence of reading disability among delinquents. Both conditions may be related to an overcathexis of the tactual sphere and preverbal state and a lack of differentiation of the ego and super-ego systems. There is a lack of differentiation in the character structure of individuals with these disabilities. When they experience conflict, it is characteristically generalized and diffuse, in contrast to the more specific, isolated conflicts which are present in the neuroses. The tendency to react in an all-or-none manner leads to events being experienced dramatically and interpreted subjectively as crises. The actions of these individuals resemble qualities of the primary processes; their sense of time is seriously impaired, which probably contributes to the reaction of urgency to trivial events.

Since the concept of character, in a general sense, is involved with a social, evaluative judgment, the factor of control, which is associated with the capacity to tolerate frustration, anxiety, and aggression—thus allowing behavior that is in conformity with social and moral expectations—is an important factor in evaluating character.

It is no accident that the individual whose impulses are the least controlled—the persistent delinquent—manifests the greatest deficiency in the ability to control. Persistent enuresis and persistent delinquency generally indicate character disorders with the common denominator of lack of control.[93] Obversely, overcon-

Downloaded from www.dbraulibrary.org.in

trol of impulses and actions even to the point of passivity and hyper-morality would be found in the obsessive compulsive individual. In view of these observations, the need for studying the relationship between all types of action in behavior such as acting upon impulse, "acting out," "living out," abreacting, becomes obvious. Furthermore, it seems that as much emphasis should be given to the somatopsyche as has been given to the psychosoma. The complexity and variegation in character structure and the total personality make it difficult to include all the pertinent and significant basic factors.

One of the difficulties in developing a theory of character is the fact that the theory of neurosis had as its central core the factor of conflict. Atkin[8] and A. Reich[102] have demonstrated sublimations and reaction formations in their patients as ways of dealing with conflict. When traits of character, however, develop as a solution, they become ego syntonic and thus create more difficulties for the environment than do neurotic symptoms. Although Freud dealt primarily with reaction formation and sublimations and seldom elaborated upon that part of character which pertains to unchanged perpetuations, he stated, in discussing character formation:[36]

> One can give a formula for the formation of the ultimate character from the constituent character-traits: the permanent character-traits are either unchanged perpetuations of the original impulses, sublimations of them, or reaction-formations against them.

In the impulsive psychopathic character with a history of persistent enuresis, the continuation and persistence of enuresis is an "unchanged perpetuation of the original impulse," where there has been little if any sublimation of the urethral component. The tendency to uninhibited reactions as revealed in the persistent enuresis permeates the whole character. It is this writer's impression that in the character disorder in which primary acting out or acting upon impulse[91] plays such a predominant role, a large increment of unchanged perpetuations of the original impulses will be found.

## ¶ Biological Aspects of Character Structure

It is necessary to regard character structure as a biopsychosocial phenomenon. American psychoanalysts tend to shy away from the subject of constitution, as if this connotes an irreversible process with a pessimistic outlook. There is something in the American scene which fosters an exceedingly optimistic point of view and appeals especially to that group of psychoanalysts whom we might label as culturalists. Freud[48] always took constitutional factors into consideration in his explicit statement about the complemental series: "The constitutional factor must await experiences before it can make itself felt; the accidental factor must have a constitutional basis in order to come into operation." Momentarily, I propose to be the devil's advocate and discuss some aspects of constitution which are ordinarily bypassed; I do not, however, mean to minimize the experiential and psychological factors which play such a significant role in the development of character structure.

There are many biological factors which need to be considered—some of these will be elaborated, others will be mentioned briefly. The factor of age must be taken into consideration, with character formation and development varying accordingly. Organic disease of the brain may lead to a reduction in the inhibitory factors and result in a caricature of character traits. There are specific psychoses which occur more frequently in certain racial or ethnic groups, e.g., the higher incidence of manic-depressive psychoses among the Jews. Drugs, hormones, and body build play roles in the determination of character structure.

The problem of integrating the organic bases of character and personality is a difficult one, methodologically. So too is the construction of an acceptable theoretical framework. Nevertheless, the factor of basic disposition related to constitutional factors requires consideration, whether one regards this disposition as psychosomatic or somatopsychic.

From the time Galen described the four humors to the period when Freud formulated libidinal types, medicine has recognized the relationship of somatic factors to character and personality. Kretschmer[82] attempted to correlate certain body types with specific mental disorders. In this country, Sheldon and his co-workers[111] developed a more intricate schema and related it to embryologic conceptions. Utilizing Sheldon's concepts, the Gluecks[60] reported a very high incidence of mesomorphic (muscular, solid) dominance in the body structure of persistent delinquents, and they also found less disharmony in physique among a delinquent group than in a nondelinquent group.

In the field of psychosomatic medicine, similar efforts were made in drawing profiles of personality characteristic of specific disease syndromes, e.g., Alexander and his co-workers,[5] Binger, *et al.*,[14] and Dunbar.[23] Alexander sought to establish whether there is any constant parallelism of psychologic features in cases with the same organic syndromes of the gastrointestinal tract. Apart from identical conflict-situations (intensive in-taking tendencies both of a passive-receptive and of an aggressive-taking nature), a remarkable similarity has been found with respect to emotional attitudes toward the environment. These conflict situations may develop in very different personalities. In contrasting patients with ulcerative colitis, Daniels' impression[21] was that the difference lies in the more narcissistic organization of their personalities, the underlying reaction being more closely related to a psychotic than to a psychoneurotic one. Results have been suggestive, but inconclusive.

Electroencephalographic finding have indicated some type of nonspecific abnormalities of the electroencephalogram in certain clinical entities. Hill[72] reported that the electroencephalograms of behavior problem children and adult psychopaths often showed abnormalities which in younger age groups would be considered normal. The relationship of certain conduct disorders to organic disease of the brain was especially highlighted by Bender[9] in children with postencephalitis. Glover[55] has proposed a primary functional stage in which there are simple disorders of excitation and discharge without fixed psychic content, giving rise to the purest form of psychosomatic reaction. He[58] goes so far as to raise the question of whether there is a functional delinquency (psychosomatic) as distinct from a "conflict delinquency." From another angle, Jones[77] suggests the presence of an organic factor related to the capacity of inhibition. He stated:

> The capacity to endure the non-gratification of a wish without either reacting to the privation or renouncing the wish, holding it as it were in suspense, probably corresponds with a neurological capacity, perhaps of an electrical nature, to retain the stimulating effects of an afferent impulse without immediately discharging them in a different direction.

In a personal communication, Valenstein, reviewing neurophysiologic studies on animals, stated that there are neurophysiologic receptors and feedback mechanisms between the periphery and the central nervous system which may block the very transmission of perception beyond the peripheral receptors themselves.

Ferenczi[28] speculated that there may be a kind of physiological precursor of the super-ego, which he called sphincter morality. He believed that this physiological morality may form the essential groundwork of later mental morality. Conversely, it is possible that the early sphincter immorality of persistent enuresis foreshadows later social immorality. The data[94] indicating a high incidence of persistent enuresis in severe delinquents would tend to corroborate this thesis. Some of the hypotheses suggested by these observations were: (1) Persistent enuresis is a biopsychosocial paradigm for behavior that is characterized by the lack of control due to deficiency in inhibition. (2) The general pattern of lack of control permeating all levels of the persistently enuretic delinquent-psychopathic personality (impulsive psychopathic character) can be considered as a short-circuiting in a neurophysiologic sense and an acting out (characterological) from the psychoanalytic standpoint.

It is of some moment that contributions to the problem of constitution, predisposition, and innate endowment have come primarily from observations of infancy and childhood. Four

Downloaded from www.dbraulibrary.org.in

main areas might be delineated: (1) sensation, (2) motility, (3) instinctual drives, and (4) the autonomic nervous system. In the sensory field, Bergman and Escalona[11] reported five cases which seemed to indicate a relationship between unusual early sensitivities and psychosis. They suggested that the "protective barrier against stimuli, 'Freud's Reizschutz,'" should refer to all data about the sensitivity or excitability of a newborn infant relating to either outer stimuli (sensorium) or inner stimuli (organic needs). They concluded that an organism insufficiently protected against stimuli by a "thin" barrier may need to develop certain ego functions precociously. These ego rudiments appear to break down under the impact of early traumata. Laufer and his associates,[86] using photo-Metrazol determinations in children with a hyperkinetic impulse disorder, characterized by hyperactivity, shorter tension span, and impulsiveness, showed a lower threshold to stimuli in the children.

Psychologists and psychiatrists have conducted series of interesting experiments on sensory deprivation. Hebb and his co-workers[12] have been studying the effects of isolation, with the aim of reducing the pattern of sensory stimulation to the lowest level. Lilly and his group[87] have carried on somewhat similar experiments reducing the absolute intensity of all physical stimuli to the lowest possible level. Both groups have been studying the effects of sensory deprivation on the reactions of individuals. Some of their findings indicate that, under sensory deprivation, the individual may become apathetic, aggressive, and even confused. In regard to motility, Fries,[49] in a series of publications, classified infants according to their congenital activity into three "normal" types—so-called active, moderately active, and quiet—and two pathological ones at either extreme—hyper- and hypoactive. The hyper- and hypoactive types were more vulnerable to the psychopathies. Mittelmann[97] has published a series of papers on motility and psychodynamics. He believes that the control of motility gradually becomes an important aspect of impulse mastery. The relationship of motility to tics has been demonstrated by Mahler.[89]

With reference to drive variations, Alpert, Neubauer, and Weil[7] have reported a series of studies on the unusual variations in drive endowment. They concluded that the ego, with its own autonomous potentiality of variation, interacts from the very beginning with the drive variations of a given individual and is influenced by these variations, and later the ego itself also modifies the drive expressions.

Regarding the autonomic nervous system from the standpoint of biochemistry, Grinker[64] states that there are many important constitutional differences in biochemical processes which are not clear, yet influence the child's needs and demands. In a clinical study he[64] showed how the ego development was influenced in a child who had celiac disease from infancy. Grinker[65] also remarked that the infant is born with a significantly variable hereditary or intrinsic visceral behavior pattern, which can be measured as a base line, on which subsequent influences impinge, producing alterations. From a study of three-day-old neonates, Richmond and Lustman[106] concluded that inherent autonomic endowment is one of the factors in the autonomous conflict-free sphere of ego development and, as such, participates in and markedly influences subsequent ego development. Studies have also been undertaken on ego variations. From clinical work with children Beres[10] has designated certain types of children as presenting ego variations and Gitelson[54] has described patients with ego distortions.

Greenacre,[63] combining considerations based on the analysis of particularly severe neuroses in adults and reviewing some experimental work and observations in infants and children, has thrown significant light on the general problem of predisposition to anxiety. For example, in a paper on "the biological economy of birth," she states:

> Important in the anxiety potentials in any human being, is the degree of tension existent, dependent on the sensory-motor balance, that is, the ratio between the sensory stimulation and the capacity (development and opportunity) to effect some sort of discharge.

In another paper on "the predisposition to anxiety" she stated:

Downloaded from www.dbraulibrary.org.in

Severe suffering and frustration occurring in the antenatal and early postnatal months, especially in the period preceding speech development, leave a heightened organic stamp on the make-up of the child, . . . this organic stamp of suffering consisting of a genuine physiological sensitivity, a kind of increased indelibility of reaction to experience which heightens the anxiety potential and gives greater resonance to the anxieties of later life.

Stone[115] believes that the earlier and more profound the psychic disturbance in an individual (whether endogenous or experiential), the more liable it is to cause neurotic disturbances of growth, of sugar metabolism, of vascular tension, of cardiac rate and rhythm, and kindred fundamental pathologic changes. From the above reports we see efforts to study the constitution and predisposition pertaining to sensory thresholds, variations in motility, variations in drive endowment, autonomic endowment, ego variations, and the predisposition to anxiety.

I referred earlier to Freud's basic concept of the complementary series regarding heredity and environment. In concluding this section I should like to quote, from "Analysis Terminable and Interminable,"[35] one of his last formulations concerning constitution: "Three factors which determine the result of analysis are the effect of traumas, the constitutional strength of the instincts and changes in the ego."

## ¶ Sociological Aspects of Character Structure

It is interesting that we are freer to approach the so-called normal character types without ethical and moral value judgments, probably because they represent "good" characters in contrast to the neurotic impulsives who represent "bad" ones. This leads us to the question of choice of symptoms—why does one individual develop the "bad" character, another the "good"?

The problem of the choice of neurosis has not been solved; neither has the problem of the choice of symptom and of organ. The insight gained into the dynamics of neurosis led to the concepts of somatic compliance. The problem of the choice of character structure is a much more complex and difficult one, but, just as somatic compliance evolved in the study of the neurosis, the aspect of social compliance must be further delineated in the study of character structure. Hartmann[66] discussed the relationship of social structure to personality type and vice versa—the relationship of personality structure to social change. In fact, he introduced the concept of social compliance when he stated that "a given social structure selects and makes effective specific psychological tendencies and their expression and certain developmental trends."

The solution to the problem of somatic compliance requires the collaborative efforts of the physiologist and the psychoanalyst. The solution to the problem of social compliance requires the integrative efforts of the psychoanalyst and the social scientist. Such interdisciplinary collaboration carries certain dangers—if a psychoanalyst gets interested in the social sciences, he may become a social scientist; if a social scientist becomes seriously involved in psychoanalysis, he may become a psychoanalyst. The analyst might say that the social scientist who becomes an analyst is a better sociologist. When you question the social scientist about the analyst who becomes interested in social science, he will tell you that he is a better psychoanalyst.

The fact that there is an actual contemporary shift to a higher incidence of character problems (Ackerman[2]) compels us to observe more carefully the cultural influences which may play a significant role in this shift. Erikson's *Childhood and Society*,[25] demonstrates how psychoanalytic concepts can include the idea of social compliance. The specific concept which bridges the gap between the inner development of the individual and the impinging forces of culture is his meaningful construct of the idea "identity." The dynamic concept of phases of development, based on libidinal theory yet enlarged to include intimations of social values, is an integrating force. The concept of identity permits us to extend Freud's basic principle of the complementary series within the individual—i.e., the relative inter-

Downloaded from www.chauhanlibrary.org.in

action of constitution and environment—to the enlarged complementary series of the individual and society. Erikson[25] writes:

> The integration now taking place in the form of ego identity is more than the sum of the childhood identifications. It is the accrued experience of the ego's ability to integrate these identifications with the vicissitudes of the libido, with the aptitudes developed out of endowment, and with the opportunities offered in social roles.

An example of social compliance can be found in studies based on observations of men in military service. Porter and the writer[96] reported a high incidence—over 10 per cent—of psychopathic personality and a low incidence—0.3 per cent—of compulsive neuroses among soldiers with neuropsychiatric conditions admitted to hospitals or separated from the military service. The soldier with the compulsive neurotic character structure is able, in military service, to augment and strengthen his defenses, because the military services are vast compulsive organizations. On the other hand, the uninhibited tendencies of the impulsive psychopathic character lead to overt problems in such a closed, restrictive organization. Valenstein, Evje, and this author[119] presented further data which offer some confirmation of the positive relationship of certain personality types (compulsive) to a specific social structure (army).

With this as a background, how can we understand the "so-called normal characters" which Atkin[8] demonstrated were really not so normal? His patients appeared "normal" according to the usual criteria of being able to love, to work, and have satisfactory social relationships. If our culture accepts, as normal, material success, adjustment to reality, and money in the bank (with a premium on the ability to live within one's budget), we can see that the patient Atkin discussed, whose inner economy revolved around the "adding machine complex," balancing input and output with his culture, merely developed a character structure congruous with the current value system. These are aspects of an oral orientation within a social culture which fosters some of these elements. Thus, we see social compliance in this resonance of society with the inner needs of the individual. There is also a kind of inner somatization with an outer social somatization—the concern on inner organs being paralleled by the cathexis on external concrete things; neurotic hypochondriasis and a social hypochondriasis.

Viewing dispassionately the "adding-machine complex" of Atkin's patient, one would describe it as a philosophy in which his inner life is conducted as an efficient business organization—profit and losses are balanced—with an accounting always taking place. It does not require much imagination to find the external counterpart of his culture in the present business world, e.g., Fromm's[50] marketing orientation.

In Atkin's patient, a man's inner business life found its complement in the outer business culture. There are examples which reverse the process, in which a specific cultural pattern may resound on the inner life of an individual. I am indebted to Drs. John P. Spiegel and Florence Kluckhohn of Cambridge, who have given me their permission to use the data that they and their collaborators have obtained in their investigation of the impact of the cultural situation on Italian families, a study titled "Family Processes."[112] In most immigrant Italian families marriages are initiated through familial arrangement rather than on the basis of individual selection. In this Italian custom, the husband is loyal primarily to his family, the wife to hers, thus producing a certain degree of stress. Specifically, there is the constant tension created by the need for individual satisfactions, especially sexual on the one hand, and the need to satisfy the demands of the extended family groups, including aunts and uncles, on the other.

Spiegel and Kluckhohn have been making comparative studies of so-called normal Italian families and "disturbed" Italian families. The combination of loyalty to family, love, and duty gives the impression of an unusual degree of closeness and dependency—a sense of togetherness not only between the individual members of a family but also with immediate relatives. In a "so-called normal" family the only major difficulty observed was the depressive reactions of the wife which occurred dur-

Downloaded from www.pdfbooksfree.pk

ing the summer, when her husband took his vacation with his brothers and left her at home. Her depression and unhappiness lifted when he returned home to her. The immediate precipitating factor was the separation and his seeming preference for his own family.

The presenting problem in a "disturbed" family was a boy of 8 years with a history of asthma, persistent enuresis, a food problem, and aggressive behavior. This family had three children, 3, 8, and 9 years old respectively, who were persistent enuretics; of some interest was the fact that the parents sought psychiatric help only after prolonged discussions with all the relatives. The father was quite narcissistic, suffered from migraine and hypochondriasis, and had a weight problem. The mother was phobic, refusing to leave her home. (This tendency is related to the cultural pattern of immigrant Italian families in which members stay close to home). She also was troubled with irregular menses, gynecological disturbances, and headaches. Her overt expressed wish and longing was for their family to move to another state where her mother lived and rejoin her mother's family.

When separations occur in a cultural pattern which tends to bind the extended family so closely, a disruption in the family pattern is significant. Conflict about separation seemed to occur in both families. In the so-called normal family, the depression of the wife developed when she was separated from her husband. In the disturbed family, although separation as an external event was not so evident, it is of some significance that there was such a generalized psychosomatic orientation. I would specifically emphasize the problems in the boy —eczema, asthma, a food problem, and persistent enuresis. We know that, in this type of psychosomatic problem, the factor of separation of the child from the mother is significant. It may be that I am reading too much into the above example in assuming a relationship between the effect upon the boy's mother of the separation from her own mother and the significance of the child's symptomatology, which seems to exhibit some aspects of separation effect. Nevertheless, although the relationship in this case may be obscure or nonexistent, reactions to the effects of separation in such a cultural pattern and the occurrence of individual psychosomatic symptoms may indeed show a relationship upon further investigation.

The sociological approach by Reiss in his paper, "Delinquency as the Failure of Personal and Social Controls," is quite interesting. He indicates that "primary groups are the basic institutions for the development of personal controls and the exercise of social control over the child. Delinquency may be seen as a functional consequence of the type of relationship established among the personal and social controls."[105] He further expected "that personal and social controls are less effective in governing the behavior of delinquent recidivists than non-recidivists." Thus, there is a common meeting ground in the significant phenomenon of control, as this author[93] previously demonstrated, though Reiss's approach is sociological rather than psychobiological.

Medicine is gradually abandoning the myth of the normal person—although we still think of a person as being healthy—"normal"—if he is not sick. The statistical yardstick is still the measure of all things. From an analytic point of view, there is no such animal as the "normal" person except as an ideal—we are all relatively neurotic. The basic tenets of psychoanalysis affirm that conflict is the essence of life and that instinctual renunciation is the price of being a civilized human being. Paraphrasing Pope's phrase "To err is human," we would say, "To be neurotic is human." If we accept the truth of these concepts, then we would not have to be on the defensive in regard to the criticism that we work only with abnormal people. The more psychologists and social scientists become enlightened to this reality, the less will they be concerned with the problem of normals and controls.

## ¶ Treatment and Summary

Classical psychoanalytic technique was evolved specifically for the treatment of the psychoneurosis, and, before the development of structural theories, the therapeutic emphasis was on the cure of symptoms. Reich[103] led the way to a therapeutic approach to the analysis of character problems. He showed how the

Downloaded from www.pbookshop.com

initial transference resistance was expressed in a form which was characteristic of the patient's character. There was a consistent application of the newer method of resistance analysis to analysis of character, corresponding to the progress of analytic therapy from symptom-analysis to the analysis of the total personality. With the greater knowledge gained by the study of the ego and its defense mechanisms (particularly the work of Anna Freud),[32] the emphasis shifted toward characterological manifestations and the resistances which occurred in the character structure of the individual. Changes in techniques were evolved for the psychoanalytic treatment of children, delinquents, and psychotics. The variations in technique were especially emphasized by Eissler[21] in his statement that the basic model of psychoanalytic technique can be discussed with relative ease in the case of hysteria. More complicated cases in which there is a variation in technique—for example, in the case of a phobic who is advised to face the specific situation which gave rise to the phobia—are designated by him as parameters. This parameter is described as "the deviation—both quantitative and qualitative, from the basic model technique, that is, from a technique which required interpretation as the exclusive tool." It follows that, as a disorder increases in complexity, there will be a greater number and variety of parameters. Tartakoff[118] has done an illuminating study and review of recent books on psychoanalytic technique. A. Freud,[33,34] Glover,[59] and Stone,[116] among others, have written about variations of technique which apply especially to character problems.

A significant first step in the treatment of an individual with a character disorder would be to bring about a state in which the characterological difficulties are converted into neurotic symptoms. If the character disorder is of a serious, diffuse nature, where the patient shows little insight, experiences little suffering, and exhibits ego syntonic behavior, considerable preparation will be necessary.

In this chapter I have dealt largely with the impulsive type (neurotic and psychopathic) of character, inasmuch as this type has received less attention from the psychoanalysts. I hope that this delineation of the impulsive type in some detail may serve as a paradigm of the complexity of a specific type of character with its many facets. There is an enormous psychoanalytic literature on the other types of character[1,20,27,57,78] to which the reader may refer. Such character types as the phobic and hysterical, compulsive, cyclic, and schizoid are discussed by Fenichel.[26] Although, in this exposition, psychologic factors have not been elaborated extensively, I would like to stress that this should in no way minimize the great importance psychologic factors have in the development and formation of the character structure.

CHAPTER 20

# MINOR MALADJUSTMENTS IN THE AGED

Alvin I. Goldfarb

Downloaded from www.dbraulibrary.org.in

THE ABSOLUTE AND RELATIVE INCREASE in the number of older persons in our society has turned the attention of psychiatrists to the ensuing social changes and to the individual problems arising in this age group. The psychiatric problems presented by aged persons are diverse, and the treatment methods—indicated or possible—encompass a broad range. This chapter will deal briefly with an orientation and attitude, stemming from psychodynamic theory and practice, useful in the psychotherapy of the aged. The operational concept discussed may be regarded as basic to the rational medical-psychiatric treatment of aged ill persons but is of especial value when psychotherapy is attempted. Many aged persons can be helped to acquire new ways through increased self-understanding, and even the very old and sick can benefit from reassurance and support. To initiate and maintain the controlled life experience called psychotherapy through which increased self-understanding or augmented confidence and self-worth can be gained, it is necessary to elucidate what reassures and supports the patient and how this may be offered. For this purpose a theoretical framework around which therapeutic action may be elaborated and on which the therapist and his assistants may lean for their own support and reassurance is proposed in this chapter.

## ¶ Historical Data

The number of published psychiatric works on old age and aging is too large to be listed here. Like philosophies, they appear to be "the products or expressions of the general conditions of society" and of their times. There was not a real scarcity of old persons in the past: in 1900, 1 in 25 persons was over 65 years of age, as compared to 1 in 12 in 1955. Until this decade, however, there appears to have been little interest in psychotherapy for the aged.

The lack of clear definition of what is meant by old age has resulted in some confusion. In

1919 Abraham,[1] for example, referred to persons in their 40's and 50's as being of "advanced age." Perhaps this is because he was himself at the time only 31 years old. He recommended psychoanalytically oriented therapy for older persons but was careful to point out that poor vocational and sexual past performance as well as early onset of symptoms were unfavorable prognostic signs. He emphasized the tendency of many older persons to regard the doctor as a father figure from whom will come suggestions and guidance. In 1925 Jelliffe[47] encouraged psychiatric interest in the psychotherapy of persons in the seventh or eighth decades of life. With only one exception, however, his illustrations of successfully treated persons are in the sixth decade of life. Of interest is the exception, a 72-year-old merchant whose temper improved, and whose hypertension appeared meliorated, through therapeutic sessions. He advocated treatment, saying, "Pessimism closes the door—optimism, even if an illusion, is worth the effort." Kaufman[54] and Atkin,[8] in 1940, appeared to regard the climacteric as the onset of old age, and they, too, referred to persons in their 40's and 50's as old or aged.

The importance of considering the older person in relation to the family and to the community was emphasized by Flügel in 1921; in his *Psychoanalytic Study of the Family* he made clear that it is for the well-being of society that there be respectful and helpful attitudes toward older persons, and that the success of a culture may be measured by the extent and quality of its provision for its aged. In an admirable paper, Kardiner,[51] in 1937, outlined the social forces which underlie attitudes toward the aged. The relationship of the subsistence economy to the ability and willingness of the family to protect and preserve the aged and the occurrence of child-parent reversal in attitude and action were cogently discussed by him. He gave an example of successful treatment of one older person which included manipulation of the social environment. Unfortunately, the ages of the persons used as illustrations were not given.

All the authors mentioned were concerned with aging and the aged. However, psychiatric difficulties of the fifth and sixth decades, to which most of them referred, are now better understood as problems of the middle years when many a person sees, or thinks he sees, his true trajectory in life and views it with disappointment, horror, or fright, without being able significantly to alter his course. Although this development probably has nothing to do with "involution," either physical or mental, it is nevertheless the possible beginning of chronic invalidism or of a mental state, which, even if not itself chronic, may create a social situation which steadily worsens. The disorders of middle life, or those developing in later years which are in all significant aspects like them, are dealt with in other chapters.

After World War II, however, a number of authors, notably Cameron,[15] Rockwell,[76] Wayne,[99,100] Herkimer and Meerloo,[45] Grotjahn,[43] Steru,[90-92] and Goldfarb,[32-40] reported specifically on the individual psychotherapy of the aged. Others, among them Zeman,[103-105] Ginzberg,[29,30] Allen,[2-6] Clow,[16] Linden,[60-65] Silver,[88] and Hollender,[46] reported on hospital, group, and milieu treatments. A number of reviews of theoretical and practical value have appeared, and a number of investigators, notably Busse and Barnes,[13,11] and Perlin,[70] are making sound medical-psychiatric contributions on which therapy can lean.

The fruitfulness of basic study of this age group is affirmed by the following findings in one institution for the aged. Klopfer[57] deduced that brief psychotherapeutic sessions would be effective; Perlin[70] noted that psychiatric interview was not always helpful in the proper selection of residents; Ballard[10] observed that certain types of older persons do not repeat suicide attempts; Shrut[87] noted that change of residence to an institutional type was related to increased anxiety and fear of death. The continuation of youthful attitudes and tendencies to remain active into old age, despite illness, was demonstrated by Oberleder.[67] Also, Kahn[48] noted that alert, assertive individuals seemed less prone to develop physical symptoms; and Pollack[71] reaffirmed the importance of good early socioeconomic circumstances and of at least minimal education in preserving intellectual ability with the progression of years.

Downloaded from www.vidyarthiplus.in

These authors have clarified some of the problems of psychiatric treatment of aged persons and have contributed to their solution. They have shown that, although some aged persons are in a position to review their patterns of behavior and gain insight into their dynamic determinants so as to make sweeping changes in themselves, most must be helped to regain or to utilize more efficiently their old effective patterns of action and to do so with a sense of purpose, restored interest, and pleasure. The psychotherapeutic interrelationship in which the older person regards the therapist as parent or child-parent and the utilization of this relationship for the patient's benefit has been demonstrated. The need for flexibility in the approach to treatment has been repeatedly emphasized. Appointments may be infrequent, sessions brief. Environmental manipulation and the role of ancillary personnel in treatment may be even more important than the sessions with the therapist. The need to work with the family or the persons who have assumed responsibility for the care of the relatively dependent person and the usefulness of the social worker in this respect have been emphasized.

## ¶ The Aged and Their Maladjustments

### *Who Are the Maladjusted Aged?*

Chronologic old age, poor functional status, and the stigmata popularly considered pathognomonic of senility are by no means consistent correlates. However, for the sake of clarity, because it has some traditional and legal standing, and because so-called senile changes do not occur earlier with great frequency, we shall consider all persons 65 years of age and older as "the aged." This arbitrary definition has the combined merit of simplicity and of forcing our attention at once to the fact that we must avoid thinking in terms of a stereotype when we consider the aged human being. Individuals ranging from 65 to 90 or more years of age differ in strength, skill, endurance, appearance, intelligence, education, occupation, economic status, and social position; they have physical and mental disorders which cut across varied constellations of social, medical, and chronological characteristics.

Aged persons commonly referred to the psychiatrist are complaining, quarrelsome, restless, negativistic, depressed, agitated, or angry, and are regarded as threatening, on a verbal or physical level, of suicide or assault. Somatic complaints and paranoid ideas are common, and suicidal attempts are not infrequent. Less frequently than is popularly believed, sexual behavior unacceptable to the community is the reason for referral. This may vary from exhibitionism to not-unreasonable desires to remarry. In shelters for the aged, the most common reason for referral appears to be behavior which has "nuisance" value: noisiness, querulousness, physical complaining and somatic preoccupation which is unresponsive to the usual medical and nursing care available, and clinging, demanding, or hostile behavior. Quiet, subjective suffering on the part of older persons is often missed or neglected, even as it is in younger ones. Psychoneurotic behavior of all kinds is found in aged persons: dramatization, exploitation, and aggravation of disability or weakness are common, and obsessional characteristics are frequently troublesome. Among somatic expressions of emotional distress commonly encountered are headaches and vertigo, constipation, anorexia, sleeplessness, and early morning waking. A sense of heat and burning of the skin, intermittent sweats, flushing, and fatigability are frequent complaints. The loss of "loved" persons may result in accentuation of physical complaints or the appearance of new ones. Real depression, with guilt, self-depreciation, hostile and paranoid elements, and anxiety, does occur, but it may be less frequent than are states of pseudo-anhedonia characterized by social withdrawal, lack of interest, loss of purpose, and relative inactivity.

Frequently, the behavior giving rise to psychiatric referral is too quickly and too completely attributed to brain damage, although it is true that brain damage may contribute to these symptoms a coloring or flavor which often makes the disturbance appear, at first glance, to be more bizarre and more intense

Downloaded from www.cobrulibrary.org.in

than more thorough study proves it to be. Careful note must be taken, however, of Rothschild's[78] careful documentation, in 1937, that the amount or extent of brain damage found at necropsy cannot be exactly related to the amount or intensity of the psychopathology or disordered behavior in life.

## *Psychosis, Psychoneurosis, and Disturbed Behavior*

Seemingly similar mental disturbances in the aged, from the standpoint of nosology or the most relevant etiological factors, may require different methods of treatment because of individual differences and differences of the ecological situation. On the other hand, dissimilar disturbances occurring in a specific type of environmental setting, such as a shelter for the aged, or a mental hospital, may need, as a basis for treatment, the same general approach. It is the purpose here to discuss a general approach to aged disturbed or suffering persons. Clear-cut specific disorders occurring in the senium but common to younger persons are discussed elsewhere in this handbook.

The matter of differentiating between major and minor disturbances in older persons must be discussed briefly, because of the real difficulties in making such diagnostic decisions as well as because of the concern of the general public, the courts, and the mental hospitals about who belongs where and who should be treated or cared for by whom. Traditionally, psychoneuroses have been considered the minor, and psychoses the major, mental disturbances. An individual may be psychotic from the medical and psychiatric point of view and yet make a good, or at least passable, socioeconomic adjustment, whereas, on the other hand, many persons whose disorder is defined as psychoneurotic may undergo extreme suffering and may present great problems of disability requiring long-term care. Brought along into old age are many mental disorders which did not trouble the family or the community, or which were tolerated or even protected, because of special circumstances or the person's occupational adjustment or special skills. Psychoses, psychoneuroses, and behavior disorders of every variety may be revealed late in life when circumstances change or when attractive appearance, opportunity, skill, or position is lost. Such disorders, as noted above, may contribute to, or be accentuated by, brain damage which is characterized by evidence of defective memory and orientation and is ascribed to cerebral arteriosclerosis or to a little-understood process called senile deterioration. Also, an old person may be chronically or acutely ill or malnourished. Any one of these troubles, or a combination of them, adversely affects cerebral functioning. This adds to the problem of differentiating between what is to be considered a minor and what a major disorder. Symptomatic evidence of chronic brain syndrome, associated with cerebral arteriosclerosis or senile sclerosis, can be considered a major disturbance of mentation, because of its tendency toward inevitable progression, its disabling effects, and its association with emotional dyscontrol, personality change, behavioral disorganization, and the loss of productive capacity and social adaptability. Strong emotion, however, may result in exaggeration of defects of comprehension, orientation, memory, and judgment, and may lead to a mistaken impression about the severity of the disorder and to the belief that treatment is useless. Often, persons who appear to have moderate to severe brain damage, and whose behavior is grossly maladjusted, improve on the establishment of good patient-doctor relationships in a properly supportive environmental setting. This is in line with our knowledge that, except at the antipodal ends of the spectrum, actual brain damage and disturbance of mentation cannot be correlated.

Seemingly psychotic behavior of older persons with brain damage may differ from apparently similar conditions found in younger persons, in that there is fluctuation more or less in parallel with the general physical condition and with identifiable external situations provocative of strong emotion; there is also discernible improvement when the environment provides gratifications, a sense of security, and relief of physical or mental pain. Thus, it is very difficult to define the behavior of

Downloaded from www.dbraulibrary.org.in

brain-damaged and chronically ill older persons in the usual terms of psychoses or psychoneuroses. When chronic brain syndrome is present, there is often a florid development of symptomatology having the characteristics of psychoses.

It is apparent from the foregoing that there are large numbers of persons who might, for one reason or another, be classified as suffering from a so-called major disorder who may, nevertheless, be surprisingly improved through the exercise of treatment methods commonly effective in minor disturbances. For these reasons, it is better to talk of *behavior disorders or disturbed behavior in older persons*, with or without chronic brain syndrome, rather than to attempt to make strict differences between psychoneuroses, psychoses, and organic symptoms. Traditional diagnoses are not to be discarded as useless. Evidence pointing to brain damage is a grave prognostic sign. However, from a practical point of view, whether or not evidences of chronic brain syndrome are present, there is much to be gained by determining (1) whether potentialities to harm self or others exist, and to what extent these are modifiable; (2) to what extent nuisance value is present, and how far this is modifiable; and (3), most important, the extent and quality of the patient's suffering, and how one may modify or eradicate it. In any case, a psychotherapeutic trial, in addition to good nursing and medical care, is indicated. A knowledge of the symptomatology is less important than information about the modifiability and the medical, environmental, or emotional changes required. The psychoses and psychoneuroses in older persons, in the absence of chronic brain syndrome, which are often indistinguishable from those seen in younger persons, respond about as well to equivalent treatment.

## ¶ Changing Attitudes Toward Psychiatric Treatment of the Aged

There is now widespread an expanding interest in active psychiatric treatment, especially psychotherapy, of aged persons with behavior disorders, whether chronic brain syndrome is present or absent. The great relative and absolute increase in the number of aged persons is not the only or chief determinant of this development. Civilized man has always desired to prolong life and to ensure strength, productivity, and the capacity for pleasure during life. Cultural and technical influences now favor a trend toward the psychiatric treatment of disorders previously considered irreversible or irremediable, and even of persons who, until recently, were generally regarded as having too short an expected life and too limited a capacity for worth-while activity or productivity to warrant the expenditure of any great amount of time and effort. For the sake of brevity, some of the influences favoring psychotherapeutic approaches to the aged are itemized below:

1. There is increasing understanding that the chief determinant of long-term illness and dependency upon shelter care is not physical disability but personality factors, and that mental disorder is often the major primary disability of those who require long-term medical or shelter care.

2. There is a growing conviction, based upon actual observation, that, as stated in 1956 by The Commission on Chronic Illness, "many patients having another primary diagnosis suffer also from mental illness; and most long-term patients have emotional problems sooner or later."[18]

3. The rapid increase in effective methods of prophylaxis and treatment for the many acute infections and some chronic severe illness has freed the physician for work with the so-called deteriorative and degenerative diseases of the elderly and has brought him face to face with the complex interweaving of psychological, emotional, and physical factors in disorders of aged persons.

4. The increased number of psychiatrists has favored the emergence of a number who have special interest in the elderly.

5. The rapidly expanding interest in sociologic factors in mental disorders as part of holistic or comprehensive medicine, as it has developed from psychobiology to psychosocial medicine, provides a theoretical base for treatment as well as a framework for investigation

Downloaded from www.dtic.mil

and research. With rational, consistent operational concepts, the previous medical pessimism and withdrawal can be replaced by optimism and interest.

6. An increasingly sound appraisal by psychiatrists of their position and their role as doctors whose obligation it is to meliorate where they cannot cure, and to relieve pain and suffering even when no basic alteration of the disorder can be expected, makes rational and reasonable the expenditure of time and energy with persons of limited life expectancy and potentialities.

7. There has been decreasing resistance to psychiatric concepts on the part of the general public. Real interest in and desire for psychotherapy has grown as increased freedom from preoccupation with ensuring subsistence has permitted the emergence of drives for gratification.

8. The incorporation of rehabilitation concepts into general medicine, as social workers, physical and occupational therapists, nurses, and other technical or nontechnical personnel have become integrated into teamwork approaches to individual patient care, has required the orientation of the team members, the use of psychodynamic concepts, and the help of psychiatrists with the patients.

9. Of considerable significance in promoting interest in psychotherapy for the aged is the great help persons who care for the aged derive from an orientation program. This aids them to realize that the aberrant behavior of their charges is motivated and can be understood as a complaint or plea for help, to which they can respond constructively.

10. Persons who attend the chronically ill, terminally ill, debilitated and dependent, or emotionally and behaviorally disturbed aged have found psychiatry and psychiatrists of assistance in the mitigation of the anxiety and anger which they themselves experience during the discharge of their duties. Situations frequently occur which provoke feelings of helplessness, either because they epitomize what may happen to oneself as one ages, appear to be insoluble problems, or tend to revive unresolved emotional problems in their relationship to their own parents or parental surrogates. Properly conducted group or individual conferences with staff members who are in any way concerned with the care of aged persons can lead to improved orientation and to significant changes in attitude which aid them in understanding and helping disturbed aged persons.

## ¶ The Predicament of the Aged Patient

The well-adjusted person of 65 or over appears to have emotional needs that do not differ greatly from those of younger persons. He desires friendships, of varying types and intensity of intimacy, with both sexes. He wants to keep busy at work, or a play equivalent, which is within his physical capacities, which is commensurate with his intelligence and background of training, and from which he derives a sense of accomplishment. He looks for, and objects to frustration of, opportunities for the relief of biological tensions such as hunger and sexual desire. In addition he may crave, in varying degrees, appreciation, marks of affection, and reassurance that he has made an impression upon this world by means of his words, his deeds, or by having reproduced himself. Thus his self-esteem, which in the past rested upon and was reinforced by his performance, can be maintained. In all this there may be some differences from youth, characterized by mellowness—a lack of haste, an inner patience, and a philosophic tolerance growing out of a satisfied curiosity. Obviously, emotional problems may be encountered among elderly well-adjusted people. They may meet these successfully alone or may require counsel, guidance, information, or even psychotherapy, as may any younger person under special stress. These persons may be found in their own homes, living with relatives, or, much less frequently, in old-age shelters.

In homes for the aged, nursing homes, and hospitals are a large number of aged persons who, like some others in their own homes or in a boarding-home arrangement, are less fortunate. In our society at the present time, large numbers of older persons tend to find

Downloaded from www.dbtbanglore.in

themselves in roughly similar predicaments, from the physical, social, economic, and psychological standpoint. Not uncommonly they have lost the resources required for more or less comfortable survival. The loss of friends and relatives, work opportunity, and income leads to deprivations and frustrations on the levels of both subsistence and of gratification. Small quarters, the greater tendency of families to move about, economic inflationary forces, and the increase of population concentration in urban centers complicate and multiply the problems of survival and comfort for the older person. Moreover, there are declines in the efficacy of sensory function which contribute to isolation and decrease the steady stream of incoming stimuli which promote pleasurable action; there may be central-nervous-system integrative defects which impede communications with others and, in a manner of speaking, with oneself.

## ¶ Basic Concepts for Treatment

Decreased homeostatic efficiency limits function and may turn ordinary situations into minor or major emergencies, and effector inefficiency also severely limits the capacity for mastery and the unaided successful relief from tension. The chief resemblance of persons within the group we have defined as "aged" who come to psychiatric attention appears to be that they come to depend greatly on others. This dependency they may attempt to hide and may succeed in hiding both from themselves and from others. When their need, whether for medical care or because of inability to sustain themselves socially or financially, propels them or causes them to be propelled to a shelter or to others for aid, what the observer sees as their dependency is felt by the person as helplessness and is accompanied or followed by anxiety and a variable degree of anger. Each patient bears scars from early life—inhibitions or fears which have impaired his effectiveness in the past. New disabilities which occur in old age, however mild, may result in anxiety and anger, which go beyond alerting and organizing the individual and tend to disorganize and impair functioning.

The disturbed behavioral functioning of an aged person has as its core the early patterns of that person's behavior. These patterns of feeling, thinking, and acting are developed in a child-parent relationship which is the unavoidable biologic imperative for survival. Learning and mimicry reinforce or modify the behavioral patterns developed in the dependency period. One discovers, therefore, elaborate patterns of action which cluster about the emotional core of the personality developed in infancy. Among these patterns are tendencies, in variable degree, to exploit, exaggerate, or dramatize one's incapacity. The utilization of illness and inefficiency to punish oneself and others, to justify failure, to symbolize one's wishes, and to substitute for their fulfillment can be developed early and does not disappear with the accumulation of years. Disability, prolongation, and intensity of illness far beyond that warranted by the pathological structural changes may thus commonly occur in persons of advanced age. Disability may progress when emotional stress initiates or aggravates irreversible changes.

Fear and anger can prove disorganizing in the young and relatively intact person. Elderly people may even more quickly reach a point at which function becomes aimless, or efforts fragmentary and unsustained, when fear and anger arise. Emotional storms or immobilization may occur. More and more, we are coming to see how apathy can deepen, not only in the absence of stimuli adequate to maintain intrapsychic function and to promote adaptive contact with the world, but also in the presence of continuous severe stress beyond the person's powers, or his belief in his powers, adequately to master the situation or adapt to the change. This apathy appears to be an inhibition of function, an active process of damping out or overcontrol. When it is eliminated, the potential abilities of the person may once again assert themselves.

In many older persons, self-reliant, goal-oriented, problem-solving activity may have been at a low level to begin with; when it is further decreased by new functional losses,

Downloaded from www.drahuja.blogspot.in

then previously precariously balanced or already low self-esteem suffers and falls progressively, as failure follows failure. As failures occur, a sense of helplessness arises. With feelings of helplessness, fear is provoked and mounts. Fear, an ever-growing sense of ineffectuality, and feelings of worthlessness accentuate each other in a vicious cyclical manner. With failures to master change, to act effectively so as to relieve tensions growing out of social, personal-environmental, and intrapersonal relationships, there is discomfort. Moreover, gratifications are not achieved, nor can substitutes or compromises for them be made. The sense of frustration and feelings of deprivation grow, anger supervenes, fear of retaliation and guilty fear may arise, and the personal suffering increases in a complicated tangle of emotional overreaction, behavioral disturbance, and physical disorder. In this helpless, disorganized state, the patient's behavior is patterned along lines of the culturally acceptable manifestations of dependency as previously internalized through learning and mimicry. The behavior is motivated by his need for help and clusters about his specific propensity for the development of a child-parent type of relationship. In some, this is of an affectionate character; in others, it clusters about attitudes of domination and submission.

## ¶ Approaches to Treatment

Phenomenologically, there appears to be greatly diminished cortical reserve in many elderly persons. They are prone to develop behavioral disorders with anoxia, and often are overly sensitive to neurodepressants and neural stimulants. They may develop confusional states with infections, with pain, and in response to minor environmental or social changes. Often, they are hypersensitive with respect to their own ruminations, and they react stormily to their own fears and angers. An injury or illness, a disappointment, a death, or a separation, may be followed by galloping progression of puzzling bewilderment and memory loss. Even in aged persons with loss of memory, stress often yields a depressed-apathetic, clinging-fearful, noisy-abusive, or frantic person. Illness in the aged is characterized, as Zeman has felicitously phrased it, by "multiplicity, chronicity and duplicity."[104]

The psychiatrist must be a member of a treatment team, each of whom is on the alert for signs about which the others should be informed. In an elderly or aged person with disturbed behavior, the symptomatic or specific treatment of a physical illness—measures instituted to correct drug intoxication or infection or to relieve a painfully distended bladder, a troublesome phlebitis, a painful ear, or an impairment to vision—may contribute to marked improvement. In the absence of reassuring "organic" factors which we can tackle with pharmacological or physical methods, however, we may feel overwhelmed. There seem to be very few resources with which to work. The frustrations we feel, when confronted by the patient who poses this problem, provoke anxiety. This may lead us to fruitless pity and harmful excesses of compassion, or to self-defensive anger against the patient's threat to our self-esteem; our anger and the guilt which accompanies or follows it may lead us to hostile acts disguised as kindly measures. We may refrain from doing essential operations because of the patient's age, or we may overtreat them in a backward somersault away from such negligence; we may protect and coddle them into apathy or overstimulate them into panic. Misguided protective treatment or undue neglect augments the fear and anger of one who already feels helpless and vulnerable; such attitudes worsen the psychological difficulties, increase the patient's inefficiencies, and further disorganize his overt behavior. This fact makes it imperative that the family, or those who act in nursing and attendant capacity, be properly oriented to the patient's needs and that they have a working concept which can sustain them by providing them with a belief in their own capacity to master the problem. One cannot overemphasize the importance of a cooperative social environment when psychiatric treatment of the aged is attempted. Of equal importance is the existence of good general medical care for the patient. In the absence of efforts in these directions, the psychiatrist

Downloaded from www.pbookshop.com

works in a vacuum. This does not mean that psychiatry can offer nothing except where the environment is ideal and medical care is perfect; on the contrary, psychiatric influences can act to improve both the patient and his lot.

## ¶ Aims and Techniques

The aim of treatment in aged ill persons is to decrease the disorganizing fear and anger; to reduce the amount and intensity of unreasonably aggressive behavior, which provokes exacerbation of guilt and, at times, invites environmental retaliation; to increase comfort and satisfaction; and to restore and enhance the sense of worth and dignity. In selected cases the restoration of productivity of even a minor degree may be an aim. Artists, scientists, professionally trained persons, and others with special aptitudes, skills, or interests, may occasionally be assisted toward rewarding avocational—if not vocational—pursuits. Restoration or increase of dignity, self-esteem, or worth may, in fact, be the method rather than the goal of treatment, and may be the maneuver which decreases fear and anger, with subsequent improved behavior.

The sense of worth appears to depend not only upon attitudes toward oneself, developed early in life by way of internalization of parental attitudes and the organization of self-image around early successes and failures, but also upon one's view of oneself as currently capable of mastering problems and gaining pleasure. Pleasure cannot be forced upon people and does not necessarily accrue from having one's dependent needs catered to, nor does it even follow upon the provision of luxury. Pleasure appears to arise out of two conditions of the organism: first, the adoption or the existence of a sense of purpose or direction of effort; and second, the sense of solving problems, mastering change or difficulty, or winning over threatening forces. The two may be subsumed under the term "mastering," and pleasure may be considered as that affect which arises in a setting of successful, or effective, effector synthesis accompanying or leading to actions of mastery. Treatment efforts may therefore be directed toward augmenting the patient's ability to master problems and to obtain pleasure for himself, or toward inflating his belief that he can and does master current problems, as well as toward changing his views on what constitutes success and decreasing the hostile action of critical internalized attitudes.

Even in a setting of cerebral damage, anxiety may have an organizing effect by increasing alertness and promoting action. Anxiety may be followed by anger which exerts an organizing action, and which, in addition, tends to enhance the individual's sense of strength and pride. The rise of fear or anger in a withdrawn or disorganized person may lead to attempts at problem solving. This, especially if successful, may result in increased self-esteem, a decreasing sense of helplessness, and the establishment of a more or less continuous pleasurable state. Consequently, it is often of therapeutic value to permit the arousal or augmentation of anxiety or anger to occur. This may favor successful action and be accompanied by a double gratification—that of tension relief and that which accrues to the mastering action. Patients are not provoked or "baited" to develop anxiety or anger when it is desirable that these emotions be permitted to arise; rather, this tends to take place spontaneously, as when the patient is referred to the psychiatrist (because of what is implied by being sent to a doctor). Where this appears to work in the patient's best interest, premature efforts to meliorate the emerging emotion should be avoided. "Preparation" for the interview may be unwise. An offer to the patient of specific medical attention initiates a situation in which fear and anger play prominent parts. It is the propensity of all ill and troubled persons to regard a doctor as a person of power with potentialities to help or to harm, and to anticipate an appointment, and look on the doctor himself, with fear and anger. The patient, in his helplessness, which we see as dependency, elevates the physician to parental status and delegates to him the tasks which were naturally assumed by the parent in the original child-parent relationship. The necessity for recognizing this and making intentional, consistent use of it has been recognized for centuries and was neatly

Downloaded from www.dbraulibrary.org.in

recapitulated in 1904 by Freud[25] in his paper "On Psychotherapy."

The spontaneously arising relationship which is based upon the early child-parent interplay can provide a lever for psychotherapy. This relationship can be developed and maintained in relatively brief and widely spaced sessions. Formality of appointments is often to be eschewed, in the interests of the most helpful interrelationship and of enlisting the cooperation and attention of the family and/or the institution concerned with the patient's care. An able therapist maintains his position in the aged patient's eyes not by actual role playing, as does an actor interpreting his part, but rather by not doing or saying anything which is incompatible with the role the patient wishes to have fulfilled and which he has the doctor fulfill in his fantasy. This can be done if the psychiatrist reacts appropriately to the face value of the situations that arise, but within the limits defined and with the restraints prescribed by a proper grasp of the associational flow of the patient's conversation and by comprehension of his nonverbal, self-revealing communications. The patient's needs for punishment, respect, affection, protection, approval, etc., are met not so much by what is said or done by the psychiatrist as by the patient's own interpretation of the therapist's attitudes and behavior in the transaction. The patient's private interpretations fulfill his criteria for having re-established the relationship he seeks. He becomes convinced that, in the therapist, he has found a suitable substitute for the lost relationship in which he felt strong and secure, and he may say so in moving language which not only tends to convince himself but also appears to be an attempt to convince the therapist and to be a signal or set of instructions for the therapist, for example: "You are like my son but kinder." "Not since my husband died have I had a chance to talk to someone like you." "You're not like the others, you understand." "My husband was a doctor, my father was a very fine man, with you I feel the same." The therapist, by these clear signposts, recognizes that the patient has thrust him into a role, and he needs no magnifying glass to discern the outer lineaments of that role. The sick person distorts, exaggerates, or scotomizes what he must, and as he must, to maintain the therapist in the role the patient has thrust upon him. That the patient may run through a dozen different figures before finding one who will do is because of the blindness of those he elected. There are limits to the person's capacity to distort, exaggerate, or scotomize. A patient who provokes, demands, or practically begs for punishment must receive some harmless token along these lines or be lost; if he demands proof of interest by means of the therapist's intervention, then a token stand must be taken for him, or he will be lost and go on to search for another person who does not destroy his illusion of having found the longed-for parental figure.

## ¶ Illustrative Cases

Each person shows special difficulties which must be considered in the therapeutic relationship. The following is an example of the kind of patient who may be seen in private practice, in this case one who shows little of the so-called "organic" syndrome but demonstrates the reversibility of seemingly severe psychological disorder in an aged person.

An 85-year-old woman was referred for consultation because of markedly delayed convalescence from an abdominal operation. She was, by the usual criteria, physically recovered. However, she complained of weakness, ate poorly, and did not gain weight appropriately; she was apprehensive about leaving her small apartment and could not tolerate remaining alone. A prominent complaint was that the mild sedative ordered by the physician was a poison. She was critical and suspicious of her nurses, although markedly dependent upon them. She expressed ideas that her family wanted her to die and was, therefore, neglecting her. It was frequently necessary to demonstrate to her that items out of her sight had not been stolen.

Her heartsick family feared she was progressing to an irreversible paranoid senile state, because these symptoms did not respond to the excellent

Downloaded from www.freelibrary.org

treatment of their long-time family doctor, a very capable internist, or to their own solicitous attentions. They were fearful that a psychiatric consultation would complicate and aggravate matters by frightening and antagonizing their already obviously apprehensive, angry, and distrustful mother. Tentative overtures to the psychiatrist were made; appointments discussed, made, put off, made again, and canceled. A visit to the patient's home finally crystallized, and a daughter hovered protectingly over the patient during the consultation.

The associational trend of the patient, in at first hesitant but finally friendly conversation, revealed that she was greatly concerned about whether so old a woman could really recover from a major operation. There were also doubts that she had been told what was really wrong. She suspected that the care shown her constituted the last courtesies of old friends and faithful relatives in view of an inevitable fatal end. It became obvious to her that the physician called in consultation was a psychiatrist, and as this became clear she indirectly "gave proof" of her sanity by telling a detailed story which an old acquaintance, now mentally ill, was never able to get straight. She responded with apparent pleasure to the psychiatrist's interest in this account as well as to his obvious respect for her accomplishments, which were considerable. The sedative about which she felt concern was, after discussion with her doctor, discontinued, and a very mild cerebral stimulant was prescribed instead.

In the next few days the patient showed marked improvement. She felt subjectively stronger, discharged her night nurse, began to eat well, and came willingly to the psychiatrist's office for her next appointment. In the second conversation what had occurred became clear. To this woman the fact that the family should call in a psychiatrist was proof that she must be having a nervous breakdown. This kind of action proved, therefore, that she was not truly physically ill and consequently was in no danger of dying very soon. She was willing to enter into an arrangement with the psychiatrist to explore why she had become so apprehensive. She remains improved after a year, in which period she has been seen five times.

*Comment:* Obviously, the threatening surgical experience was not alone the determinant of this patient's reaction; the intensity of her psychological disturbances was meliorated, however, with the arrival on the scene of someone whose status or whose approach was able to decrease her sense of helplessness. The arrival of a psychiatrist made the problem or the situation appear to be one with which she could grapple and solve, either by means of her own or with someone else's strengths. It is not infrequent for persons who fear they are seriously ill with a so-called "organic" disorder to be reassured when they discover it is truly a psychological or mental disorder; the converse, that people with physical symptoms of a psychological disorder welcome the diagnosis of physical illness, which presumably will respond to medicine, surgery, or manipulation, is even more frequent. Attempts openly to reassure by way of "psychosomatic" explanations, to comfort those exaggeratedly frightened by the prospect of physical illness, are, however, usually ineffective; the unvarnished administration of placebos or mock treatment is also liable to provoke more anxiety in the patient than to relieve him when he needs reassurance about his psychologically determined symptoms. The means of reassuring and supporting our patients is not based upon intuition alone; it is a skill, perhaps unwittingly acquired and unintentionally used by many, but nevertheless subject to understanding, description, and controlled application.

Those who welcome a diagnosis of physically treatable disease, when their disorder stems from anxiety, are the persons to whom nonphysical treatment of seemingly physical symptoms is incomprehensible, and who may have considerably more to lose than they can foreseeably gain from recognition of their real problems. For them, whose economic condition may be very bad, the best vehicle for psychotherapy may be medical examination, regular observation, and symptomatic treatment, whether it be pharmacological, physical, or that of a regimen.

Within shelters for the aged, many persons become acutely distressed and are disturbing to

Downloaded from www.cobrapublishing.com

other residents and staff. The patient described below had evidence of a moderate degree of brain damage.

A 74-year-old childless widow, whose late husband was a doctor, became unmanageable in the infirmary where she was being treated for cardiac failure. Her attitude to the psychiatrist was one of friendly, apologetic, ingratiating compliance. She made certain to inform the psychiatrist of her late husband's occupation. Her flow of conversation clearly indicated her dependence upon the fatherly protection of an interested physician whom she equated with her husband and her father. With both her husband and her father she had been a "good girl"—compliant, ingratiating, believing her care to be contingent on her good manners, mid-Victorian ladylike virtues, intellectual interest, and feminine submissiveness. When the psychiatrist instructed the staff to tell her that the diet and regime she objected to was given specifically on his order, she became, for the time, a model patient.

Six months later she was again referred to the psychiatrist because of memory defect, disorientation, obnoxious and unmannerly behavior, and slovenliness at the dining table. She seemed unfit for apartment residence and appeared to be a candidate for transfer to custodial care. In the course of treatment, she became querulous and seemed on the verge of relapse. In discussion, she complained about pain. Examination revealed beginning herpes zoster. Her rather stormy, painful course was weathered with no greater incident than in a more youthful, less debilitated person.

She was seen from time to time, and a few months later, by way of a dream, she informed the therapist that in her adult lifetime of lavish entertaining in a suburban home, she never was certain whether she was loved for herself or for her goods and accoutrements, both material and intellectual. When, in a few well-timed words, the therapist made clear to her that it was she who was endearing and not her gifts, she made sudden startling improvement, over and above the previous slow but steady progress, and could be discharged from regular treatment. She regularly sent the therapist sentiment-filled cards on Valentine's, Mother's and Father's Days.

A year and a half later she was hospitalized for cardiac failure and one night threatened suicide. She had paranoid delusions that the attendant was influencing her by means of voodoo and causing her heart disease. Direct reassurance and manipulation of the environment probably helped, but the chief reason for improvement in this episode was clearing of the cardiac failure. A few months later she died.

*Comment:* In the aged one, as in the youth, private motives are not put on public display; moreover, age alone does not decrease our propensity to hide from ourselves the motives that may direct our thoughts and actions. The therapist recognized this woman's hidden desire for an admiring, protective, powerful parent and her delegation to him of this role. By not discouraging her illusion that he was such a person and that she had won her place with him, he helped increase her pride, her sense of strength and confidence returned, and she functioned better.

In this woman, as in the previous patient, well-automatized patterns of social behavior and well-established mechanisms of psychological adaptation could be revived. Good early education pays dividends in old age. This patient's dissolution was heralded by the loss of memory and disorientation which persisted even in the absence of infection or cardiac decompensation. She died six years after coming to psychiatric attention.

Persons with severe brain damage do not live a long time, and, even though marked improvement in their behavior and in their subjective state may be achieved with adequate supportive care, there are limits to the length of time this can be maintained, as in the case which follows.

Mr. T., 80 years of age, a native of Germany, who never married, had been a lifelong seclusive misanthrope and a chronic alcoholic. He was considered a misfit in the family and left home when 18 years old because of a scandal involving a young woman. He came to the United States by himself in 1890 and worked in various restaurants and hotels as room clerk and cashier until 1943, when he underwent a prostatectomy, gave up work, and subsequently decided to enter the Home for Aged and Infirm Hebrews. He was

Downloaded from www.brainlibrary.co.in

admitted in 1946, at the age of 74. For three years he made a choleric, marginal social adjustment in the Home. In 1949 cerebral thrombosis caused right hemiparesis which confined him to the infirmary. There he became a serious problem because of explosive angry outbursts, with threatening and assaultive behavior, set off by the doctors' and nurses' attention to his severe conjunctivitis. He was relatively immobile, and sulkily refused to make efforts which could help the staff determine the true extent of his disability. He was referred for psychiatric help, and therapy was instituted in 1951.

In the first two very brief sessions, he was questioned about his angry behavior in such a way as moderately to reinforce his preconception of the therapist as an injunctive, prohibiting, and threatening parent. In the third interview he angrily denounced the therapist and the Home staff for implying that he was mentally ill. He went into a lengthy diatribe about how his eyes had been spoiled by an incompetent doctor before he came to the Home, and how the trouble was being perpetuated by the incompetent Home physicians who prevented him access to better ones. His hemiparesis he attributed to a trifling insult which the physicians aggravated by neglect and inept therapy, for example, the rehabilitation procedures which he violently opposed. In the session he was encouraged to vent his anger on the medical and nursing staff and especially toward the therapist, who appeared suitably distressed, cautiously self-defensive, and semiapologetic without ever admitting that the patient was actually correct.

At the end of ten minutes it was tactfully agreed that the patient could leave the interview. He departed with an air of righteous indignation triumphant. For the next few days he was relatively silent and cheerful, and there were no angry outbursts; his attitude was that of one who has bearded the lion in his den and emerged victorious; he was contemptuous of the harmful potentialities of those about him and submitted to their ministrations without protest. A further opportunity for him to vent his anger and emerge triumphant was offered in another five-minute interview about a week later.

In the fourth interview, two weeks after the first, there was a change in his attitude. The patient seemed to feel safe with the "defeated" therapist, who seemed none the worse for wear. He spoke angrily of the staff and his plight, but as though to an ally. He came to this session, for the first time, in street clothes which he had demonstrated he could help put on himself. The therapist listened sympathetically, suggested that the patient could probably do a great deal despite the opposition which he felt existed, and offered to have a medication added, which was done. Following this, in a series of interviews for backsliding on the part of the patient, there was, according to the needs of the patient, a shifting of role playing between that of the strong parent who can be vanquished and that of the strong parental ally. After eight interviews over a period of four months, there was some improvement which was sustained for eighteen months. The patient altered his status from one of angry immobility to relatively peaceful but limited ambulation.

His dependence on the therapist was subsequently assumed, without incident, by a social worker whom the patient identified with the therapist. When she "abandoned" him for a vacation, he subsided into depressed and sullen immobility, and then reacted with episodes of assaultive rage of such violence as to require transfer to a psychiatric hospital before opportunity for further therapy. Mr. T. died one year later.

*Comment:* This man, whose lifelong feelings of helplessness were reinforced by hemiplegia and the concomitant effects of brain injury, handled the anxiety thus generated by an angry show of force. This was ineffective in overcoming his fear and, in fact, increased his retaliation fear. In this setting he was depressed, immobile, and had explosions of anger. The therapist stepped in to provide him with an illusion of omnipotence through triumph over a powerful, threatening physician. Some of the omnipotent feelings could only be short-lived, but they were later replaced by acceptance of the "defeated" therapist as a powerful parental ally. Safely entrenched with him, the patient's helplessness decreased, his anxiety diminished, and reparative rage was unnecessary, so that there was simultaneous improvement in behavior and decrease of his suffering.

Not all persons who have brain damage do

Downloaded from www.dbraulibrary.org.in

badly, as is testified by many prominent figures alive today. One patient, who achieved some fame in her later years subsequent to the incidents described below, is such a person.

Mrs. N., a vivacious, witty, 72-year-old woman of masculine appearance and dress, was admitted directly to the Home for Aged and Infirm Hebrews from a hospital where she had spent sixteen months after cerebrovascular accident with no significant residual signs. She had considerable hypertension. While hospitalized, she had a few episodes of "somnambulism." She had apparently reveled in the institutional environment, where she had found many people admiring and affectionate.

Her past history revealed that she was reared in a large, congenial, but rigidly Victorian, "stiff-upper-lip" English literary family, in which complaining was anathema and expressions of anger were unforgivable. She was orphaned early, met financial reverses, felt obliged to care for a younger sister because of a maternal injunction, and was widowed at the age of 24 after three years of marriage in a country strange to her. She then traveled widely, working variously as a probation officer, teacher, and finally as housemother in a girls' detention home, in seeming constant denial of her frustrated desire for the early loving atmosphere of her childhood but almost always in an institutional atmosphere which was, in many ways, reminiscent of the large-family life of her girlhood.

On admission to the Home she at once assumed a position of leadership, denied her discomfiture on various occasions when this was obvious, but clearly expressed her dissatisfaction and anger by manipulation of other residents and by her trenchant wit. She appeared to regard her roommate as especially troublesome. In this setting, three weeks after admission to the Home, she began to have almost nightly episodes of "somnambulism" which, in this woman with a history of brain damage, could not clinically be distinguished from psychomotor epilepsy.

Therapy was instituted, and she welcomed an opportunity to aggrandize and equalize herself with the therapist, whom she at once identified as an affectionate, interested protector who was like her well-educated, loving father. The social worker simultaneously made it possible for her to work along lines which gave her prestige status in the Home. The "somnambulism" disappeared. Sudden return of these fuguelike episodes, one of which terminated in rigidity and frothing of the mouth, was correlated with injunctions from a new resident physician, and from a doctor in the clinic she went to for ancillary neurological study, that she was "after all not as young as you used to be and should take it easy." To this woman, who suppressed and repressed large amounts of rage, this medical injunction (as a parental prohibition, absolute) meant restraint, curtailment of aggressive leadership, and relinquishment of office-holding, or mothering, and the control of others—in short, loss of prestige and social dominance. This restriction resulted in increasing anger without room for its expression. Resumption of therapy, in the course of which she disclosed these feelings, and removal of the injunction were followed by complete disappearance of the nocturnal fugues.

Behavior disorders of the aged are so complexly interwoven with physical illness and socioeconomic difficulties that they seem to present insoluble problems of care. The gratification of particular needs, so as to create for the patient the illusion of having achieved a situation of secure dependency, may quickly dissolve the behavioral difficulty.

Mrs. T., a native of Germany, came to the United States in 1941 with her husband when she was 64 years old. She had supported herself by work as a domestic with her husband and his first wife for many years. Two years after her employer was widowed late in life, she married him in opposition to the wishes of his grown children. Shortly after the family came to the United States, Mr. T. died. Estranged from her stepchildren, Mrs. T. continued to work as a domestic until 1949 when she was 72. She then entered the Home to make provision for her financial and physical care; she indicated also that she wished to be with contemporaries who might be more cordial than her stepchildren.

She was a seemingly independent, aggressive, tense, and dominating woman who, after admission, had trouble with a succession of roommates because she could not share or compromise about room arrangements. She complained of intense head pains and of nervousness which she attrib-

Downloaded from www.dbraulibrary.org.in

uted to chronic tinnitus, seemingly based on arterial central-nervous-system changes related to diabetes. After a year in the Home, she was referred to the psychiatrist upon complaint that her tinnitus was so annoying that unless relieved she would "go through the window."

This woman had looked to the staff of the Home for protective care. In two brief interviews the therapist made it clear that there was real interest in her and concern for her welfare, and that, while ventilation of anger was permissible, nevertheless tantrumlike, suicide-threatening behavior must lead to the opposite of the desired affectionate care. At the same time that this "punishing" disapproval was offered, implicit assurance of forgiveness was tendered. Mrs. T. made rapid recovery from the depression, and, after five sessions in twelve months, treatment was discontinued. A year later she was seen by another psychiatrist because of complaints by her roommate, who was a psychiatric patient. It was found that Mrs. T. had been the *provocateur*, and a short injunctive psychiatric session, followed up with evidence of interest in her by the social worker, served to control her.

There were no complaints of tinnitus at this time, nor have any new episodes of upset behavior been reported. If Mrs. T. has been troubled by tinnitus since, this has been her closely guarded secret. Now, eight years after the first incident, she remains cheerful and active and always singles out the therapist when he is within sight to greet him happily and thank him profusely for his aid and interest. The patient's "warmth" is obviously her means of sustaining a protective alliance.

What the sick people seemed to need above all was to maintain their conviction that there was hope and help. The therapist's job was to see to it that the person should not become disillusioned about the powers of the person to whom he turned. It was important that he not be discouraged in his particular way of believing in the doctor as a person who is in a position to help him and over whom he had some control. Disillusionment would simply lead to further anxious search.

The need to find a convincingly helpful figure is a trend hidden from oneself as well as from others. It is not consciously embarked upon and carried out. The manner in which the campaign is conducted can deceive the delegated assistant as well as the frightened patient. A person, viewed as potentially helpful, to be dominated, manipulated, or maneuvered, is what the patient appears to be searching for without appreciating the fact, or even while consciously denying it. This may be mistakenly regarded as a search for love or for understanding. Actual domination or manipulation of another, however, is not essential for these patients to gain benefits from a relationship. Rather, it is the unverbalized conviction or belief that they are doing or can do so which serves to reassure them. To remain in the good graces of such persons, patients will perform seemingly miraculous feats, such as employing long-unused muscles or performing intellectual tasks considered no longer possible. Moreover, the patients' belief that such a person has been found and the initiation of efforts to bring their selected protector's powers to bear on their own problems constitutes a sense of purpose. "Joy's soul lies in the doing . . ." for ". . . man prizes the thing ungain'd more than it is." Wooing, beseeching for the ungained prize, brings to the attention of the participating, previously inactive, person the unrealized extent of his own powers. It is these efforts and these real or illusory successes which reassure and support, not the pats on the back or the words of the physician.

## ¶ Summary of Effective Factors in Treatment

Age, other things being equal, is no barrier to treatment. When, with advanced age, there is a loss of resources required for the meeting of social and material problems and a profound sense of helplessness in the patient (as may also occur in younger persons), a therapeutic transaction begins with the delegation to the doctor of great powers. The patient appears to select the physician to play a part in a personal relationship from which the patient will gain gratification and a sense of security. On the simplest level this may lead to fear or anger which exerts an organizing effect upon be-

Downloaded from www.pdfbooksfree.pk

havior. The patient often perseveres, as long as nothing is done to disenchant him, in believing that the therapist has increasing interest in him. With this belief comes a rise of satisfaction, of pleasure. The pleasure is derived from the conviction that this interest guarantees continual "care" and that the "care" has been gained through the patient's own efforts. Because he feels that interest is displayed in him, the person comes to believe that he has won, charmed, tricked, forced, or otherwise personally gained this social advantage. The receipt of medicine, assistance in environmental manipulation, or specific advice within acceptable ranges is often taken as a token or symbol of having gained the therapist as ally, friend, or protector, and, simultaneously, as proof of having triumphed over, of having dominated him. This sense of triumph, of having won the therapist's powers and of owning them, may be carried out of each session; a parent figure has been incorporated. There is sustained gratification from feeling favored in what may constitute a sibling-rivalry situation. When these events take place in a hospital or shelter where other aged persons reside with whom the patient feels in competition, he "lords it over the others." He not infrequently behaves as though he were endowed with the therapist's imagined powers.

Real success, motivated by the desire to please the doctor—the making of a rug or an ash tray as a gift for the doctor, for himself, or for another—which the doctor can be shown or about which the doctor may be told by the patient or may hear from others, provides gratifying elevation of self-esteem. The real success may take place in improved social relationships. Some persons obtain a special sense of satisfaction by withholding information of such success from the doctor; keeping it as their secret is felt as virtuous, and the pride is redoubled. The withholding of information about illness, pain, or trouble from the doctor may be a potent source of pride for the patient —self-praise for the virtue of being uncomplaining, undemanding, and long-suffering. This occasionally leads to the neglect of treatable illnesses and is a reaction for which the physician must be on the alert.

Visits to the doctor arouse both fear of punishment and guilty fears in some patients, with consequent decrease of their aggressivity in the family or in community situations. Conversely, disorganizing guilty fear may be decreased because the physician's behavior is viewed as permissive, forgiving, and accepting of the patient. Once some of these bonds of relationship have been established, a sense of purpose is derived from sheer continuation of the transaction which is easily transferred from one therapist to another, or even to the "department," as symbolized by nonmedical personnel within it or its delegated representatives.

## ¶ Results

In the author's experience with aged patients who do not suffer from fairly well-defined psychoses of schizophrenic, paranoid, manic-depressive, or involutional type, but whose behavior disorder can be classified as psychoneurosis or personality disorder in the absence of brain damage, psychotherapeutic efforts appear to be rewarded either by improvement or stabilization, a halt in progression of the disorder, in about half the patients. In cases of chronic brain syndrome with disordered behavior, about one third of the patients improve, stabilization occurs in about a third, and the remaining third grow worse. In many cases the behavioral state improved despite progression of the physical disease.

## ¶ Conclusion

Too often, there has been a social, medical, and psychiatric attitude that people must learn to accept their limitations, must resign themselves to their disabilities, must stop their struggling and fighting so that, possibly with skilled help, they may find peace in the recognition of their deficiencies and limitations. This attitude and the treatment based upon it encourages feelings of failure, hopelessness, depression, or apathy in the patient. When therapy based upon such ideas works well for the patient, it appears to be because the sick

Downloaded from www.drjurijury.org.in

one learns to discard the therapist and gains strength from this maneuver. Still alive and with mechanisms for survival, motivated to life, persons who are disabled, depressed, and frightened live in a world which has taught them to measure themselves and others in terms of performance, power, and prestige, with which they interact even when disoriented. To encourage acceptance of limitations and disability is to foster self-recrimination and loss of self-respect; it encourages regarding oneself as crippled and weak. If we take cognizance of, rather than disregard, the tremendous pleasure an individual can derive from a relationship which takes simple shape in a special way, we can find a lever for therapy, a means of encouraging growth and expansion of purpose and of interest, in short, of energy and activity.

Once reconciled to the idea that we are not magicians and that our efforts may be welcomed as a comfort by many aged and chronically ill persons, by their families, their friends, and the community, we can approach the problem without a sense of misspent time and talent. Then we may come face to face with our own feelings of dread, helplessness, and anxiety about age, illness, death, and the care of those who are old enough to be, or to remind us of, our parents. Quite possibly these attitudes—a combination of our own fears, acquired habits of thought, and individual fantasy—contribute to our pessimism. Certainly, the task appears overwhelming, yet an unimpassioned view of older persons' psychiatric needs may reveal much room for a doctor to heal, to meliorate, or to comfort.

In 1916 Byrne* opened a lecture with the following words:

> In spite of the fact that its methods have long since been reduced to principle, it is amazing to find scientific psychotherapy so little utilized by the profession in the treatment of old age and chronic invalidism. This is all the more shocking when one considers the not inconsiderable success obtained without and within the profession by individuals who realize the value of optimism and healthful suggestion, even though they know practically nothing about the scientific application of even these psychotherapeutic measures.

* This neglected paper was eventually published in the *Hospital Bulletin* of the New York City Department of Charities, Vol. I, pp. 103–107, 1951, under the title "Psychotherapy of Old Age and Chronic Invalidism."

CHAPTER 21

# THE BORDERLINE PATIENT

Melitta Schmideberg

Downloaded from www.dbraulibrary.org.in

THE BORDERLINE REPRESENTS, in my opinion, a clinical entity (with the due reservations applying to the concept of any entity) bordering (1) on normality, (2) on the neuroses, (3) on the psychogenic psychoses, and (4) on psychopathy. It contains elements of any, and sometimes all, of these entities. It is not just quantitatively halfway between the neuroses and psychoses; the blending and combination of these modes of reaction produce something qualitatively different. This combination of different reactions is characteristic for all borderline cases. Thus, the paranoid character and the schizoid are not just attenuated forms of paranoia or schizophrenia but possess a fair degree of normal functioning which enables them to live in reality to a sufficient degree.

## ¶ Concept of the Borderline

One reason why the borderline should be regarded as a clinical entity is that the patient, as a rule, remains substantially the same throughout his life. He is stable in his instability, whatever ups and downs he has, and often even keeps constant his pattern of peculiarity.* As the borderline condition rarely

* No psychiatric entity is absolutely rigid, and patients may both deteriorate or improve: neurotics sometimes do cross the border into psychosis or psychopathy and vice versa. Although it is easy to diagnose a condition ex post facto and call it "prepsychotic" it is much harder to diagnose it in the present unless it is already a case of pseudo-neurotic schizophrenia.[7]

In the same way, though borderline seems to be an entity per se, some patients cross the border into psychosis or psychopathy, become drug addicts or alcoholics, whereas others might stabilize into a neurosis or relative normalcy. The manifold factors that precipitate such changes have not been studied sufficiently, but social conditions certainly enter. According to Hollingshead and Redlich[8,9] there are thirty-one times as many schizophenics among the poorest classes as there are among the upper and upper-middle. They explain this discrepancy by the fact that in the middle classes psychosis is discovered and treated earlier. However, this is only part of the answer: since the borderline's problem is essentially one of object relation and relation to reality, it seems therefore likely that if reality treats him better, and more leeway is given to his peculiarities, he manages better to maintain an object relation and live

ushers in a schizophrenia, it should not be regarded as a prepsychotic condition (a diagnosis usually only made ex post facto!), as latent schizophrenia, pseudoneurotic schizophrenia, etc. While some schizophrenics in remission may resemble borderlines, the latter are different, because they have not been and are not likely to become schizophrenics. The borderline concept should also be distinguished from psychotic episodes, temporary or partial schizophrenic reactions to stress, etc. The characteristic features of the borderline are not his symptoms. He certainly lacks the more obvious psychotic ones, the delusions, far-going disorganization, or regression of the schizophrenic, and though he may have marked ups and downs, he lacks the manic elation or the melancholic depression. Though he is often suspicious and collects grievances, he has no true paranoiac symptoms, nor has he the dramatic symptoms of the hysteric or marked obsessional ones. Depression, anxiety, and other painful feelings may accompany any disorder and are even experienced by normal people under stress, and borderlines often suffer from them also. More interesting is their frequent lack of normal feeling.

Many disturbances cannot be regarded as either psychotic or neurotic and have sometimes been described as "transitional" (Glover).[5] Various offenses, sexual perversions, homosexuality and prostitution, alcoholism, drug addiction, hypochondriasis, eccentricities, peculiar behavior, querulousness, and vegetarianism are often found in borderline patients, but these symptoms are not invariably the hallmarks of the borderline. Alcoholism may be found in anybody from the near normal to the gravely disturbed; exhibitionism may be found in sexually inhibited neurotics but also may be combined with many other perversions as may be a symptom of psychosis, epilepsy, feeble-mindedness, or even in fairly normal persons under stress or temptation.

Characteristic of the borderline is the severe disturbance of the personality. The differentiation between a simple neurosis and a full-blown psychosis or psychopathy is easy; the diagnostic problem is to differentiate it from the normal person under stress (especially if we happen to dislike his personality), the milder forms of simple schizophrenia, and the character disorders. Borderlines should be broken down into major subgroups, such as depressives, schizoids, paranoids, querulents, hypochondriacs, antisocials (representing attenuated forms of psychopathy), mixed cases, etc.* It is preferable that the classifications should be in terms of clinical concepts, rather than in descriptive or dynamic ones. Thus, the "emotional unstable drifter" (in German, *haltloser Psychopath*) is usually a schizoid with some depressive or paranoid traits.

## ¶ Dynamics

Borderlines suffer from disturbances affecting almost every area of their personality and life, in particular, personal relations and depth of feeling; identification and empathy; their attitude to society and reality; volition and self-control; sublimations; activities and capacity for work; capacity for enjoyment and need for pleasure; sex life; the experiencing of and control of emotions; phantasy life; ideals, values, and aims in life; and a fargoing lack of integration in their personality. Their object relations are shallow and weak, and they lack depth of feeling, steadiness, empathy, and consideration for others.

Experienced psychiatrists diagnose borderlines by the clinical impression rather than by any particular symptom or trait of behavior.

within reality. In other words, he does not become psychotic. Psychosis is so often the solution of despair.

It is well known that there are many more offenders among the poor than among the rich, and it is not merely a question of apprehension and conviction against which the rich are better protected. In the middle classes more scope is given to delinquents while at the same time a great deal of pressure is used to socialize them. The way social factors affect mental reactions and hence further or hinder adjustment and deterioration must be studied in greater detail.

* As Kraepelin remarks, "there are innumerable types of psychopathy." Klages enumerates 4,000 words in the German language alone, descriptive of character traits, each of which could be used as basis for classification of character types. "Numerous authors have described systems of classification, which are difficult to compare, because sometimes for similar meanings different names are used, and sometimes for different meanings similar ones." (E. Trillat[15])

Downloaded from www.dbraulibrary.org.in

This impression is gained from the lack of genuine contact or its very short-livedness, the blankness of facial expression, and other indications of lack of feeling.

Some patients are aware of their inability to experience genuine emotion and suffer from it; others are unaware of it (probably because they never experienced it and hence do not miss it). Psychiatrically, if the patient is aware of and perturbed by his inability to feel, it is classified as a depersonalization phenomenon—a very frequent characteristic of borderlines. Patients who suffer from their inability to feel sometimes work themselves up into hystericlike scenes and overemotional reactions, or take drugs or alcohol, commit offenses, or have pathological sexual reactions to escape both their painful feelings and their lack of feelings.[14] Much of their acting out and emotional outbursts constitutes an attempt to break through their insensitivity. But though they often quite consciously long for the experience of genuine emotion, they are unable to tolerate it, and react very badly to any expression of it. They often break with the person toward whom they displayed affection, or they react with hostility. Others protect themselves against feeling by managing to keep their personal relations superficial or by frequently changing their jobs or abode. This largely accounts for their instability.

Borderlines are fundamentally nonsocial, and some are openly antisocial. They are severely disturbed in their relation to people, to reality, and to society. They cannot visualize the future in any realistic manner and cannot tolerate emotional continuity. They have a great deal of underlying hostility and negativism. The querulents in their self-righteousness and insistence on law and order cause untold trouble to others.

Schizoids and depressives are nonsocial by default and withdrawal; they drift, fail to work, stay in bed the greater part of the day, etc. Schizoids with psychopathic traits use their withdrawal to hurt others. One such patient, whenever he was severely depressed, usually as an aftermath to failure, would stay in bed for days and would count with a sort of fascinated horror how often the phone rang, which he failed to answer, well knowing that it was his mother or me calling him.

Paranoid reactions may sometimes cause aggressive behavior, but more often they cause withdrawal and disrupt personal relations. An adolescent of this type would leave his job on the spur of the moment, without waiting for his pay, if he did not like the way somebody looked at him; he would change trains for the same reason and travel in another direction. One left his ship during the war and became a deserter because he did not like the way the captain looked at him. Because the anxiety determining such behavior is not always obvious, such patients are often merely called drifters, or emotionally unstable psychopaths, or the like—a description that lacks understanding.

As adults, our main relation to reality and society is via our work and employment. Working, cooperating with others, getting on with fellow employees and the boss implies well-adjusted social behavior. Earning money honestly and planning to spend it realistically requires foresight, self-control, and the facing of reality. Thus, it is not surprising that the borderline is disturbed over work and that attempts to get him to take and keep a job constitute a large part of his treatment. Though some borderlines are of superior intelligence and perform occasional feats of brilliancy, they can rarely keep it up, as they lack powers of concentration, perseverance, and the willingness to make a steady effort. Often their memory is poor as far as work and studying is concerned. They have a particularly low tolerance for frustration, are oversensitive to criticism, react to the setbacks they bring on themselves with excessive self-pity, grievances, hostility, and withdrawal, and make little attempt to mend matters realistically. Because of their poor performance and unsatisfactory personal relations, they are frequently fired, or they throw up the job. They have underlying ideas of grandeur, actually resent having to do anything at all, and, in any case, expect praise and recompense out of all proportion. These attitudes also interfere with their acquiring any real knowledge. They cannot tolerate the frustrations and narcissistic hurts of the efforts and

Downloaded from www.libraryofpsychiatry.com

setbacks inherent in the process of learning. Learning presupposes the admission of one's ignorance, and this is a painful experience.

More important still than their intellectual difficulties is their inability to accept rules and routine, their underlying or open defiance, their not wanting to be like others, their resenting having to get up in the morning, to take the subway, to do tedious work. There are many vicious circles and chain reactions involved. Their poor performance stops them from getting or holding good jobs, and the resentment over this frustration throws them back further upon their narcissism.

Some change their jobs constantly; some just manage to hold one; others sponge on their families; many drift into unemployment, crime, alcoholism, and go down further because of their inability to hold a job. Whether they are able to hold a job, though with difficulties, depends not merely on their state of mind but on their intellectual ability, charm, social connections, or whether they have a family willing and able to get them a job or at least give a spurious reference. Many just manage to hold a job in times of prosperity, but if a depression comes, they are the first ones to become unemployed, and then their degeneration is hastened.

Their thinking disturbances, as a rule, do not attract much attention and are not as pronounced as in the psychoses, but there is, in almost every case, a disturbance of judgment, memory, observation, empathy, understanding of others, of connecting cause and effect, of foreseeing consequences, and, in particular, of what is called "common sense." The primary processes of cognition are intact, but, owing to strong denial mechanisms and the ensuing disturbance of normal associative processes, their faculty of observation and memory is often poor. However, these failures are selective, emotionally conditioned, as indicated by the fact that such persons sometimes remember a trivial grievance for twenty years.[13]

Logical thinking and observation are rooted in reality, and, at the same time, bring us nearer to it, and this situation the borderline tries to avoid. Again, failure to learn and to observe necessarily leads to a lack of knowledge—practical, social, scholastic—and this intensifies their emotional difficulties.

Their difficulties in work and learning are largely due to their failure to judge what is relevant. Many factors contribute to this failure to think properly. An important one is the inability or reluctance to identify, and thus, to learn from others. Here, again, important chain reactions are taking place. The difficulty over identifying is due to a poor development of object relations, but the failure to understand others and to consider them inevitably leads to friction with these persons. This, in turn, induces the patient to withdraw or to react with hostility, and the ensuing retaliation, on the part of others, makes him still more reluctant to have contact. *Identification* with others implies a consideration for them and a curbing of one's own reactions. Because the borderline is reluctant to impose on himself this amount of self-control, he refuses to identify. Also, he is narcissistically self-centered and does not want to get involved.

We learn much, even without being aware that we are doing it, by identifying with others. This applies, in particular, to what is usually described as common sense. The borderline, owing to his inability or reluctance to identify, has often failed to learn the most elementary matters, and, in particular, to understand other peoples' mentality and to anticipate their reactions. Unable (because unwilling) to foresee the reactions to his behavior, he is naturally insecure and hence is full of grievances, anxiety, and sensitivity. But he also likes to cultivate his sense of being wronged because it justifies his nonsocial attitude. His ignorance and lack of logic and foresight are largely selective.

He is capable of denying, to an amazing degree, the most commonplace knowledge in order to avoid the involvements arising from it, because these involvements might lead to action he wishes to avoid or might cause hurts or anxiety to him. After all, the disturbances of volition affect mainly activities and situations that involve his relation to reality, and it is this that the borderline tries to avoid.

These patients function poorly, suffer from severe disturbances of volition, and are reluctant to assume responsibility. The withdrawn type

Downloaded from www.dbraylor.com

seems to lack drive and even strong enough incentives for any type of action. However, if such patients change during the course of treatment, they suddenly show very strong needs and impulses, leading either to acting out or to rational acting. This indicates that what originally seemed a lack of drive was not primary but merely served to avoid the chain reaction of wanting, being frustrated, having to struggle, being involved in reality, being vulnerable. The acting-out type seems to have, at times, too much drive, but he is unable to keep it up in a steady manner. His acting-out behavior is largely a compensation for his failure to act—an abrupt reaction to his procrastination and inhibition—and alternates with periods of deep depression, anxiety, and withdrawal. Also, these patients spend so much energy on getting themselves into trouble, and out of it again (as a patient said "not only in going round in circles, but in arabesques"), in making the most complicated efforts to avoid work, or to face a problem realistically, that they have no energy left for normal thinking and remembering.

The borderline is thoroughly unhappy, even when he does not suffer from acute depression, because he is disturbed in both important and in unimportant areas. The average person gets quite a lot of pleasure out of trivial situations and even his day-to-day duties. The borderline, with ideas of grandeur at the back of his mind, jeers at these, spoils them for himself, and is then left with nothing to enjoy or to identify. The ensuing sense of dreariness and loneliness creates an excessive need for pleasure, greed for money, sex, food, spectacular situations, ostentatious spending, etc. It may also lead to the craving of the addict or alcoholic, the lawbreaking of the offender, the despair of the suicide. Such patients find routine and ordinary duties or social consideration too much to bear, because they have no capacity for enjoyment to compensate for the displeasures of delay or self-control.

Borderline patients may suffer from impotence and frigidity, or from excessive sexual needs and promiscuity, and, in the case of frigid women, from both. Their attempts to break through their depersonalization may lead to excessive sexual activities, and they need the sexual pleasure to compensate for the lack of affectionate feelings. Similar mechanisms apply to the excessive greed frequently found in delinquent children, and in alcoholism, addiction, and perversions. The immediate pleasure is to take the place of the personal relation, and it must be immediate and excessive because there are no happy memories and little hope or sense of continuity or forepleasure.

The lack of satisfactory personal relations may create a fanatic idealist as well as a criminal. Sometimes both extremes can be observed in the same person—an ascetic contempt for worldly possessions and the pleasures of the flesh combined with excessive sexual needs, uncontrollable ambition, possessiveness, envy, and greed, alternately and almost simultaneously. The borderline is a study in contrasts. He has characteristically inconsistent extremes of standards and behavior. A woman might get up in the middle of the night to clean the kitchen with obsessional thoroughness, but neglect to clean the room in the daytime; a bank robber might lie awake at night worrying about a debt of twenty cents; a patient could feel haunted by guilt and worry over not doing his job well, but would do nothing realistic to improve his work.

The extreme contrasts in borderline personalities are only partly due to a lack of integration. The normal person undergoes, in the process of growing up, a slow and steady blunting of his impulses, and he learns to compromise and to accept inconsistencies and shortcomings in himself and in the outside world. Borderline patients have failed to do so. Many offenders have told me that, as they could not live up to their ideals, with a feeling of despair they just gave up their ideals or religions and became criminals.

These patients are also particularly aware of and sensitive to any social injustice or inconsistencies, unless they go to the other extreme, figuratively close their eyes to the world, and withdraw. One such patient described his mentality as that of the "hyperbole." (This geometric figure is constructed by the positive and negative opposites on both sides of the axis.) The strong negativism and sadomasochism are

Downloaded from www.PsychiatryOnline.org

further factors in creating these extremes which reflect their ambivalence. It is important, for therapy, to be aware that the patient is dominated by such contrasts, because he can only be influenced therapeutically if both sides are reached almost simultaneously. It is necessary to be inconsistent in handling them and to contradict oneself in almost the same breath: to discuss their hostility, we have to mention their affection and appreciate simultaneously their idealism and antisocial attitude, their overvaluation of materialistic things, and their ascetic withdrawal.

Some borderlines—mainly schizoids and depressives—have not only an empty and vacant expression but seem to have a blank mind. Their main reason for not speaking is because they have nothing to say; there is really nothing in their minds. This emptiness is the result of repression, condensation, and denial mechanisms and is often a defense against very sadistic, frightening, peculiar fantasies, but it may, to some degree, be primary. Other types of borderlines, however, have very peculiar and abnormal types of fantasies quite consciously. They withdraw from reality for fear of turning their fantasies into real deeds and because their sadomasochism colors their concept of the world. The excessive living in fantasy interferes with their coping with reality, which intensifies, in turn, their anxiety and hostility.

Further characteristics are their querulousness, collecting of grievances, and hypochondriacal complaints. The latter concern not only the body but the mind; they describe worriedly and repetitiously their complaints, painful feelings, and peculiar reactions. Their fear of going crazy is akin to the fears of the bodily hypochondriac. Their querulous grievances and overawareness of social injustices and wrongs are also a sort of hypochondriasis concerning the outer world: the wrong (like the pain) should not exist, something must be done to stop it immediately—like a child who would still, at the age of ten, yell for his mother when defecation was painful. Such hurts to their narcissism they cannot tolerate; the world, as well as their own bodies and minds, must be perfect.

But these reactions serve a secondary purpose as well. One patient said he collected grievances like others collect butterflies, and who could expect him to give up the most precious pieces of his collection? If others are in the wrong, or if something hurts him (mental or physical hypochondriasis), this diverts attention from all he has done wrong or failed to do; it is a defense against guilt.[18] For that reason, proving the querulent wrong usually only makes him worse. Also, he clings to abstract standards and extreme ideals because he lacks security. He has no easy give and take, his parents usually were harsh and unforgiving, he could, at best, hope for rights but not for kindness and forgiveness.

While the classical neurotic symptoms are due to an excess (and secondary failure) of repression mechanisms, hypochondriasis, querulousness, and similar conditions are largely due to insufficient repression. The patient cannot forget and forgive, he cannot repress his hurts, the injustices he suffered, the little aches and pains he felt, as would the ordinary person and also the neurotic. This failure of the repression mechanisms to function adequately in the right place and way is one of the hallmarks of borderline patients, and this observation is of great therapeutic importance. Not only should we be careful not to remove indiscriminately their repression mechanisms, we also have to teach them how to repress and provide the motivating force for so doing. Many patients dwell on their grievances to prove that they are no cowards, assuming that forgetting a wrong is cowardice. Actually, they usually suffer more from anxiety than does the average person, and they have often acted cowardly. Teaching them to deal with anxiety-provoking situations or threatening persons in a social and realistically adequate manner helps these reactions a great deal.

## ¶ Therapy

The borderline patient poses a serious therapeutic problem, as the accepted methods with which we approach both the psychoses and the neuroses are inadequate. Medication may sometimes be used as an adjuvant but generally

Downloaded from www.brainlibrary.org.ir

serves little purpose; the same holds true for shock treatment; institutional treatment is, as a rule, undesirable, and ambulatory treatment full of difficulties; simple re-education, suggestion, or hypnosis are of very limited value; orthodox analysis is usually contraindicated or ineffective. Thus, new methods must be developed. In the last twenty-five years, I have treated several hundred patients belonging to the above type, including offenders, and I have long follow-ups on many of them. I have, for these patients, increasingly modified the orthodox Freudian analysis to meet clinical exigencies, utilizing an ego-directed and reality-directed analytic method combined with much re-education and education.*

The aim of therapy is to strengthen the more desirable or, at least, less pathological mechanisms and to counter the more abnormal ones. In other words, therapy must be selective, directive, and clinically purposeful. Undirected classical analysis is counterindicated, as the analytic process produces regression which the well-developed ego of the classical neurotic carefully selected for analysis can tolerate, but which the poorly developed ego of the borderline and the antisocial personality is unable to withstand. As Freud always stressed, orthodox analysis was devised for the classical neuroses only,[1] and in applying it a transference neurosis develops, but with a borderline psychotic, a transference psychosis is likely to take place (or a transference delinquency, drug addiction, etc.), and we can by no means be certain that we can make it disappear again. We cannot, as in classical analysis, remain detached onlookers, allowing the therapeutic processes to unfold. We should not allow even a temporary regression or deterioration, as this might lead to a serious disorganization or dangerous acting out. Free association furthers autistic thinking and withdrawal from reality, which is opposite to what we want to achieve with the borderlines. The detached and passive attitude of the analyst has a bad effect on the patient for various reasons, which I will discuss later. Carefully selected and worded interpretations are often helpful, but ill-advised ones may be dangerous. We should not give an interpretation without anticipating what effect it will have on the patient. The mere fact that it is correct does not justify giving it. Analytic knowledge is of great value in assessing the dynamics of the case, for handling the patient, and for judging progress or deterioration during treatment, but we must distinguish between the knowledge the analyst has and the one he conveys to the patient.

According to Freud, in the psychosis the ego is overwhelmed by the id,[4] which detaches it from reality.[2] Hence, our aim in therapy must not be to bring the unconscious indiscriminately into consciousness (Who is more dominated by his unconscious than the schizophrenic?) but to strengthen the ego and its control over the id, and develop its relation to reality. Thus, therapy must be directive and ego- and reality-oriented.[12] Treatment must improve the borderline's relationship to people, develop his reality sense, judgment, sense of continuity, forethought, and awareness of the consequences of his actions; in short, socialize him and develop controls.

If we regard neurotic mechanisms and symptoms in borderline cases as defenses against psychotic conditions, it is obvious that we must be very careful not to activate or intensify the underlying psychotic condition, but strengthen the existing defenses rather than break them down. This is achieved by selectively increasing repression, giving values and higher standards, furthering object relations and the relation to reality, while selectively and with discrimination undoing the effect of repression in other areas.

A therapist treating borderline cases has a serious responsibility. His prime duty is to pre-

* I want to stress the fundamental difference between Ferenczi's "active therapy"[2] (Rosen's "direct analysis"[11] and other similar methods) and the ego-oriented directive analytic method I developed. Ferenczi departed from the passive listening attitude in order to get more material and libido into the analysis. He was concerned only with the effect of his maneuvers on the patient's unconscious, and, incidentally, as he stated in later papers, was disillusioned with the result. I, on the other hand, depart from the passive listening attitude for clinical reasons, not to evoke interesting analytic material but to consider the patient's feelings, state of mind, behavior, and the effect of the treatment on the patient's life situation. I sometimes use devices to stop him from producing interesting material if it is pathogenic or clinically undesirable.

Downloaded from www.dbraulibrary.org.in

vent the patient from getting worse, to watch for danger signs or the beginning of disorganization or dangerous acting out, to prevent emergencies arising, and to cope with them if they do. Depressives may become potentially or actually suicidal, psychopaths potentially or actually criminal, and schizoids may easily regress into a full psychosis. Just as we will do all in our power to prevent a latent tuberculosis from flaring up into an open one, it is all important not to allow a latent psychosis to develop into an open one, or, at least, to limit it as much as possible.

For this reason, treatment of borderline cases must be planned, and the goals of therapy must be based on an evaluation of the patient's personality and dynamics, his environment, and his chances in life, with a minimum of the therapist's personal bias. Some aspects of the personality or certain reactions should be intensified, or modified; others should be minimized or underplayed. Certain people should become more aggressive, others less; sometimes, they should become more aggressive in some areas and less so in others. Usually, the goal is not so much to "get the patient's aggression out" as to make him more effective. Irritability and bad temper springing from helplessness or aggressiveness to bolster one's self-esteem are not desirable aims.

The purpose of the treatment is to diminish the patient's abnormality and increase his normality. As his normality increases, he becomes more receptive to normal strivings; as the area of this normality widens, he will be more ready to give up his abnormality. The more he is capable of socializing, the more other people begin to have a beneficial effect on him. The influence of others in normalizing the patient, whether it is done in a planned manner by the parent and probation officer or spontaneously by friends, is of great value. Improvement is like a stone thrown into water, creating ripples that are wider and wider. The therapist can utilize both good and bad situations that arise in the patient's life; and sometimes, try to bring about both kinds. Bad situations can be utilized to point out to the patient the consequences of faulty behavior or reactions or to teach him how to handle and accept them rationally. Good situations are, of course, encouraging and he should be reminded of them when things go wrong again or when he gets depressed. Also, sometimes it is useful to point out that he brought about the improvement himself by more socially desirable behavior.

Every possible device should be used to cajole, push, or let the family push the patient into normal situations, and afterward to make him aware of having acted normally. The strongest factor in socializing a patient is the fact that he has acted normally and socially and gained satisfaction from so doing; the knowledge that he is capable of being social and that he enjoys it is the strongest inducement for similar behavior in the future.

Improvement should be stepwise. Setbacks must be expected; they are not only inevitable but may be utilized for therapeutic purposes in motivating the patient for further effort and insight, teaching him what brought on failure, and desensitizing him to disappointments. With some patients, too much emphasis on "whys," too much dwelling on causes and on the past, counters their facing immediate problems and coping with present-day reality, and stops them from developing volition and ego controls and accepting responsibility.

Much has been written about the weakness of the ego, but little has been said concerning the specific therapeutic measures that develop ego strength. Two rather contradictory ideas are current: (1) that analytic treatment develops ego strength; (2) that ego weakness makes analytic treatment impossible. What, then, is to develop the ego?

The ego develops largely through its identifications, and, hence, identification with a therapist who has a strong personality is desirable. For that, however, the therapist must avoid a mirrorlike, objective attitude and must not be afraid to be himself, take responsibility, voice opinions and values, and show initiative. This is yet another reason why the too great detachment and self-effacement of the classical analyst is ill-advised for borderline patients. Much of this detachment is defensive on the part of the therapist and is unnecessary if we are capable of coping with the patient. We should not be too afraid of being maneuvered by the patient,

Downloaded from www.pdfbooksfree.pk

as this is, for many, the only means of establishing contact, but we should be able, on the contrary, to maneuver and, when necessary, stop the patient. The therapeutic relation consists, to some degree, in allowing the patient to test and even to take advantage of the therapist, and once a relationship is established, the patient should be molded with therapeutic ends in view.

The borderline patient with weak object relations has little capacity to identify in a favorable manner; hence, simple re-education is rarely effective. Before educating the patient, we must make him educable, and before we can achieve lasting favorable identifications and relations, we must make him capable of identifying. We must utilize his flimsy attachments, immediate needs, and passing interests and build on these. We must get him to accept many unpalatable insights, controls, and changes of attitude, which he will do only if he gets positive satisfaction and support from the therapeutic relation.

Therapeutic detachment is largely due to the fear that there is danger in making the patient dependent on the therapist. Naturally, there are possible dangers in any effective therapeutic device, whether it be medication, surgery, or psychotherapy. To change the patient, he must be influenced, and he becomes amenable to influence only through dependence. Obviously, the therapist should not only be ethical but should handle the situation with common sense, and the dependence should be for clinical purposes only. The patient's dependence should be utilized to solve his problems, to develop social adjustment and better relations, and to help him be more successful. As this happens, he will automatically become more independent. Thus, there will be no problem in stopping the therapeutic relation. Excessive dependence on the therapist (or anybody else) over a prolonged period is an indication of therapeutic failure.

To establish contact, we have to meet the patient on his own ground—socially, intellectually, and emotionally. We must show some understanding for the feelings of the depressed, for the withdrawal of the schizoid, for the situation of the former convict. Contact must be made with both the normal and the abnormal part of the personality; contact with the former alone is not likely to be lasting in a very abnormal person; contact with the latter alone is not curative. Once contact is established, it must be used to change the patient.

Going down to the patient's level must be done with the therapeutic purpose of eventually moving him into other directions. Merely to have a good relation with the therapist is rarely therapeutic in itself, though it may sometimes work with milder cases, provided the environment uses its pressure in a desirable way. For the more abnormal patient a good relationship, with a too forgoing or prolonged tolerance for his pathology, does more harm than good. The relation with the patient is no end in itself but a means toward clinical aims, and these must be carefully chosen. Hence, the need for a directive ego- and reality-oriented therapy.

In handling the patient, one should distinguish between long- and short-term aims, and often one may state this distinction to the family and patient as well. The short-term aim is to establish contact, bring some relief, make the situation tolerable for the patient and others, and, in particular, limit his acting out or withdrawal. Then we can gradually proceed to socialize him. Without initial improvement, treatment is likely to be broken off. I rarely aim at a systematic anamnesis or diagnosis in the first interview, but try to establish immediate contact. One always can get more detailed information later. I talk spontaneously, and often make a point of appearing nonprofessional. If a patient finds it difficult to talk, I ask questions or talk myself, attempting to put him at ease. Sometimes, I may start talking about myself or my interests, with controlled spontaneity, or I discuss subjects in which he might be interested. I occasionally offer a cigarette, have coffee with the patient, lend him a book, etc.

An experienced therapist should be able to give interpretations on the basis of little verbal material, drawing conclusions from the patient's behavior and character, his history, his symptoms, and his general pattern; from information received from the environment; from

Downloaded from www.dbraulibrary.org.in

analytic theory; and by putting himself in the patient's place and imagining what he himself would feel.

With a shy or distrustful patient, the therapist must take the initiative and show understanding and sympathy; once a relation is established, he can then help the patient to straighten out some of his practical problems. If the therapist takes the time to show personal interest in him, the patient becomes convinced of the therapist's genuine desire to help. Only then does he begin to identify. The relation should be essentially a friendly one, with controlled spontaneity on the part of the therapist, containing elements of both tolerance and authority.

The one thing that has a bad effect on a borderline patient is weakness and detachment; we need authority to have influence over him and his environment. Sexual and aggressive impulses, if they arise in the transference, often should be minimized and diverted rather than analyzed, and it may sometimes be better not to bring them into consciousness. If these impulses manifest themselves openly and strongly, it may be desirable to trace them to their source. By stressing the past, we also divert the patient from the immediate situation and make him less tense. Altogether irrational reactions should be discouraged, and, on occasion, definitely stopped or utilized for more normal purposes.

It is essential to clarify the difference between self-control and inhibition. Self-control is essentially conscious, a function of the ego, though it is aided by unconscious mechanisms. Failure of self-control, or failure to trust one's ability to self-control, exposes one to many anxieties—the fear of being overwhelmed by uncontrollable impulses and of the ensuing social and practical consequences. Patients who do not trust their capacity for self-control will avoid situations of temptation (sexual needs, greed, etc.) or hurt (which provoke uncontrollable aggression) and thus limit their lives.

The aim of therapy is not, as some therapists currently seem to feel, to remove inhibitions indiscriminately and to lower standards, but, as Freud always stressed, to replace the automatically functioning and unconscious mechanisms, which often realistically hamper the patient, by conscious self-control which is deliberately planned and directed. Thus, with a better developed ego the patient begins to cope with situations and to desensitize himself. Self-control, like any other faculty, is developed slowly and stepwise and is stimulated by overcoming difficulties. If no difficulties are encountered, the individual fails to learn to desensitize, to develop defenses and self-control, like a child who, if never exposed to bacteria, would fail to develop antibodies. Development of self-control is closely related to personal relations, reality sense, foreseeing of consequences, and development of the ego, and hence it goes hand in hand with modification of the narcissism.

Borderlines are excessively hurt by things other people regard as an ordinary part of life, yet they are remarkably thick-skinned, in many respects, to other peoples' feelings and demands. This oversensitivity is largely due to their excessive narcissism and feelings of grandeur—hurts and frustrations should not happen to them.

The borderline does not fit into any rigid treatment situation. His intolerance of emotional continuity and of steady object relations, his excessive changes of mood, and his defiance of routine often interfere with regular attendance. His inability to relax, his fear to lose hold on reality, his paranoid (or, in the case of delinquents, realistically justified) apprehensions hamper free associations; alternating between withdrawal and being overwhelmed by intense upsets, prone to dangerous acting out, he often needs contact between his regular sessions, though he may not attend the latter. Such patients are only little influenced by insight and tolerate silence badly. They need a very elastic technique and much latitude. Yet the latitude should not spring from weakness. After a while, when the patient normalizes, he should learn to show consideration for the therapist, and, in return, for what the therapist gives him, to make an effort. The therapist should sacrifice his comfort when necessary—as does every medical doctor—but he should not allow the patient to take too much advantage of him in the long run. These patients, even after they have normalized and

Downloaded from www.dbnpublications.org

are at their best, are still no subjects for classical analysis or for any method that has taken over its ritual.

The relationship between the therapist and the patient should not be the intensive, exclusive kind, reminiscent of a possessive, dominating parent. It must be such that it does not interfere with other relationships in the patient's life. A good relationship with the therapist is one of the strongest socializing forces; the therapist should use the patient's attachment to induce him to change and adjust. But the relation—often the first relation the patient has been capable of—also acts as a pattern for other relations. Adjustment to please the therapist is not necessarily of temporary value only, as it sets up many beneficial chain reactions. The patient learns to deal with his impulses by better ego controls and hence will be happier and less anxious; he learns to get on better with people—in short, he learns to gain satisfaction from living more successfully in reality and will, therefore, have an inducement to continue to do so, even after the therapeutic relation stops.

The patient should feel that the therapist has his interests at heart, but that is not tantamount to condoning everything he does. Mere assurances that the therapist is "his friend" carry little weight; if the patient feels that he is receiving genuine sympathy or practical helpfulness, he will himself come to this conclusion.

There is a trend to disparage early improvements, because they may not last or may represent a "flight into health." They may or may not be lasting, but if the therapist disparages them, they are sure to be crushed, and sometimes the patient does not recover from this disappointment, so that no further improvement takes place. Improvement gives hope and stimulates effort, and it is on the initial and often fleeting improvements that the more permanent ones are built. It is up to the therapist to intensify, stabilize, and utilize the initial and passing improvements. True, a very abnormal patient should not be allowed to get so elated over an initial improvement that he breaks off treatment. If the elation must be countered by pointing out all that is still wrong with him, it should be done so as not to kill his confidence. The therapeutic goals one holds out to and expects for the patient should be realistic, based on one's clinical experience and the therapeutic results one has achieved with similar cases. Too-extreme concepts of normality crush the patient. It is like giving him too high a wall to scale.

Analytic psychiatrists are often uncertain in their own minds as to whether it is desirable for symptoms to disappear. Characteristically, while we speak in medicine of the "relief from symptoms," in psychiatry we often speak of "losing" them. But they are certainly no loss to the patient. They constitute suffering, maladjustment, and failure. If the therapist is ambiguous in his own mind as to whether he wants symptoms to disappear, or feels uneasy if they do, they are not likely to disappear, or they will return. Analysis has taught us that symptoms are expressions of an underlying conflict and, in the borderline, often a defense against psychotic reactions. However, we must evaluate the importance of a symptom clinically as well as dynamically. Some symptoms are relatively unimportant in the patient's life, even if he is unduly concerned about them, while others seriously interfere with functioning.

As to the former symptoms, it may be desirable to get the patient to accept them, at least for the time being, to minimize them, to divert his attention from them. We must, however, try to curb symptoms that seriously interfere with adjustment, and the ensuing relief and better adjustment are of great therapeutic value. I usually go first for the symptom that is either easiest to influence or is most disturbing, because the resultant improvement is a main factor in establishing a relation. At the same time, we should try to deal with underlying conflicts and strengthen the patient's personal relations, which is the best antidote to possible psychotic reactions. We can deal with the underlying conflict even without revealing it to the patient; for example, if it concerns his unconscious hostility toward his father, we can find other acceptable outlets for his aggression, make him less sensitive to guilt, improve realistically his relation to his father and to father substitutes, make him

Downloaded from www.vlebooks.com

more independent, and remove some of the causes of his resentment.

The main difference between classical analysis and psychotherapy is that the former works from the depth to the surface only, while the latter attacks in many direction. Normality is not tantamount to rigid stability, but, like the dynamic equilibrium of the physiologist, is the outcome of innumerable chain reactions and checks and balances. Psychotherapy can attack any of these chain reactions, and the more it influences, the more effective it will be. It can affect the environment through the patient, the patient through the environment, and every member of the family through each other. Dynamically too, it can work from the surface to the depth, and vice versa; it can increase repression and decrease it (often simultaneously in different areas), attack the infantile origin of a symptom or its present-day meaning, or influence it by environmental manipulations, by increasing or decreasing pressures, by giving or denying outlets, etc.

Psychotherapy is the combination and integration of many therapeutic devices affecting many chain processes in a planned manner for attaining clinical goals. Not only are there these constant chain reactions, but the mind is not really compartmentalized; it has only been described in compartments by the scientific observer. The subject himself, unless he is scientifically trained, is not aware of volition, cognition, emotion, etc., as separate entities, as they constantly merge into each other. Such distinctions are necessary for scientific description, but they are artificial and do not exist actually.

It is important to make the patient aware of his disturbances in thinking and judgment in a way that does not undermine his self-confidence, and to teach him in concrete terms how better to handle any of these situations and how to think more realistically. We can, afterward, analyze the reasons for these disturbances, but it is more important to point out the malfunctioning in great detail with a view to correcting it step by step. This is one of the most important aspects of the patient's re-education (or often education). Here again, there are constant chain reactions. If we can teach the patient forethought, he will think about the consequences of his actions and develop a greater measure of control; a better understanding of other people leads to more consideration and this, in turn, to more control. Some patients require vocational or scholastic training. Apart from its practical usefulness, the process of learning teaches the patient that steady effort is required to gain one's ends. Thus, the "pleasure principle" of the small child (for whom there is little difference between wishing and having, naming something and knowing it) is countered, his ideas of grandeur and his living in fantasy are curbed, and his adjustment to reality is furthered. The psychological value of learning and of steady effort consists largely in the way it attacks primitive narcissism and modifies it into a more realistically justified self-esteem based on actual achievement.

It is essential that the therapist develops the patient's judgment and acts as an organ of his reality sense until such time as he himself can function adequately. The borderline is narcissistically centered, though he may be full of self-hate. It is important to make him gradually aware as to how others see him and by what means he provokes favorable or unfavorable reactions in others. If the patient understands the cause-and-effect relation and ceases to feel like a pawn in events, and knows that he can produce desirable reactions in others, feel more confident, he will have less anxiety, and become more social.

As stated before, the acting out of borderline patients should be curbed and their antisocial or dangerous activities stopped. But what about making them act normally? How can therapy initiate activity and develop will power? It has been argued that a patient cannot become independent if he acts because of dependency on the therapist. But changes in character and personality are a stepwise process. First, we must get the patient to be more active and successful, and then he will gradually find new people and interests in his life, and thus become increasingly independent. The main thing is to get him moving. He has been in a rut for many years, maybe all his life. Often, his lack of experience and his helplessness add to his anxiety. Merely to point out to him his anxieties and inhibitions will

Downloaded from www.PsychiatryOnline.com

effect a change too slowly or even make him feel none. The failure to act is not always due to inhibition; sometimes, it is a primary failure of not having learned how to act, and therapy then has to imply education rather than re-education and develop something that has hardly existed heretofore.

To get the patient moving, we have to utilize any incentive inherent in his life situation or pressure emanating from his environment. If it is impressed upon him at the right moment and in the right way that he is more likely to find a nice girl, or that he will make a good impression on the probation officer of whom he is afraid, if he finds himself a good job, he is likely to want to look for one. And only when he wants a job, should the therapist offer his advice on how to go about it. Then, once the patient has embarked on looking for a job, we can discuss his difficulties, anxieties, and inexperience. It makes little difference how the patient is originally motivated as long as he embarks on an activity that in the long run is to his advantage, because the gratification he derives from it acts as an incentive to proceed.

Naturally, the patient is aware that it is to his advantage to have a good job, or that certain hobbies are pleasant, but the mere knowledge that something is desirable produces remarkably little effect unless emotions are evoked. Students are usually more motivated to study by the fear of exams than by the knowledge that this studying is essential to their future. Psychologically, we become aware of the outside world only through the emotions it evokes, and it is essentially emotions that provide the drive for action. Thus, any disturbance of emotions, or of the linkage between stimulus-emotion-volition, leads to disturbances of volition and action. The emotions acting as incentives may be positive (desire, pleasure, greed, sexual needs, ambition) or negative deterrent ones (fear, guilt, shame, disgust, etc.). Usually, we are motivated by a combination of positive and negative incentives. These considerations are of therapeutic importance. We must arouse emotions and desires, direct these incentives into the right channels, and link them with the desirable course of action. We can utilize or reinforce any emotion inherent (or potentially inherent) in the patient's life situation, for example, use fear of the court as deterrent, or stimulate desires as positive incentives. We can also create new associations or reinforce or redirect existing ones. Moreover, we can channel generalized or irrational emotions so that they act as levers for normal behavior. If the patient's generalized anxiety can be focused onto his fear of the police, he will stop committing crimes; if his bad feelings can be concentrated onto guilt toward his wife, he might act better; if his good feelings can be connected with the awareness of having acted well, he is likely to continue to do so. We must connect emotions with volition, create the desired associations, and in this be led by clinical and social values. We can influence the patient directly as well as indirectly. It is often stated that suggestion is ineffective or short lasting. This depends on the influence we have over the patient, and that is why therapeutic dependence is essential. True, the patient does not accept everything he is told, and it has to be repeated often, in many ways. One patient said he does everything I tell him—but a year later. Many patients do not even know that they are acting on what I told them long ago. Whether a change is lasting or not depends largely on whether it is ultimately in the patient's interest: The rewards inherent in the change are a strong motivating force to make it permanent. Patients usually change stepwise, with setbacks, but after repeated partial improvements, these tend to become permanent.

An excellent device for channeling feelings and creating or modifying associations is by means of clinically tendentious interpretations. According to E. Glover, inexact interpretations are more often therapeutic than correct ones.[a] To interpret to the patient, "you unconsciously thought" is usually more effective than any direct suggestion.

While analytic psychiatry has paid a great deal of attention to emotions, not too much has been written as to how they should be handled therapeutically. Indiscriminate abreaction or intensifying of emotions is undesirable with borderlines, and, while an occasional abreaction in an inhibited patient or one under great stress may be of value, repetitious abreac-

Downloaded from www.dbeatlibrary.org.in

tion easily turns into an undesirable conditioning. Sometimes, it is good to evoke emotions but, as a rule, only up to a point; in other cases the patient should acquire more self-control. We must teach the patient how to cope with his painful feelings, and, to some degree, he will copy his therapist's reactions—an experience he foregoes if the therapist remains continuously detached. One way of coping with emotions is, for example, to bring out some anxiety, discuss it for a while, then minimize or divert the patient from it. The patient must also be conditioned how better to tolerate unpleasant feelings and it is reassuring for him to hear that others, too, suffer from painful feelings. It is a hurt to everyone's narcissism to be exposed to painful emotions, but the borderline resents this especially. He builds complicated spirals around the initial painful feeling, takes it as an indication that he may be going crazy or is inferior, and then is worried about his state of mind. If these secondary spirals can be reduced, the patient learns to tolerate better the primary bad feeling, and this usually goes hand in hand with some modification of his narcissism. Also, painful feelings can be channeled and therapeutically utilized or even be given a narcissistically positive value. It is easier for the patient to tolerate anxiety if it is lessened, especially if it is impressed upon him that it is now different from his former pathological reaction. We must appeal to his sense of responsibility to develop volition and self-control and convey to him that the effort is up to him. He must be told directly as well as by implication that he is capable of coping with his emotions himself. At the same time we must have succeeded in reducing his bad feelings to a degree where he really has some control over them. To give one example, in a severe depression the patient has lost all hope that he will ever feel otherwise, and he will fight even a momentary improvement for fear that after a brief spell he will again feel depressed, and then, by contrast, experience the depression more. He will refuse to make any effort as long as he has no hope of feeling better, and he cannot feel better unless he has hope. We must break through his depression by any means at our disposal—by medication, diversion, getting out some aggression (an often very helpful factor in depressed patients), by somehow building up his self-esteem or just pouncing on a spontaneous change of mood and reinforcing it. Once the patient feels better, even if only for a few moments, we can draw his attention to this improvement, and capitalize on it. If we can plausibly (whether it is actually justified or not) connect it with therapy, this is all to the good, as it gives the patient more trust in therapy, and he will then be more ready to make the necessary effort. By describing to the patient in detail how a depressed person feels, contact can sometimes be established which might form the basis of attachment. Once we get some attachment, the patient is likely to feel better, and thus, a favorable chain reaction develops.

To influence the patient, we must approach him both intellectually and emotionally; the two cannot be separated. Reasoning evokes emotions, and emotional contact makes the patient more receptive to reasoning. To evoke emotions in withdrawn patients, we must, ourselves, show emotion and spontaneity, and this is yet a further reason against a detached analytic attitude. Most borderline patients are not motivated the way the psychiatrist may wish them to be. Often, they come for treatment only under pressure of their families, or, if delinquent, they are sent by the court. But even if they come on their own, they come because they feel unhappy or do not have a job, or have trouble with those around them, and they would like this to change. However, that does not mean that they really want to change themselves or that they realize that the cause of the trouble lies within themselves. Even if they have some insight, it rarely lasts or is a sufficiently strong motivating force. It is the task of therapy to motivate the patient for therapy, and that is done more by getting attachment and giving help than by reasoning. If the patient feels and functions better, he feels gratitude which helps to cement the therapeutic relation. But as soon as the pressing need lessens, his motivation also tends to wane, and we must motivate him again and again. Motivating is a continuous process; not only is it necessary to make him cooperate, but

Downloaded from www.freebrain.com

it stimulates and parallels the development of his reality sense. Insight is a particularly weak tool for influencing borderline patients. They are narcissistic; their super-ego and judgment are poorly developed; they have weak motivations, marked disturbances of volition, and their relation to reality is disturbed. They are reluctant or unable to connect consequences with their behavior and make excessive use of projection and denial mechanisms. They have much more effective ways of warding off insight than do the neurotics; they fail to attend regularly, come only when they are in trouble, and then want an immediate solution of their immediate difficulties. They alternate between feeling indifferent and desperate, and in both of these states are difficult to reach. When they are indifferent, they are not interested in the treatment, and when they are desperate, they are too preoccupied with feeling desperate even to discuss intelligently what brought on their situation. They do not listen to what the therapist says, or they disparage it. They are able, to an amazing degree, to forget any insight they may have shown on occasion. They dwell on their grievances and the shortcomings of others, or of society, and do not see realistically what is wrong with themselves. Even their self-deprecation is a defense against genuine insight involving change. They accuse themselves excessively or suffer from extremes of depression to ward off possible criticism. In other words, they use all their energy, intelligence, and conscious and unconscious defenses to ward off the most elementary common sense. Trying to reach such a patient by insight is like battering the walls of a castle with a tin spoon. We must get under his skin and devise methods of gaining influence over him and, more important, get him into such a frame of mind that insight becomes tolerable. For instance, as long as the patient feels too guilty or unhappy, or is behaving very badly, he cannot accept interpretations that increase his guilt, but once the therapist has made him act better, he is more able to tolerate the realization of his faults.

Some interpretations reassure the patient while others upset him. This depends not only on the form of the interpretation but also on the content. If we want to reassure the patient, interpretations should be given so that they are not interpreted as reproach. At the time of, or even better, before, interpreting antisocial impulses, it is good to draw attention to his affection. With some patients, a generalization, such as "It is only natural that you resented . . ." is preferable to a straightforward interpretation of his hostility. The patient is more willing to admit that he felt angry for a brief moment in a justified situation than that he has sadistic ideas. If the patient does not tell, one can make safe guesses. It is likely that a girl, who has been in an institution, feels resentment against the matron. But the girl may insist that the matron was nice and treated her well. "Surely," I say, "she does sound like a nice person. But you know, nobody is perfect. Sometimes something must have annoyed you." Then she starts talking, and after fifteen minutes the matron does not sound like a nice person at all. In testing out interpretations, one should go cautiously and watch the patient's reactions, starting on comparatively safe topics. Sometimes, it is better to give interpretations phrased as questions. A boy is less likely to feel guilty about hostility toward his teacher than toward his own father. The order of interpretations is important, and it may make a difference whether a certain interpretation is given five minutes earlier or later. One has to watch the patient's reactions to the interpretations. If he is upset, one can either analyze the upset or reassure him, or do both, or to a certain extent, take back the interpretation and divert him. This step-by-step method makes it possible to control the effect of interpretations.

Even correct interpretations may have ill effects. Withdrawn or obsessional patients may dwell on insight in order to avoid action; interpretations may provoke regression, acting out, or intense anxiety. The fact that the analyst knows what goes on in the patient's mind may evoke paranoid fears of his omniscience. A psychotic may fit the insight into his paranoid ideas, a psychopath use interpretations to justify his antisocial behavior; they may also intensify a depressive's self-accusatory reactions or induce a further schizoid with-

Downloaded from www.dbraulibrary.org.in

drawal from reality. My first antisocial patient, a schizoid prostitute, became homosexual and a thief in the course of being analyzed. The analysis consolidated her latent homosexual trends into manifest homosexuality, and her previously vague antisocial tendencies into definite law-breaking activities. This effect was undesirable, and I have never since analyzed borderlines without balancing interpretations by very careful countermeasures. In current psychiatric thinking, the impression prevails that defenses are something undesirable or even pathological. On the contrary, they are as essential for mental functioning as is any vital organ of the body.

As the aim in treating borderlines is to strengthen the ego and its control over the id, we must be careful not to weaken the existing defenses by interpretations, by encouraging the unconscious material to emerge indiscriminately as in free associations and uncontrolled fantasying, or by being unduly tolerant of pathological manifestations and impulsive behavior. Moreover, we should develop the existing defenses and build new ones, utilizing our understanding of dynamics for this purpose. Anything that develops the ego also strengthens its defenses. In particular, setting limits, developing volition, forethought, responsibility, and consideration for others, stressing consequences, socializing the patient, and giving him values force him to develop defenses. Values and standards are of positive emotional significance; they are as important for normal development as the fulfillment of material or sensual needs. They fashion the personality and form an important part of it. Values, ideals, and standards act as levers that check primitive impulses, and thus further repression and other defense mechanisms, but they also give positive satisfaction that compensates the instinctual frustration.

In the same way, standards are not something negative, to be combated; they give security, direction, are of positive emotional value, and supply a sense of belonging to the community. Confusion of, or lack of, standards makes for insecurity. Lack of ideals and hope causes dissatisfaction and increases the need for material pleasures, which, if excessive, is bound to lead to competitiveness, hurts, unhappy experiences, and pauper emotions.

Real achievements, social acceptance, and greater self-control lessen anxiety. Guilt is effectively diminished by stopping the patient from doing guilty deeds and inducing him to do positive things that satisfy his conscience. For normal adjustment it is just as important that the woman clean her rooms in daytime as that she stop her obsessional cleaning at night, or that a patient not only give up his neurotic worries over work but become more efficient. If the patient has extreme ideals and standards, and the latter fail to influence his behavior, we have both to modify his standards and make them more effective. With others, their standards are ineffective, simply because they are too low, and we must set higher ones. Each patient must be treated individually, according to need, and even differently at different times. Sometimes, he needs more instinctual freedom, sometimes more control; in some areas his standards may be too high, in others, too poor, and we must use our influence in an elastic manner. We must, on occasion, sensitize the patient toward his own impulses and ideas if we want him to control them better; sometimes, desensitize him toward them if he is unduly afraid of them. Analytic interpretations are important tools toward achieving this, and we should evaluate interpretations more from the point of view as to whether they sensitize or desensitize, than according to their content. This sensitizing or desensitizing effect is to quite a degree achieved by the wording, tone of voice, comparisons used, etc.

The treatment of borderline patients is fraught with difficulties and possible dangers. That is why many psychiatrists refuse to treat them outside institutions. The main dangers lie in extreme withdrawal reactions or in acting out, such as suicide or impulsive or criminal acts. But even apart from serious dangers, impulsive or aggressive behavior must be limited. The longest analysis will not help a marriage if, in the meantime, the marital partner has filed for a divorce. Loss of a good job, expulsion from medical school, or breach with the family should be prevented. Hence, some im-

Downloaded from www.dbraulibrary.org.in

provement must be achieved quickly, and the treatment conducted so as to lead to a minimum of upset in the patient's daily life.

The main method of preventing dangerous acting out lies in a positive relation to the therapist. I encourage difficult patients to phone me in an emergency, and I will either talk to them on the phone or see them outside their regular session, if necessary. The patient often tells more on the phone than face to face, partly because he appreciates the trouble the therapist goes to for him, and partly because the emergency usually makes him more talkative. One can give interpretations on the phone, reassure him, or merely encourage him to talk. It is important, however, to reduce these emergency contacts as time goes on, and to get the patient more adjusted to therapeutic routine. Although the therapist feels and shows concern for the patient, he should not transmit his anxiety to him. To prevent dangerous acting out, one must cope early with the situations that are likely to cause the patient to get upset, and must limit and channel his painful feelings.

The chief reasons for dangerous acting out are despair and revenge; if life is made more tolerable and the patient is given hope, he is less likely to do anything desperate. It is bad if the transference relation is too intense and the therapist is the only one he has to fall back upon. The patient should be able to act out his ambivalence to some degree and turn from the therapist to others when he feels angry or hurt. Any personal relations the patient has should be encouraged, and even unfavorable ones only reluctantly broken up until there is something better to take their place. One can introduce new persons into the patient's life, get a social worker, probation officer, or medical practioner to take an interest in the patient, or, if he is well-to-do, engage a companion or nurse, find the patient a job or some occupation, or get the family to take more interest in him. I, myself, have a psychiatric assistant, but I have, on occasion, used my maid, or, in the London clinic, the caretaker. Many persons, professional or nonprofessional, can be utilized for therapeutic purposes. It is possible, and often necessary, to create an institution outside an institution, to regulate the patient's day-to-day life and routine, and even have him under supervision or restricted. Sedation, sleeping drafts, and placebos are often useful. It is essential to teach patients how to cope with their loneliness, mainly over the week ends and how to deal with anxiety or upsets. In advising the patient to plan his day, or in deciding what interests to encourage or discourage, we should not be guided just by common-sense considerations as to what a normal person in such a case would do. We must utilize our knowledge of dynamics to assess the likely psychological effect of any occupation or situation on the patient (or sometimes on his environment). For instance, a patient with overintense guilt reactions or one suffering from a severe depression often reacts badly to the things that normally would give pleasure. Hence, he is made worse by them, and, in such a case, it is better to advise occupations that entail hardship but satisfy his super-ego and, by keeping him busy, divert him from thinking about his depression. This is one value of work and routine. Sometimes, with oversensitive patients, we have to find something that is as far away from their real interests which would evoke conflicts, as possible. (I made one patient take courses in Greek philosophy and ceramics for this very reason.)

Because it is essential to avoid a too-sudden increase in guilt reactions, indiscriminate encouragement toward sexual activity or pleasure may be dangerous. Some borderlines react in a psychotic manner to the realization of their sexual desires and, in a few cases, the impending marriage or permanent sexual relation seems to have triggered off open schizophrenic breakdowns. While with certain inhibited schizoids, it is desirable to encourage sexual and permanent relations, there are others where one should do all in one's power to discourage and postpone it. Sometimes, a year or two later, if the patient has normalized in other areas, he can tolerate such relations. The careful handling of the patient, based on the constant analytic evaluation of his reactions to stimuli and stresses, is the key to the treatment of borderline patients, rather than interpretations, and the handling has to differ according to how the patient himself changes or the environmental situation fluctuates.

Downloaded from www.dbraylibrary.org.in

While it is safe to encourage certain patients who change only slowly, there are others who change too quickly from a depression into an elation—even if there has been no manic episode in their history—and dangerous acting out or psychotic reactions may ensue if the elation is not stopped in time. Depression is more painful to the patient, but apart from the possibility of suicide, it is rarely dangerous. Elation may trigger off the freeing of oneself from controls and the limitations of reality, leading to manic reactions, schizophrenic ideas of grandeur, delusions, and even to catatonia. This development is an important factor in the cases where analytic psychotherapy has led to an open psychosis.

The orthodox analyst takes only classical neurotics who come on their own volition, have insight, and on whose cooperation he can rely. He avoids contact with the family, as this might interfere with the transference situation. Many borderline patients, irrespective of their age, are not self-supporting; in other respects also they are very much dependent on the environment, because they cannot cope with life. Moreover, such patients often attend irregularly, and keep the most relevant things to themselves; but we must know what goes on as they are still our patients, whether we see them or not. For that, we need the family to cooperate, or at least to keep us informed. I encourage both patients and members of the family to phone me, though I may limit the number of calls or the time I speak to them. Sometimes I phone the patient or family myself. I have, in emergencies, gone to the patient's home or sent my assistant. If there is a serious possibility of suicide, one has, of course, to take careful precautions.

One must have a relation with the family (1) to get information from them currently, though not necessarily frequently; (2) to be able to influence their behavior and advise them how to handle the patient in specific situations, tell them what is important, what not, and teach them the danger signs; and (3) to sympathize with their side of the picture and help make life bearable for them while the patient is being treated. Of course, one should not have too many illusions about the family's cooperativeness. Abnormal patients usually have difficult families. But we have to work with them as they are. The therapist must assess the amount of cooperation he is likely to get, determine in what areas the family can help, and decide which member will be most useful. On the other hand, the therapist must get some improvement or, at least, better behavior from the patient, so that the family is willing to continue making an effort. It is impressive to note the degree to which very abnormal parents have changed when a son or daughter improved. While, originally, the parent sets up a pattern of abnormality in his child, after a while the child's abnormality imposes a terrible strain, and, in turn, produces abnormal reactions in the parent.

While I do not hesitate to remonstrate with a parent over some aspect of behavior, I will not hold him wholly responsible for the child's abnormality. I will convey to him that I know he had tried his best, even if he did the wrong thing. When I criticize parents or want them to change their behavior, I do not discuss their unconscious attitude or ambivalence. Analytic interpretations should be restricted to the analytic situation; they tend to evoke guilt and, if combined with definite blame, may provoke excessive and unfavorable reactions.

We should not take away or break up anything in a patient's life before he has something else upon which to depend. Simply because a patient is abnormal and his home life is unsatisfactory is no reason to encourage him to leave home. Often, he is so abnormal that nobody but his family will put up with him. Then, again, breaking away may produce a loneliness that is worse than family quarrels. Leaving home should never be too glibly recommended by the therapist, but a great deal of thought should be given as to how and when it should be advised and how it should be carried out.

# PART THREE

## *The Functional Psychoses*

Downloaded from www.dbraulibrary.org.in

CHAPTER 22

# MANIC-DEPRESSIVE PSYCHOSIS*

Silvano Arieti

Downloaded from www.dbraulibrary.org.in

As VARIABLE as its clinical picture is, as unconfirmed as its dynamic interpretation remains today, as controversial as its etiology continues to be, manic-depressive psychosis nevertheless strikes the student of psychiatry for its relative simplicity and for the facility with which its nosologic concept is grasped even by the beginner.

It is therefore appropriate to start the section on functional psychoses with the study of this condition, for it can serve, in part, as an introduction to the study of more complicated disorders.

## ¶ Introductory Remarks and Historical Notes

Already, at this point, several questions may have occurred to the reader, on account of the fact that we have labeled the disorder a "functional psychosis." Why a psychosis, and why functional? Since many cases of manic-depressive psychosis are very mild, and the percentage of these mild cases seems to increase in relation to the total incidence of the disorder, it would seem logical at first to call the condition a psychoneurosis rather than a functional psychosis. The term psychosis, however, does not indicate only an actual or potential severity of the disorder (a severity which may be reached even by some psychoneuroses) but also connotes the fact that the psychopathological way of living is, in a certain way, accepted by the patient. No matter what transformation

* In this chapter is included the study of the disorders which, according to the official nomenclature of the American Psychiatric Association, are called:

000-X10—Affective reactions (301.2)
000-X11—Manic-depressive reaction, manic type (301.0)
000-X12—Manic-depressive reaction, depressive type (301.1)
000-X13—Manic-depressive reaction, other (301.2)
000-X14—Psychotic depressive reaction (309.0)

The number in parentheses at the right is the code number from the International Statistical Classification (from Committee on Nomenclature, *Diagnostic and Statistical Manual: Mental Disorders*, 1952).

the psychotic patient has undergone (either a predominantly symbolic transformation as in schizophrenia, or a predominantly emotional transformation as in manic-depressive psychosis, or a predominantly cognitive defect as in organic conditions), that transformation becomes his way of relating to people and of interpreting the world.

The manic-depressive patient does not fight his disorder, as does the psychoneurotic, but lives in it, and therefore is psychotic. In this respect he resembles persons who are affected by character neuroses, and who do not even know of the pathological nature of their difficulties. The distortions of the character neuroses, however, are susceptible of at least partial adaptation to the demands of society, whereas in psychoses such adaptation is not possible.

Several psychiatric authorities sharply oppose the use of the word "functional" on the grounds that each condition is at the same time organic and functional, since an organ must always be there to mediate a function. Stanley Cobb,[21] for example, states that "every symptom is both functional and organic."

In the neuropsychiatric frame of reference, this statement is perfectly valid: Every symptom is functional inasmuch as it consists of a physiological function of the organ, and organic inasmuch as it requires the organ that mediates it, either in its anatomical integrity or in its pathological alterations. The statement carries the implicit admission that such states as the functional and the organic do exist. Neither state, however, can exist without the other; we may conceive them separately as abstract concepts, but in the physical world they are always together.

How is it then that the term "functional" has been retained in American psychiatry and is so widely used? According to the present writer, its use is not maintained merely through semantic inertia. Like many other words in every language, it has enlarged some of its meanings and lost some others, and has come to convey a group of concepts which, at the present stage of our knowledge, may still be useful.

A functional point of view about a psychiatric disorder does not exclude the possibility of a hereditary or constitutional predisposition that makes the functional transformation possible. It does not exclude recognition that any function is accompanied by a physical, molecular substratum. It does not even refer to the fact that functions are generally transitory and reversible, whereas organic alterations are not, because this is not true in every case. A memory trace may be permanent, and an anatomical alteration may reverse completely. The functional point of view focuses on the fact that, no matter what the complex causality of the disorder may be, it is the particular form of functioning (or of operating) with its content that constitutes the predominant and primary (although not exclusive) essence of the disorder and leads to secondary sequels, both organic and functional.

It also implies that the dysfunction is predominantly determined by, or connected with, an emotional maladaptation, which, in its turn, is at least partially provoked by a human environment. For instance, it is obvious that functional cases differ from psychoses occurring with tumors of the cerebral hemispheres. Here the normal functionality is secondarily expelled by the histologic alteration.

It is certain that the last word has not been said on this important subject; for the time being, however, the concept of functional disorder is found useful by many, and therefore retained in the classification adopted in this handbook.* In the European literature functional psychoses are generally called endogenous. This classification implies that these psychoses are based primarily on hereditoconstitutional factors or causes within the nervous system, in contrast to the disorders which are exogenous—that is, originating from causes outside of the nervous system. This classification is no longer acceptable to the majority of American psychiatrists.

The following definition of manic-depressive psychosis is based on the fundamental Kraepelinian concept, and we shall use it only as a preliminary statement in order to proceed in our study until, toward the end of this

* The present author would prefer the designation "psychosomatic" to functional. See Chap. 24, p. 491.

Downloaded from www.dbraulibrary.org.in

chapter, we shall attempt a more complete one.

*By manic-depressive psychoses is meant a group of mental disorders characterized by periodic attacks of melancholia or elation of rather marked proportions, accompanied by retardation or hyperactivity.*

## *Historical Notes*

The reader who is particularly interested in the historical perspective of the concept of manic-depressive psychosis is referred to the excellent article by Jelliffe[41] and to the monograph by Zilboorg[94] for the prepsychoanalytical literature; for a historical survey of the analytical literature, the reader is referred to Lewin's monograph[61] and to Roi's article.[82] In this volume we shall restrict our discussion to a brief exposition.

### Ancient Times

As Zilboorg[95] aptly says, manic-depressive is a condition which has been known since antiquity and which seems to have changed comparatively little in its symptomatology—much less than other mental disorders. According to Jelliffe,[44] the disorder is "the only form [of psychosis] whose chief features may be unequivocally recognized down through the ages." According to Koerner,[51] the earliest record in Indo-Germanic cultures is that of the melancholia of Bellerophon in the Homeric epics. In the writings of Hippocrates, we find many references to mania and melancholia. He considered manic and melancholic states to be chronic conditions, although he admitted the possibility of recovery in some cases. He distinguished various forms of melancholia and swings of mood, although it seems certain that he did not make any connection between the elation of the manic and the melancholia of the depressed patient.

Not until several centuries later, when Aretaeus appears on the scene, was any additional contribution made to this subject. According to several authors, Aretaeus lived in the second century of the Christian era, but other authors, such as Cumston and Zilboorg, think that he lived toward the end of the first century. Aretaeus was born in Cappadocia, a kingdom in a region of Asia Minor. The kingdom of Cappadocia was part of the Roman Empire, and it is possible that Aretaeus practiced most of his life in Imperial Rome. He was particularly interested in the condition that we call manic-depressive psychosis. His observations are so exact and deep as to be comparable to the modern views on this disorder. He not only described the symptomatology of manias and melancholias but also saw a connection between the two states. He observed that young people are more susceptible to mania and older people to melancholia, and that, although the two states are related, mania is not always an outcome of melancholia. He seems thus to have anticipated for at least seventeen centuries the contributions of Kraepelin. In certain ways he went even further than Kraepelin, for he felt that spontaneous remissions were not reliable. The intermittent character of the illness was clear to him. He also described very well the religious, guilt-ridden, and self-sacrificing attitudes of the melancholic and the gay and overactive behavior of the manic. He reported how a severe case of melancholia, about whom many physicians were pessimistic, recovered fully after the patient had fallen in love.

### Classical Period of Psychiatry

The teachings of Aretaeus were soon forgotten or ignored, and not until 1851 did a French psychiatrist, Falret,[30] again describe the condition and grasp its intermittent and circular character.* Kahlbaum's attempts in 1863 to consider mania and melancholia as two simple states of *vesania typica* (the general form in which he included all functional psychoses, with the exception of paranoia) were not successful.

Kraepelin, who was obviously influenced by the works of Falret and Baillarger (another French psychiatrist who made important studies of this condition, at approximately the time of Falret), studied many patients and conceived the concept of manic-depressive

* According to Cameron,[18] earlier authors grasped the intermittently manic and depressed character of the psychosis. Bonet in 1684, Schacht in 1747, and Herschel in 1768 (all quoted by Cameron).

Downloaded from www.dbaalibpur.net.in

psychosis as one syndrome which, in its many varieties, included simple mania, most cases of melancholia, and the periodic and circular insanity. It included also "some cases of amentia" and some affective moods, which, although not of such severe proportions as the previously mentioned disorders, were regarded by him as "rudiments" of the latter. Kraepelin's reason for including all these syndromes in a large nosologic entity was based on the fact that these syndromes, in spite of many external differences (1) have common fundamental features, (2) not only cannot be easily differentiated but may replace each other in the same patient, and (3) have a uniform prognosis. The outcome was thus, for Kraepelin, as important a nosologic characteristic for manic-depressive psychosis as it was for dementia praecox. Kraepelin worked in the field of manic-depressive psychosis for many years, but it was only in the sixth edition of his *Lehrbuch der Psychiatrie*, published in 1899, that he used the term "manic-depressive insanity" and only in the eighth edition (1913) that he fully expanded this nosologic concept.

At first, Kraepelin's concepts were not unanimously or universally accepted. (See, for instance, Tanzi.[91]) Later, however, his concepts were generally accepted, although attempts continue to be made even today to separate the single or recurring depressions from the complete manic-depressive circular syndrome.

### THE PSYCHOANALYTIC SCHOOL

We must turn to the psychoanalytic school to find an attempt to go beyond descriptive and nosological concepts. Exceptionally, it is not Freud himself who introduces manic-depressive psychosis into the field of psychoanalysis, but his pupil Abraham. In 1912 Abraham had the original idea of comparing melancholic depression with normal grief. Both conditions are due to a loss that the person has suffered, but, whereas the normal mourner is interested in the lost person, the depressed patient is tormented by guilt feelings. The unconscious hostility that he had for the lost object he now directs toward himself. Abraham also assumed that there was a regression to an ambivalent pregenital stage of object-relationships, that is, a return to an anal-sadistic stage.

Freud,[32] in a paper titled "Mourning and Melancholia," accepted Abraham's ideas that there is a relation between mourning and melancholia and pointed out that, whereas in mourning the object is lost because of death, in melancholia there was an internal loss because the lost person had been incorporated. The sadism present in the ambivalent relationship is then directed against the incorporated love-object. This concept of introjection helped Freud to develop the concepts of ego-ideals and, later, of super-ego. In a subsequent work published in 1921 (*Group Psychology and the Analysis of the Ego*), Freud advanced the idea that in mania there is a fusion between the ego and the super-ego. Thus the energy previously used in the conflict between the two parts of the psyche is now available for enjoyment. Freud also pointed out that this fusion between ego and super-ego may be based on biologically determined cycles (something similar to the cyclic fusion of the ego and id, which periodically occurs every night during the state of sleep).

In later works Abraham[1] confirmed Freud's findings and clearly postulated the factors which are prerequisites for manic-depressive psychosis: (1) a constitutional and inherited overaccentuation of oral erotism; (2) a special fixation of the libido on the oral level; (3) a severe injury to infantile narcissism, brought about by disappointments in love; (4) the occurrence of this disappointment before the Oedipus complex was resolved; and (5) the repetition of the primary disappointment in later life.

After Abraham and Freud, Rado and Melanie Klein have, perhaps, made the most important psychoanalytic contributions to this subject. For Rado,[76,77] "melancholia is a despairing cry for love." The ego tries to punish itself in order to prevent the parental punishment. The patient attempts to repeat the sequence—guilt, atonement, forgiveness—which, according to Rado, is connected with a previous sequence occurring in the infant—wakening rage, hunger, appearance of the mother's breast, and ensuing satisfaction. The excite-

Downloaded from www.brainpan.com

ment of being nursed by the mother is compared to a sexual orgastic experience, and mania is compared to an oral fusion, an equivalent of the breast situation.

Freud's and Abraham's theories about the incorporation of the object receive further elaboration by Rado. He believes that there is a splitting of the incorporated object: The good part of it, by which the child wants to be accepted and loved, remains in the super-ego, whereas the bad part of it, which the child despises and even wants to kill, becomes part of the ego.

Melanie Klein[50] sees in the infant baby the mechanism which may develop later into full psychosis. She describes the paranoid position and the depressive position. Whereas the first consists of mechanisms by which the child "spits out" or eliminates or projects to others what is unpleasant, the second or depressive position occurs at the time of weaning, that is, around the sixth month of life. The child has an innate fear of death, and the "positions" are defenses to guarantee the survival. Thus, for Melanie Klein, this depressive position is a normal event in the life of every child.* It is the inability adequately to solve this position that presumably leads, later, to the disorder. The mother who before was seen as two persons (one good and one bad) according to Klein is seen as one person; she continues, however, to be internalized as a good or bad object. The child is afraid that his instinctual aggressive impulses will destroy the good object, and interprets the loss of mother's breast and milk at the time of weaning as the result of the destructive impulses.

### The Existentialist School

It is difficult in an American textbook to give, within the limits of the assigned space, an adequate account of the contributions of the new existentialist approach to manic-depressive psychosis. Any account presupposes a familiarity with existentialist philosophy, and especially with the works of Heidegger, which most psychiatrists do not have.* Moreover, the interpretation of these writings is not an easy task for those who are not well acquainted with the intricacies of the German philosophical language. A brief resumé will, however, be attempted here.

In the existentialist school, manic-depressive psychosis is not, as a rule, studied as a unit; mania and melancholia are the objects of separate studies. Contrary to what we find in the other schools (particularly in the psychoanalytic schools, where melancholia receives the main consideration), it is mania which has attracted the interest of the existentialists. Binswanger has devoted six long articles to mania. He asks himself the usual existentialist question: What, for the manic, is the way of being in the world? It is a world of festivity, of the victory of the instinct over restraint and inhibitions. It is a world that tends to abolish logic and real difficulties; it is a direct and immediate world, the world of optimism itself. Optimism is a special style of thinking and living. In this way of living the patient becomes big and the world small.

In the flight of ideas, we have three factors —the regression, the play of words, and the logorrhea. Because of the regression, language ceases to be a means of communication and ends by becoming an end in itself, a kind of play at the service of the existential joy (*Daseinsfreude*). Playing has invaded the whole human structure of the manic, and play of words is part of it. The logorrhea manifests a *grossmauling* way of existence.

The ambivalence of the manic-depressive is different from that of the schizophrenic. Whereas the latter may hate and love at the same time, the manic-depressive, at certain periods of time, may only love or hate, although alternately he does both.

Binswanger[14, 15] attributes to the flight of ideas

* This point of view has been sharply criticized by Spitz,[88] who has found infantile depressions (which he calls anaclitic) only in pathological conditions and determined by the fact that the mother was removed from the child between the sixth and eighth months for an approximate period of three months.

Several of Klein's conceptions seem only adult personifications of the infantile psyche. Although these conceptions are thought-provoking, there is nothing to indicate that they relate to the processes or activities of the infant's cerebrum.

* See Chap. 66 of this book for a succinct, comprehensive presentation of the existentialist approach. See also the recent article by Kahn.[45]

Downloaded from www.libtool.com.cn

the following characteristics: (1) an affective tone of optimism, (2) a particular way of experiencing space and time, (3) a volatile and confused character of thought and meanings, and (4) the prevalence of projections.

Existential studies of depressions have been made by Le Mappian[59] and by Ey.[28] For these authors, as well as for other existentialists, the depressed state is constituted by an arrest or insufficiency of all the vital activities. It is a "pathetic immobility, a suspension of existence, a syncope of time" according to Ey. As a consequence, the patient experiences a feeling of incompleteness, of unreality, and of impotence; a special, inhibitory way of living then ensues. Most authors emphasize the particular attitude of the patient toward time. Only the past counts; it extends into the present to torture the patient and to remind him of his guilt, his unworthiness, and his inability to accomplish. "Time was lost," the future is not even contemplated. Sommer,[88] quoted by Roi,[82] points out how the patient, although self-accusatory, does not want to repair; he wants to be punished.

The studies of the existentialist authors give us a more accurate account of the uniqueness of the subjective experiences of the patient, permitting us to become more aware of their particular ways of living and offering an enrichment of the understanding obtained by the dynamic, sociocultural, and formal approaches.

## ¶ The Manifest Symptomatology of Manic-Depressive Psychosis*

Manic-depressive psychosis manifests itself with recurring attacks of depression and of manic elation in various forms and cycles. We shall take into consideration (1) the depression, (2) the manic attack, (3) the course of the disorder, and (4) the diagnostic criteria.

* This section will be relatively short in comparison to corresponding sections in other textbooks of psychiatry. Kraepelin devoted 206 pages of his monograph to the description of all the varieties of the disorder. This is not feasible any longer in a modern textbook of psychiatry, where an attempt is made to focus the interest of the reader also on other aspects of the problem.

### *Depressions*

Depressions are characterized by the following triad of psychological symptoms: (1) a pervading feeling of melancholia; (2) a disorder of thought processes, characterized by retardation and unusual content, and (3) psychomotor retardation. In addition, there are accessory somatic dysfunctions.

The pervading mood of depression at times has its onset quite acutely and dramatically, at other times slowly and insidiously. The patient generally had previous attacks of depression which, because they were mild in intensity, passed unnoticed or were considered by the patient and his family as normal variations of mood. Even the psychotic attack is misunderstood at first. An unpleasant event, such as the death of a close relative or a grief of any kind, has occurred, and a certain amount of depression is justified. When, however, a certain period of time has elapsed and the depressed mood should have subsided, it seems instead to become more intense. The patient complains that he cannot think freely, feels unable to work, cannot eat, and sleeps only a few hours a night.

As the symptoms increase in intensity, the patient himself may request to be taken to a physician; often, however, the illness is advanced to such a degree that the patient is no longer able to make such a decision and he has to consult a physician at the initiative of the members of the family. When the patient is seen by the physician, the latter is impressed by his unhappy, sad appearance. He looks older than his age, his forehead is wrinkled, and his face, although undergoing very little mimic play, reveals a despondent mood. In some cases the main fold of the upper lid at the edges of its inner third is contracted upward and a little backward (sign of Veraguth).

In most cases the examiner is often taken astray by the complaints of the patient, which consist of physical pain, a feeling of discomfort, digestive difficulties, lack of appetite, and insomnia. The physician may interpret these complaints as simple psychosomatic dysfunctions; in the majority of cases, however, the

Downloaded from www.dbraubibrary.org.in

mood of melancholia is prominent and leads to an easy diagnosis.

The patient is often at a loss in describing the experience of melancholia. He says that his chest is heavy, his body is numb; he would like to sleep but he cannot; he would like to immerse himself in activities, but he cannot; he would even like to cry, but he cannot. "The eyes have consumed all the tears." "Life is a torment." There is at the same time a desire to punish oneself by destroying oneself, and at the same time to end one's suffering. Suicidal ideas occur in about 75 per cent of patients, and actual suicide attempts are made by at least 10 to 15 per cent. Often the suicide attempt occurs when it is not expected, because the patient seems to have made some improvement, as the depression is less pronounced (see p. 438). In a minority of suicide attempts, the suicidal idea was carefully concealed from the members of the family. The desire to end life applies only to the life of the patient himself, with one important exception, to be kept in mind always: young mothers who undergo psychotic depressions often plan to destroy not only themselves but their children, who are presumably considered by the patient as an extension of herself. Newspaper reports about mothers who have killed themselves and their little children in most cases refer to patients suffering from unrecognized attacks of manic-depressive psychosis.

The other important symptom of depression concerns the content and type of thinking. As far as the content is concerned, the thoughts of the patient are characterized by gloomy, morbid ideas. In some cases, at the beginning of the attack, ideas occur which cannot be recognized as part of the ensuing picture of psychotic depression. They seem to be neurotic obsessions, phobias, what the patient calls "unclean thoughts." They are followed by discouraging ideas which acquire more and more prominence. The patient feels that he will not be able to work, he will lose his money, something bad will happen to his family, somebody is going to get hurt, or the family is in extreme poverty. There is no great variety in the patient's thoughts. It is almost as if the patient purposely selects the thoughts which have an unpleasant content. *They are not thoughts as thoughts; they are chiefly carriers of mental pain.* The distortion caused by the unpleasantness of the mood at times transforms these melancholic thoughts into almost delusional ideas or definite delusions. They often represent distortions of the body-image and hypochondriasis. The patient thinks he has cancer, tuberculosis, syphilis, etc. His brain is melting, his bowels have been lost, the heart does not beat, etc. Delusions of poverty are also common. Ideas of guilt, sin, and self-condemnation are very pronounced, especially in serious cases. At times these self-accusatory ideas are so unrealistic that the name "delusion" seems appropriate for them. "It is all my fault," "It is all my responsibility." In some cases the tendency to blame oneself reaches the absurd; the patient blames himself for being sick or for "succumbing to the illness." In some cases he feels that he is not really sick but acts as if he would be sick. This impression is almost the opposite to that which we find in some schizophrenics. In the latter there is the idea that what happens in the world is an act, a play, the world is a big stage. The depressed patient, on the contrary, feels that he is acting the part of the sick person. This idea, incidentally, occurs generally when the patient starts to recover from the depressed attack.

These delusional ideas cannot always be traced back to an exaggeration or distortion of mood. In cases that have a mixed paranoid and melancholic symptomatology, the delusions are more inappropriate and bizarre and are in no way distinguishable from those of paranoid patients.

Together with this peculiar content of thought, there is retardation of thinking processes. The patient complains that he cannot concentrate, he cannot focus his attention. At first he can read but cannot retain what he reads. Writing is more difficult for him because composing a letter requires tremendous effort. If the patient was a student, he cannot study any longer. Thoughts seem to follow each other at a very slow pace. Talk is also slow. In a severe state of stupor the patient cannot talk at all.

Hallucinations are described by many authors in manic-depressive psychosis, especially

Downloaded from www.dtic.mil

in the old textbooks. According to the experience of many psychiatrists, however, they are much less common in manic-depressive psychosis than they used to be. This difference is not apparent, in the sense that patients who hallucinate are now diagnosed as schizophrenics. According to the present author, hallucinations do occur in some severely depressed patients. They have the following characteristics:

1. They are relatively rare in comparison to their occurrences in schizophrenia.
2. They do not have the distinct perceptual and auditory quality that they have in schizophrenia. The patients often cannot repeat what the voices say; they sound indistinct. The patients describe them as "as if rocks would fall," or as "bells which ring," etc. Often they seem more illusions than hallucinations, or as transformations of actual perceptions.
3. Much more easily than in schizophrenia, they can be related to the prevailing mood of the patient. Their secondary character, that is, secondary to the overall mood, is obvious. They are generally depressive in content, and denigratory, often commanding self-destruction or injury.
4. More frequently than in schizophrenic patients, they seem to occur at night; more seldom during the day. The manic-depressive, who is more in contact with external reality than the schizophrenic, possibly needs the removal of diurnal stimuli in order to become aware of these inner phenomena.

The third important sign of depression consists of retarded hypoactivity. The actions of the patient decrease in number, and even those which are carried out are very slow. Even the perceptions are retarded. Talking is reduced to a minimum, although a minority of patients retain the tendency to be loquacious. Solving of the usual small daily tasks of life is postponed or retarded. The patient avoids doing many things but continues to do what is essential. Women neglect their housework and their appearance, discontinue the use of lipstick and powder, and always wear the same dress. Every change seems a tremendous effort. Interpersonal relations are cut off. In some mild cases, however, the opposite seems to occur at first. The patient, who is prone to accuse himself and extoll others, becomes more affectionate toward the members of the family and willing to do many things for them in an unselfish manner. Later, however, when the disorder increases in intensity, he becomes indifferent to everybody.

The accessory physical symptoms that accompany depressive attacks are reduction in sleep, decrease in appetite, and considerable loss in weight. These symptoms do not seem to be due to a specific or direct physiological mechanism, but rather are related to, or a consequence of, the depression. Many patients complain of dryness of the mouth, which is to be attributed to decreased secretion of the parotid glands.[90]

Other frequent symptoms are backache and amenorrhea. There is a definite decrease in sexual desire, often to the point of complete impotence or frigidity. In many patients sugar is found in the urine during the attack. The basal metabolism tends to be slightly lower than normal. Kennedy[49] believes that in many patients the symptomatology consists almost exclusively of these somatic dysfunctions. He calls these syndromes "manic-depressive equivalents."

The above are the fundamental symptoms found in depression. The early authors have described with great accuracy and at great length several varieties of depression. It will be sufficient to give a brief description here of the main types, which are still accepted.

### Simple Depression

Simple depression is characterized by a relative mildness of the symptoms. Neurotic symptoms may be prominent and may make the diagnosis of psychosis difficult. Delusions and hallucinations are absent. Although retarded, the patient is able to take care of the basic vital needs. Suicidal ideas and attempts, however, occur in this type too. In recent years cases of simple depression seem to have increased in number, relative to the total incidence of manic-depressive psychosis.

Downloaded from www.dbraulibrary.org.in

### Acute Depression

In acute depression the symptoms are much more pronounced. Self-accusation and ideas of sin and poverty are prominent. Some depressive ideas, bordering on delusions, are present. Hallucinations may occur in some cases. The loss of weight is very marked.

### Paranoid Depression

In paranoid depression, although the prominent feature remains the depressed mood, delusional ideas play an important role. The patient feels that he is watched, spied on, or threatened. Somebody wants to hurt him. Hypochondriacal delusions with pronounced distortion of the body-image may occur. As in the case of hallucinations, these delusions seem secondary to the prevailing mood of the patient. They disappear easily when the mood changes. Hallucinations may also occur.

### Depressive Stupor

Depressive stupor is the most pronounced form of depression. Here there is more than retardation: the movements are definitely inhibited or suppressed. The patients are so absorbed in their own pervading feeling of depression that they cannot focus their attention on their surroundings. They do not seem to hear; they do not respond. They are mute, with the exception of some occasional utterances. Since they cannot focus on anything, they give the impression of being apathetic, whereas they are actually the prey of a deep, disturbing emotion. These patients cannot take care of themselves. Generally, they lie in bed mute, and have to be spoon-fed.

Unless they are successfully treated during the attack, physical health may suffer severely. They lose up to a hundred pounds in certain cases; they are constipated, and their circulation is enfeebled.

## *The Manic Attack*

In the manic attack, as in depression, the symptomatology is characterized by: (1) a change in mood, which is one of elation; (2) a disorder of thought processes, characterized by flight of ideas and happy content; and (3) an increased mobility. Accessory bodily changes also occur.

It is difficult in many instances to determine the beginning of an attack. The patient is often in a lively mood. His personality is described as that of an extrovert, active individual who likes to talk a lot and do many things. At the time of the attack, however, the overjoyousness of the patient seems somewhat out of proportion, occasionally even inappropriate, as, for instance, when he easily dismisses things which should make him sad and continues to be in his happy mood. The patient seems exuberant, very sociable, and, at times, even succeeds in transmitting his happiness to the surrounding persons. This mood, however, does not seem to be a constant or solid one. We are not referring here to the alternations with depression but to the fact that this euphoric mood may easily change into one of irritation, or even rage and anger, especially when the patient sees that the environment does not respond to his enthusiasm or does not react in accordance with the exalted opinion that he has of himself.

The thinking disorder is prominent and reveals itself in the verbal productions of the patient. The patient talks very fast, and cannot concentrate on any subject for more than a few seconds. Any marginal idea is expressed; any secondary distracting stimulus is allowed to affect the patient. The thoughts expressed are not disconnected but maintain some apparent ties. We can always determine that the individual ideas are connected by the elementary laws of associations, but the talk as a whole is verbose, circumstantial, not directed toward any goal or toward the logical demonstration of any point which is discussed. The ensemble of these thought and language alterations is what we call "flight of ideas."

Actually, this type of verbal behavior has a goal—that of maintaining this superficial effervescent euphoria and of escaping from intruding thoughts which may bring about depression. In not too-pronounced cases the patient realizes that he unduly allows details to interfere with the original goal of his conversation and tries to go back to it, but again he is lost in many details.

Downloaded from www.dbpublishing.com

In this incessant logorrhea, the patient makes jokes. The propensity toward associations leads to repeated clang associations, which the patient uses to make jokes, puns, etc.[5] In some rare cases the lack of thought inhibition facilitates a certain artistic propensity, which does not, however, lead to achievement because of the lack of concentration.

Lorenz and Cobb[64] and Lorenz,[63] who have made an accurate study of speech in manic patients, report that in manic speech there is a quantitative change in the use of certain speech elements, namely: (1) a relative increase in the use of pronouns and verbs, (2) a relative decrease in the use of adjectives and prepositions, and (3) a high verb-adjective quotient (that is, the proportion of adjectives is decreased). These authors found no gross disorganization at the level of structural elements and postulated that the defect in manic speech occurs at higher integrative levels of language formulation. They conclude that, "If the assumption of a correlation between emotional states and verb-adjective quotient is correct, the manic patient's speech gives objective evidence of a heightened degree of anxiety."

The rapid association ability that the manic possesses enables him to grasp immediately some aspects of the environment which otherwise would pass unnoticed. The patient is in the paradoxical situation in which his ability to observe and grasp environmental stimuli has increased, but he cannot make use of it because of his distractibility.

The content of thought often reveals an exalted opinion of himself. The patient may boast that he is very rich, a great lover, a famous actor, a prominent businessman, etc. These statements receive flimsy support. When asked to prove them, the patient attempts to do so but is soon lost in a web of unnecessary details. If he is reminded of the goal of the conversation, he may become excitable. Disturbances of the sensorium are generally of minimal intensity and are caused by the exalted mood or distractibility rather than by intellectual impairment.

The motor activity is increased. The patients are always on the go. They are in a state that ranges from wild motor excitement to incessant activity. They talk, they sing, they dance, they tease, destroy, move objects, etc. In severe states these actions or movements remain unfinished, purposeless. In spite of this constant activity, the patients do not feel tired and have tremendous endurance.

Accessory somatic symptoms consist in loss of weight, generally not as pronounced as in depression, decrease in appetite, and constipation. Insomnia is marked. The blood pressure is generally lowered. Menstruations are irregular. Sexual functions, although apparently increased in hypomanic states, are generally decreased or disturbed in various ways.

As in the states of depression, many forms of manic states have been described by the early authors. Following is a brief description of them:

### HYPOMANIA

In hypomania the symptoms are not of a marked intensity. As mentioned before, it is difficult, at times, to say whether what the patient shows is his usual "extrovert" personality or the beginning of the illness. He seems full of pep and in a good humor. He wants to do a lot of things. His verbal abilities are accentuated. Although he always had a talent for foreign languages, now he speaks many of them without hesitation, unconcerned with the mistakes he may make. Some of these patients increase their activities to such an exaggerated degree as to show very poor judgment. Actually, they do so compelled by their inner excitability and by their exalted mood. They may walk for miles and miles. Generally, they have a goal (for instance, to reach the next village) but not a necessary one. They may send out hundreds of unnecessary letters or greeting cards and make a large number of lengthy telephone calls. They often go on spending sprees, with disastrous economic consequences. The sexual activity is increased, and lack of control may bring about unpleasant results. Illegitimate pregnancies in hypomanic women and venereal diseases in hypomanic men and women are relatively common.

The excitability, richness of movements, and euphoric mood give a bizarre flavor to the behavior. A female patient, in order to show a

Downloaded from www.psychiatrylibrary.com

sore to a physician, completely undressed in front of him. Occasionally, even thefts and fraudulent acts are committed. The patient retains the ability to rationalize his actions, at times to such an extent that the layman is confused and believes in the patient's sanity.

### Acute Mania

In acute mania the symptoms are much more pronounced. They may have become marked gradually, from a previously hypomanic state, or rapidly, from a normal condition. The patient is in a state of such extreme restlessness that his behavior may be very disturbing and difficult to control. He may disrupt theatrical audiences, sing or scream in the street, or ring bells. If an attempt is made to control him, he may become belligerent. The mood is one of such exaltation that spontaneous thoughts of self-aggrandizement are immediately accepted. The patient believes herself to be the Virgin Mary, a new personification of Christ, etc.

A subtype, which Kraepelin differentiated from acute mania, is delusional mania, characterized by an abundance of grandiose delusional ideas reminiscent of those found in the expansive type of general paresis.

### Delirious Mania

Delirious mania represents an extreme stage of excitement. The patient is incoherent, disoriented, restless, and agitated. He may easily injure himself and others in his aimless activity. Restraint, chemical or physical, is an absolute necessity to avoid exhaustion which may lead to death. Hallucinations and delusions are frequent.

### Mixed States

In addition to the above-mentioned types, Kraepelin has described "mixed states" which are characterized by a combination of manic and depressive symptoms. He distinguished the following six principal types: (1) manic stupor; (2) agitated depression; (3) unproductive mania; (4) depressive mania; (5) depression, with flight of ideas, and; (6) akinetic mania.

The names given to these types indicate the combinations of the chief symptoms. Of the six types the most common is, perhaps, agitated depression. In this condition a motor restlessness, more typical of a manic excitement, is superimposed on a markedly depressive symptomatology.

## *Course*

Although the various types of manic-depressive psychoses have been described as if they were separate entities, all the types are related, as Kraepelin saw when he formulated the large nosological concept of manic-depressive psychosis.

The melancholic attack and the manic, which at first sight seem so different, have an intrinsic similarity. In fact, the same mental functions are altered, although the alterations are, in a certain way, opposite. Whereas in depression the mood is one of melancholia, in the manic attack it is one of elation; whereas in depression the thought processes and motor activity are retarded, in the manic attack one finds a flight of ideas and increased motility.

One of the main characteristics of manic-depressive psychosis is the recurrence of the attacks, which has conferred to the disorder the designation, often used in Europe, "intermittent psychosis."

The attack may occur in different successions, which old books of psychiatry described at great length and with many illustrations (which represented the manic attack as a positive wave and the depression as a negative wave). If we have a sequence of a manic and a depressed attack (or an attack of depression followed by a manic one) we have the typical circular psychosis. We may observe, however, that the attacks of depression far outnumber those of mania. Some patients may undergo a conspicuous number of depressions without ever having a manic attack.

There seems to be no relation between the duration of the attack and the normal intervals. At times, short attacks recur several times in short succession, but not seldom the series is interrupted by a long interval. I have seen several cases in which an attack of depression in the early twenties was not followed by a second one until the patient had reached his middle sixties or even the seventies. Many

Downloaded from www.dbraibury.org.in

attacks of depression, which occur later in life and which by many authors are considered as a subtype of senile psychosis, must be considered, instead, as late occurrences or relapses of manic-depressive psychosis, as Kraepelin illustrated. This fact has been confirmed recently by the recovery that these patients make as a result of convulsive electric treatment; the genuine senile patients do not improve.

According to Pollock, 58.1 per cent of patients have only one attack; 26.1 per cent have two attacks; 9.3 per cent have three attacks, and 6.5 per cent more than three. Occasionally, one finds a patient who had even 25 or more attacks.

The age at which the first attack occurs varies. It may happen in childhood in rare cases. By far the largest number of first attacks occur between the ages of twenty and thirty-five. Manic attacks are slightly more frequent between ages twenty and forty. After forty their ratio to depressive attacks decreases further. Women are more susceptible to this psychosis than men. (About 70 per cent of patients are women.)

The illness generally results in recovery as far as the individual attack is concerned. Repeated attacks usually cause very little intellectual impairment. Death, however may occur in two instances: suicide in depression, and exhaustion, or cardiac insufficiency, in cases of delirious mania. Another situation, which seems to increase in frequency and which we shall discuss again later, is the change of the manic-depressive symptomatology into a schizophrenic one, either shortly after the onset of the illness or even after many years of hospitalization.*

Prognostic criteria as to the future course of the condition are very difficult when the patient is examined only from the point of view of the manifest symptomatology. Contrary to what happens in schizophrenia, the manifest symptomatology of manic-depressive psychosis will rarely permit prediction as to whether the patient will have only the present attack, a few, or many in his lifetime. The prognosis is almost always good as to the individual attack but is uncertain as to the possibility of recurrence. Rennie,[78] in an accurate statistical study, found that the prognosis is worse when attacks occur after the age of forty. He found that 79 per cent of all patients have a second attack, 63.5 per cent a third, and 45 per cent a fourth. The more frequent the attacks, the worse is the prognosis.

* There are many psychiatrists who would deny such a statement. They feel that if a manic-depressive seems later to become schizophrenic it is because the right diagnosis (schizophrenia) was not made. At the present time, the prevalent opinion of people who have worked for many years in the same hospital is that some patients who once presented what appeared to be a typical manic-depressive symptomatology later disclose a typical schizophrenic symptomatology. This point of view, of course, does not exclude the possibility of wrong diagnosis being made in some cases, especially during the first psychotic attack.

## *Diagnostic Criteria*

Typical cases of manic-depressive psychosis are generally easy to diagnose, even if the examination is limited to the study of the manifest symptoms, although the beginner may have some difficulties in some cases.

An elderly man, who has lost a lot of weight, is depressed, and complains that he may have cancer, may be mistaken for a manic-depressive when actually he really has some sort of malignancy with reactive depression. An accurate physical examination will determine the condition. In psychiatric practice, however, the opposite occurrence is more common: an elderly patient has lost weight, has many hypochondriacal complaints, fear of cancer, and is depressed. Negative physical findings, retardation, and insomnia, as well as the past history will generally determine that he is suffering from a depression.

Some patients, who are very retarded, have lost accessory movements, and present a mask-like expression of their faces, are occasionally confused with postencephalitics. Manic states may be confused with the following conditions:

1. Psychomotor epilepsy. Epilectic exaltation is impulsive but is deprived of elation. Furthermore, the electroencephalogram will lead to an easy diagnosis.
2. Toxic deliriums (or amential states). The wealth of disconnected hallucinations and the poverty of external perceptions (or of reactivity to the environment) will lead to recognition of the delirium.

Downloaded from www.preprimary.org.in

3. General paresis. The physical symptoms of general paresis, and the serological findings, will lead to a diagnosis. Moreover, in the paretic the sensorium is more defective and the actions and thoughts are more incongruous than the degree of exaltation would permit, and superficial delusions more numerous.
4. Catatonic excitement. The excitement precedes or follows the catatonic state. The actions are more aimless and absurd and deprived of any feeling of guilt, the mood is more incongruous and inappropriate, and hostility toward others is more pronounced.
5. Attack of exaltation occurring in any mental diseases, including mental deficiency. The subsequent course will reveal the correct diagnosis.

For a differential diagnosis with involutional psychosis, see Chap. 26; with reactive depression, see Chap. 18.

## ¶ Psychodynamic Mechanisms

The characteristics that we have described in the previous section constitute the obvious or manifest aspects of processes of a much more subtle nature which were going on for a long time.

Because relatively few patients are found in those areas of the world where there is a considerable number of psychodynamically trained psychiatrists who are willing to study these cases (see pp. 440–443) and because psychotherapy of a manic-depressive patient presents great difficulties in a large number of cases (even greater than those presented by schizophrenic patients), our knowledge of the psychodynamics of these cases is still fragmentary. Some fundamental factors, however, seem to stand out sufficiently to permit us to explain grossly some of the most common mechanisms.

### *The Childhood of the Manic-Depressive Patient*

From the information obtained by this author and others from patients and their families, it seems a fairly well-established fact that the early childhood (at least the first year of life) of the future manic-depressive patient has not been so traumatic as those of people who tend to become schizophrenics or even seriously neurotic.

The future manic-depressive is generally born in a home which is willing to accept him and to care for him. The word "accept" has a special meaning here: the mother is duty-bound and willing to administer to the baby as much care as he requires; she is willing to provide for him everything that he needs. This willingness of the mother is, in turn, accepted by the child, who is willing to accept everything he is offered; that is, early in life the child appears very receptive to the influence (or giving) of the significant adult (parent). There are no manifestations of resistance toward accepting this influence, as, for instance, autistic manifestations or attempts to prevent or retard socialization, as one finds in schizophrenia.[4] If we use Martin Buber's terminology, we may say that the "Thou," that is, the other, is immediately accepted and introjected. The Thou is at first the mother, but this receptivity to the mother enhances a receptivity for both parents and all the important surrounding adults and promotes a willingness to accept them with their symbols and their values. It promotes also a certain readiness to accept their food (either the milk of the mother or regular food) and thus predisposes some people (but by no means all) to overeating, obesity, and the seeking of compensation in food when other satisfactions are not available.

This receptiveness to the others and willingness to introject the others determines, at this early age, some aspects of the personality of the patient. He tends to become an "extrovert"; at the same time he tends to be a conformist, willing to accept what he is given by his surroundings (not only in material things but also in terms of habits and values) and to rely less than the average person on his own resources or on his own interpretation and evaluation of the external world. This readiness to accept, this psychological receptivity, will predispose him also to pathological (or exaggerated) introjection.

Downloaded from www.dbraulibrary.org.in

In the second year of life (earlier, according to some authors), a new attitude on the part of the mother drastically changes the environment in which the child was growing and exposes him to a severe trauma. The mother will continue to take care of the child, but considerably less than before, and now she makes many demands on him. The child will receive care and affection provided he accepts the expectations that the parents have for him and tries to live up to them.

This brusque change in the parents' attitude is generally the result of many things: predominantly, their attitude toward life in general tends to evoke in the child an early sense of duty and responsibility—what is to be obtained is to be deserved. The parents are generally dissatisfied with their own life and harbor resentment, at times, toward the children, who represent increased work and responsibility. This hostility, however, is seldom manifested openly; generally, it is manifested by the fact that the parents increase their expectations too much.

Thus, the child finds himself changed from an environment which predisposes to great receptivity to one of great expectation. These dissimilar environments are actually determined by a common factor: the strong sense of duty that compelled the mother to do so much for the baby is now transmitted at an early age to the child. Generally, the families of manic-depressive patients have many children, and often, when the future manic-depressive patient is in his second year of life, a sibling is already born and the mother is now lavishing her care on the newborn with the same duty-bound generosity that she previously had for the patient. This, of course, makes the change in the environment more marked for the patient.

This displacement by a younger sibling seems to be important in the dynamics of manic-depressive psychosis, although, again, no statistical proof of it can be given.* Statistical studies have so far concerned themselves more with the order of birth (that is, whether the patient is the first-born child, second-born, etc.).*

For many patients, but not for all, the abrupt change that we have described has already taken place at the time of weaning. Premanic-depressive patients are generally breast-fed in their infancy and then suddenly deprived of mother's milk. No bottles, no rubber nipples, and no pacifiers are used. There is a sharp transition from the breast to the glass. In a minority of manic-depressive patients, this loss of the breast plays an important role, as we shall see later.

How does the child try to adjust to the new threatening situation? The predominant mechanism by which he finds security is acceptance of parental expectations. He does not reject the parents emotionally, or avoid them (as the schizoid often does), but consciously accepts them. He must live up to their expectations no matter how heavy the burden. It is only by complying, obeying, and working hard that he will recapture the love or state of bliss which he used to have as a baby, or will at least maintain that moderate love which he is receiving now. Love is still available, but not as a steady flow. The flow is intermittent, conditioned, and therefore does not confer security. The child feels that if he does not do what he is supposed to, he will be punished: mother may withdraw her love totally. At the same time that the anxiety of losing mother's love sets in, hope is given to the child that he will be able to retain this love, or to recapture it if and when it is lost. The child is thus given the illusion that he has a choice, that he has the freedom of retaining the parental love or not. There is also the implication that mother is not bad, in spite of her appearance, but, on the contrary, that she is good. She is good even in punishing him, because

* I have observed this displacement by a sibling to be an important factor also in the psychodynamics of milder depressions, which cannot be classified as cases of manic-depressive psychosis.

* Some statistical works seem, however, to indicate that the first-born child is more liable to manic-depressive psychosis. Of course, the first-born is more liable also to be displaced. Berman,[13] in a study of 100 manic-depressives, found that 48 were first-born, 15 second, 10 each third and fourth, and 17 fifth or later. Pollock and co-workers[79] found that 39.7 per cent were first-born and 29.7 per cent were second-born. Malzberg[68] and Katz[48] could not find any relationship between birth order and manic-depressive psychosis.

Downloaded from www.pbraulibrary.org.in

by punishing him she wants to redeem him, make him again worthy of her love. Thus the mechanism is different from that occurring in many preschizophrenics; although the pre-manic-depressive has an image of himself as bad, he does not feel that he is beyond the possibility of redemption, as, instead, the preschizophrenic often feels. The anxiety about being unable to fulfill parental expectations changes into guilt feelings. If affection or forgiveness is not forthcoming, the child feels that it is his own fault; he has not lived up to what was expected of him, and he feels guilty. When he feels guilty, he again expects punishment. He wants to be punished, because punishment is the lesser of the evils. He'd rather be punished than lose mother's love. If he is not punished, he often works harder in order to punish himself.

A little later, but still at a very early age, many of these children assume responsibilities such as the support of the family. If they engage in a career, it is often in order to bring honor and prestige to the family. In a relatively large number of cases, the family belongs to a "marginal" group of society because of religious or ethnic minority status, and the child feels that it is his duty to rescue the family with his own achievement.

In addition, in several patients incestuous wishes toward parents and, as frequently, toward siblings of opposite sex elicit strong guilt feelings which the patient feels must be atoned.

Other facts make the picture more complicated and difficult to understand, for instance the impression often received that the parents of several patients seem not strict but overindulgent. This is due to the fact that, in this second stage of childhood, the parents do not need to enforce any rules with their actions. The rules, the principles, have already been incorporated by the patient. As a matter of fact, some of the parents now regret that the children take rules with such seriousness.

The parents of the patient generally give a picture of cohesiveness and stability. There is no serious talk of divorce; the family seems on stable ground, reinforced by the conventions of society. Those family conflicts or schisms described in schizophrenia are not seen as frequently in the family of manic-depressive patients.

In addition to the mechanism of accepting parental expectations, two other mechanisms occur. The second is just as common as, and in a certain way a part of, the first. At the same time that the child accepts the parent or parent-substitute and tries to live up to her expectations, he harbors a strong resentment against this parental figure who has made so many impositions. Such resentment manifests itself in attacks of rage, rebellion, or even violence. Generally, however, these feelings are promptly checked and repressed, not only in childhood but throughout the life of the patient. Sadistic thoughts and impulses are, at times, very pronounced but seldom acted out. Together with the consequent guilt feelings brought about by these impulses are feelings of unworthiness and depression. The patient soon learns that rebellion does not pay; on the contrary, it increases the atonement he must undergo later. The stronger his sadistic impulses, the stronger become the masochistic tendencies. He soon desires peace at any cost; any compromise is worthy of peace. The mechanism which will permit him to maintain a certain equilibrium is the repression of this resentment. The resentment is, however, retained unconsciously, as it appears from dreams and occasional outbursts which reach consciousness.

A third dynamic mechanism which is found in many, but not all, cases of manic-depressive psychosis is the following:

The child senses that the acceptance or introjection of parents is too much of a burden and, without realizing it, shifts the directions of his incorporations: other adults in the environment (much older siblings, uncles, aunts, grandparents, friends, etc.) tend then to be internalized instead of the parents. Not only is the common tendency of children to introject adults here exaggerated, but peripheral adults become parentlike figures. The child unconsciously resorts to this mechanism in order to decrease the burden of the parental introjection, but in many cases this defense does not prove useful. As Fromm-Reichmann[35]

Downloaded from www.dbraulibrary.org.in

remarked, there will be no single significant adult to whom the patient will be able to relate in a meaningful way. The relationship with these other grownups again is determined by a utilitarian purpose, duty, or role. The introjection of such adults eventually fails to provide what is needed and may end by confusing the child (how can he satisfy all the adults?) and increasing his burden and feeling of guilt.

Here again, it is interesting to note the difference from the psychodynamics of schizophrenia. The preschizophrenic does not try to introject other parental figures but, on the contrary, often projects to these substitute parental figures (who later will become the persecutors) the bad qualities of the parents.

### *Prepsychotic Personality*

This strong tendency of the premanic-depressive to introject parental figures will also produce strong feelings of patriotism, religiosity, and loyalty to a political party, to the church, to the country. Patients often wish to have a military or ecclesiastic career. These organizations are not parent-substitutes but additional parents. Group loyalty and *esprit de corps* play an important part in the psychological constellation of these people. Actually, under the pretense of belonging to a group, to a close-knit family, or to an organization, the individual hides his loneliness.

In many cases we find a self-conscious individual, always motivated by duty, of the type of personality Riesman[81] has called "inner-directed." He is not a creative person, because he is too much of an imitator, but what he tries to do, he does well. He has deep convictions, and his life is motivated by principles. He must be a dedicated person. He is generally efficient, and people who do not know him too well have the impression that he is a well-adjusted, untroubled individual. On the contrary, he is not a happy man. He selects a mate not because he loves her but because she "needs" him. Later, he will never divorce the mate because she is in terrible need of him. At the same time, he blames himself for being so egotistic as to think that he is indispensable. The necessity to please others and to act in accordance with the expectations of others, or in accordance with the principles that he has accepted, makes him unable really to get in touch with himself. He does not listen to his own wishes; he does not know what it means to be himself. He works incessantly and yet has feelings of futility and emptiness. At times, he conceals his unhappiness by considering what he has accomplished, just as he conceals his loneliness by thinking of the group to which he belongs. But when he allows himself to experience these feelings of unhappiness, futility, and unfulfillment, he misinterprets them again. He tends to believe that he is to be blamed for them. If he is unhappy, if he finds no purpose in life, it must be his fault, or he must not be worthy of anything else. A vicious circle is thus established which repeats itself and increases in intensity, often throughout the life of the patient, unless fortunate circumstances or psychotherapy intervene.

The patient often has partial insight into his own mechanisms but does not know how to solve them. For instance, he is willing to accept the role in the family and in society which has been assigned to him, and yet later he scolds himself for playing this role, for not being spontaneous. But if he tries to refuse the role, he has guilt feelings. The conclusion is that no matter how he tries to solve his problems, he will feel he has made the wrong choice. A female patient told me that she "felt like a little girl who pretends to be grown up but is not. I am acting." But she must live in that way; that's her duty. It is her fault that she "acts" and does not accept social behavior as spontaneous or real life.

The patient also tends to put his superiors or teachers in a parental authoritarian role. Again, and quite often, he feels angry at them as they seem to expect too much, or they themselves have been found at fault. The patient does not know how to act: Should he continue to accept the authority of these people and the burden that this acceptance implies, or should he remove them from the pedestal? But if he removes them, a void will be left. His authorities are part of him, of

Downloaded from www.dbraulibrary.org.in

his values, and of the symbolic world upon which he sustains himself, and to do without them is impossible. Furthermore, he would feel very guilty. The patient often realizes (as Cohen and co-workers have clearly illustrated[22]) that he tends to underestimate himself. It is his "duty" to "undersell" himself. On the other hand, he tends to blame himself for underestimating himself and giving himself no chance to develop his own talents and potential abilities.

Another variety of prepsychotic personality is the dependent type. Contrary to the persons described above, this type includes people who, even at a superficial examination, appear maladjusted. These patients have never forgotten the bliss of the first year of life and still expect or demand a continuation of it. They demand and expect from others, feel deprived and sad when they do not get what they expect. They are demanding but not aggressive in the usual sense of the word, because they do not try to get what they want through their own efforts; they *expect* it from others. Somehow, they have not developed that complex of duty and hard work typical of the accepting, introjecting patient.

These patients alternate between feeling guilty and having the desire to make other people feel guilty. They generally find one person on whom to depend, and they make this other person feel guilty if he does not do what the patient wants. The sustaining person (generally the spouse) is empowered with the capacity to make the patient happy or unhappy and is supposed to be responsible for the despair and helplessness of the patient. Relatively often we find in this group women who depend entirely on their husbands, who are generally much older.

A third type of prepsychotic personality, the forerunner of the manic, is lively, active, hearty, and friendly. On closer scrutiny, the apparent health and liveliness are found to be superficial. In a certain way the patient actually escapes into actions or into reality but remains shallow and dissatisfied. If he happens to be engaged in work in which not concentration but action is required, he may do well and maintain a satisfactory level of adjustment; otherwise, he may sooner or later get into trouble. He claims that he has many friends, but, although the interpersonal relations seem warm and sincere, they are superficial and lack real kinship. One patient said, "I joke, I laugh, I pretend; I appear radiant and alive, but deep down I am lonely and empty." This type of person is, only in certain respects, the opposite of the duty-bound individual. He tries to escape from his inner directions, but he does not correspond to what Riesman has called the "other-directed" person. Imitating Riesman's terminology, we could call this hypomaniclike person "outer-directed" but not "other-directed." He does not escape into others, he escapes *from* his inner self (because the inner self has incorporated the burdening others).* He escapes into the world of superficial reality where meditations, reflections, or deep emotions are unnecessary. Such an individual may, at times, seem so free as to be considered psychopathic. Actually, his deep concern with conventional morality often necessitates this pseudopsychopathic escape. Some of the pseudopsychopathic hypomanics have shown asocial behavior since childhood, when, for example, in order to escape from inner and external restrictions, they run away from home or school.

The above-described prepsychotic manic-depressive personality types are seldom seen in pure culture.

### *Precipitating Factors*

The three types of personality that we have described lead not to a stable equilibrium but to an almost constant state of dissatisfaction and mild depression (or hypomanic denial of depression). In this unstable background, we generally find precipitative factors which bring about the full-fledged psychosis.

These precipating situations may be classified into three categories: (1) the death of a person important to the patient, (2) the realization on the part of the patient of the failure of an important interpersonal relationship (generally with the spouse), and (3) a severe

* As we shall see later (p. 446), he does make an attempt to contact others but not to integrate with them.

Downloaded from www.brainumany.org.ir

disappointment in a relationship to an institution or work to which the patient had devoted his whole life.

It is obvious that these situations are considered separately for didactic reasons, but actually may be reduced to a single cause: the loss of a valued object. At times, although the loss has not yet occurred, the fact that it is impending is so certain that the patient experiences depression rather than anxiety. Anxiety is the emotion associated with the expectancy of danger; depression is the emotion associated with the experience of loss—the dangerous event has already come and has produced its havoc.*

All the precipitating situations are interpreted by the patient as the proof of abandonment, of having lost the battle and consequently the purpose of life—the love of mother. The present situation reactivates the childhood threat of fear of loss of the mother's love and assumes the emotional form of the old feeling—with much greater intensity, however, because the threatened loss has already and finally occurred. All the efforts of the patients to prevent such loss (either by respect of duties and work, or by excessive, demanding dependency, or by hypomaniclike fervor) have failed.

Let us examine in more detail the situations mentioned above.

The first situation, when a person dear to the patient dies, is a symbolic reproduction of parental abandonment. The patient feels depressed not only because he feels he has been finally abandoned—that is, deprived of the sources of love—but also because he feels responsible and guilty. The guilt feelings arise from two different levels: on one level, the patient feels that he has "killed" the dead person; his bad behavior has made the person unhappy and sick and more likely to die, or has made this person want to leave the patient. On another level the patient feels guilty because he recognizes that, in those moments of reemerging resentment, he wished the death of the lost person. The wish has now become reality; to the wish is attributed the primitive power of producing the reality; consequently, the patient feels guilty for having entertained the murderous desire.

The second occurrence takes place when the patient realizes fully the failure of an important interpersonal relationship. The symbolic parent, generally the marital partner, is recognized, or half-consciously recognized, as a tyrant who took advantage of the compliant, submissive attitude of the patient, rather than as a person to be loved and cherished. The patient has tolerated everything, wanted peace at any cost, but it is impossible for him to continue to do so. He feels that he has wasted his life in devoting himself intensely to the spouse, in loving her or forcing himself to love her at any cost. The realization that the spouse deserves not devotion but hate (actually, in many cases what she got was only devotion, not love) is something the patient cannot accept because it would undermine the foundation of his whole life, would prove the futility of all his efforts. Thus he tries to repress this hate; he will deny to his friends that he hates the spouse; on the contrary, he will blame himself, for if he does not love the spouse he will be found to be unworthy and will be finally abandoned.

In the third instance the loss is less personal. A sudden event such as a dismissal or a failure to obtain a promotion makes the patient realize that his whole life has been a failure. The institution to which he has devoted so much of himself (for example the Army, the church, his profession, his work) has badly disappointed him, and again the patient blames himself.

Loss of employment is a relatively common precipitating factor. Malzberg[47] found that, during the economic depression of 1929 to 1937 the effect of loss of employment or of financial loss was statistically evident in manic-depressive patients. For instance, in the year 1933, 26.2 per cent of New York state hospital first-admission patients diagnosed as manic-depressive psychotics presented as the precipitating factor loss of employment or financial loss, whereas in the same year only 9.6 per cent of first-admission patients with the diagnosis of de-

* It is not implied here that the feeling of depression removes the feeling of anxiety. Some anxiety, at times even to a pronounced degree, is retained by every melancholic patient, in connection with additional possible losses, but depression is the typical feeling.

Downloaded from www.pdfbooksfree.pk

mentia praecox, presented the financial loss as a precipitating factor.

In some patients, an attack is apparently precipitated not by a loss but by what even seems a pleasant event. For instance, women in their forties or fifties, who may have undergone previous subliminal attacks of depression, can develop a severe attack shortly after the marriage of an only son or daughter. Here the event is experienced by the patient not as a pleasant happening but as a loss. The child whom the mother needed so much, and who was her only purpose and satisfaction in life, is now abandoning her. These cases belong to the second category.

In other cases an attack occurs after a promotion, which is interpreted by the patient as a new imposition. The patient is tired of new duties; furthermore, the new position with added responsibility removes the security the patient had established with painstaking effort. In other cases, the individual, faced with promotion, dreads the expected envy and rage of previous associates to whom he is closely bound. The expectation of such emotions in others separates him from them and thus leads to the depressive reaction.

Often, depressions are precipitated in a young parent by the birth of a child which ostensibly he had wanted. Here again, several mechanisms are put into operation by the birth. One is the desperation at the expectation of the increase in duty that the child will require, and a brooding again about the futility of life. In some young fathers the birth of a son reactivates the trauma of replacement by a new sibling (see p. 432). In these cases one finds unconscious fantasies about the lost breast (for now the baby will have the breast of the mother-wife). It is interesting that, whereas the birth of the child precipitates a schizophrenic psychosis only in the mother, it precipitates an attack of depression as frequently in fathers as in mothers. As a whole, however, postpartum depressions are much less frequent than they used to be, and much less frequent than schizophrenic reactions. Zilboorg,[93] who has made a detailed study of them, explained them as the result of a psychosexual conflict.

Postpartum manic states are less common. The patient mentioned at the end of this page underwent a brief manic state a few days after the birth of her first child. This manic state was mixed, presenting a great deal of conscious anxiety and hostility.

In many other cases psychotic attacks do not seem to be precipitated by any definite happening or loss. Here the precipitating factor is not a specific happening but a total reappraisal of life. The patient becomes more and more discontented; he claims that everything is all right, but an inner dissatisfaction, an inability to experience *la joie de vivre*, possesses him, and he finally becomes openly depressed. *It is the denial of the dissatisfaction that has led many psychiatrists to believe that these manic-depressive attacks often occur without any psychogenic cause.* At other times, the precipitating event seems to be so small as to make the psychiatrist disregard the significance of it. Kraepelin,[54] to show the relative unimportance of psychogenic factors, reported a woman who had three attacks of depression, the first after the death of her husband, the second after the death of her dog, and the third after the death of her dove. Now, from what we have so far discussed, it is apparent that each of these deaths was not necessarily traumatic per se. One may guess that the death of the dove reactivated the sorrow the patient had experienced at the previous deaths, and was also symbolic of a much greater loss, perhaps that of the meaning or purpose of life.

Manic attacks are often precipitated by seeming successes. The patient wants to keep up the fervor that the success has produced, lest he find himself later in a state of depression. A girl, who later in life had several attacks, both manic and depressive, had her first manic attack, of a few days' duration, at the age of nineteen, after winning a local radio debating contest. She was supposed to participate again in a subsequent national contest, but she became so excited, hyperactive, and euphoric that this was impossible. The opponent whom she had defeated on the local contest won. Here again, it is difficult to ascertain whether it was the success or the fear of not retaining it that precipitated the attack.

Downloaded from www.dbsalibrary.org.in

Often, however, manic attacks occur as a sudden reaction to creeping depression.

### *The Psychotic Attack*

When the precipitating event or the precipitating situation reveals to the patient that he has "lost," the attack ensues either in the form of depression or in the form of mania.

What is the meaning of the psychotic attack? Does the patient really mourn his loss? Does he punish himself? Does he want to punish others? He probably does all these things in an intense degree. Undoubtedly, he mourns his loss, but he also wants to make a desperate effort to redeem himself by punishing himself. The mechanism described earlier is again in effect, but in a more pronounced form. As Rado[76] says, "Melancholia is a despairing cry for love." Probably the patient feels: "Punish yourself as parents would do to you and you will be accepted again. You are acceptable but not accepted. Forgiveness is eventually available. The intermittent love will be given again."

At this point we must try to understand the meaning of the suicide attempt. Three possibilities must be considered: The patient (1) wants relief from suffering, (2) wants to punish himself, and (3) attempts to kill the introjected person (parent or spouse).

The first two possibilities are self-contradictory or self-exclusive until seen from the standpoint of the emotional state of the patient. The feeling that it is better to die than to suffer so much is certainly experienced. The patient would not carry out the suicidal ideas, however, if these ideas were not reinforced or sustained by the other idea that he deserves to die and that he must inflict on himself the supreme punishment. Thus these two motivations, logically self-contradictory, coexist and reinforce each other.

The more orthodox Freudian interpretation holds that suicide represents the attempt to kill the detested incorporated person.

According to our original interpretation of the psychological growth of the child in accordance with Buber's concepts of I and Thou, it appears that the manic-depressive patient, much more than the normal person, has accepted the Thou since his early infancy. At times he let the Thou suffocate or smother the I. In this light, the suicidal attempt is the culmination of this process: It is the Thou who finally kills the I, not the I who kills the Thou. If the I would kill the Thou, there would be a complete and sudden reversal of the previous and constant trend of denial of the self. Rado[77] has ingeniously tried to solve the problem by assuming that the super-ego (the Thou) is divided into two parts, one which the patient wants to love, and one which the patient wants to kill. I am convinced, however, that, at least in my personal clinical experience, the patient really wanted to kill himself. By killing himself he achieved a complete acceptance or a complete introjection of a distorted image of the Thou.*

There are several other factors that support this point of view. First of all, many cases of suicide seem to occur not when the state of melancholia is at its peak but at an early stage of remission, when the worst is over. This characteristic may, of course, be interpreted in various ways. The first explanation is a simple and mechanical one: When the patient is very depressed, in, or almost in, stupor, he cannot act, is extremely slow or immobile, cannot move or think coordinately, and therefore cannot carry out his intentions. When he becomes less retarded, more capable of coordinating his thoughts, he goes ahead with his destructive intention. There is the alternative possibility that the patient, who has gone through terrible experiences at the acme of the depression, is afraid that these experiences may recur and, rather than face them again, he prefers to die (this of course corresponds to the first possibility mentioned).

Yet neither of these interpretations seems adequate, in my opinion. It seems more likely that the patient feels that even the depth of depression has not been enough, has not succeeded in relieving him entirely of his guilt feeling, and that only by killing himself will he entirely redeem himself.

This interpretation is supported by other factors. Significantly, there is almost complete re-

* Strange as it may seem, this author thinks that it is the suicide of the schizophrenic, more frequently than that of the manic-depressive, that has the purpose of murdering the introjected other, or those parts of the self which are obtained from others. In the schizophrenic too, however, this is by no means the only mechanism of suicide.

Downloaded from www.pbraubrary.org

lief after the suicide attempt, whereas the Freudian interpretation would lead one to expect an increase in guilt feeling (for having attempted to, but not actually succeeded in, killing the super-ego) and a consequent increase in depression. As Weiss[92] and others have emphasized, in the attempt itself, that is, in the gambling with death, the patient feels that he has been punished adequately. He has done what the Thou wanted and now he can live peacefully. Often, of course, there is no need for the suicide attempt; after having gone through the acme of the depression, the patient feels suddenly relieved, and a marked improvement occurs.

According to Kolb[52] "The suicidal manoeuver is often determined by family indicated permission for acting out." In his clinical experience the psychodynamic explanation for acting out which has been given for other antisocial acts is valid also for suicide:

> In families where suicide has occurred the likelihood of suicide for the manic-depressive patient is much higher than otherwise. Where suicide has not occurred one usually finds threats of suicide or intimidating actions suggesting suicide on the part of parents.[52]

The relief experienced by the patient after the acute depression is remarkable. The patient feels guilt-free and accepted and wants to settle down in his own life. Even reality seems pleasant now; he does not want to be alone; he feels that he wants to be close to his mate. This attempt, however, will not work out unless psychotherapy intervenes.

The attack of psychotic depression, like every other psychotic defense, offers not a solution but a pseudo solution. When the patient cannot find relief with the end of the depression, he may, in order to avert the danger of recurrence, develop hypomanic traits which may eventually explode into a complete manic attack. We then have the typical circular psychosis. The manic attack thus must also be considered a defense against the depression. But in the manic attack the Thou is not eliminated or projected to the external world; it is only disregarded. The patient must continue to force himself into a distracted and frenzied mood, which shuts out introspection. In the manic state there is no elimination of the Freudian super-ego, as perhaps there is in some psychopathics: The super-ego remains, and the manic frenzy is a method of dealing with it.

But neither the depression nor the manic state actually brings about a solution to the deeply rooted conflicts. Even after having paid the penalty of the psychotic attack, the patient, after a more or less free interval, will tend to be affected again with the same difficulties, which will be channeled in the same patterns, and the cycle will repeat itself.

Today, however, we see in an increasing number of cases that a patient, after having experienced one or more attacks of manic-depressive psychosis, develops a typical schizophrenic symptomatology. In these cases, findings indicate that there were always some projective tendencies present along with strong introjective tendencies (see Chap. 23). Once the manic-depressive mechanism has failed, the individual resorts to the projective mechanisms, which until then had occupied only a secondary role. In some cases these schizophrenic symptoms consist only of delusional, persecutory trends, and they are not in themselves of grave prognostic meaning, but if a typical hebephrenic picture ensues, the prognosis is serious. As we have already mentioned, in an increasing number of cases we see, from the onset of the disorder, combinations of schizophrenic and manic-depressive patterns, both in the manifest symptomatology and in the underlying dynamic mechanisms, with schizophrenic features predominating. These are the so-called schizo-affective psychoses.

## ¶ The Study of Manic-Depressive Psychosis from the Point of View of Social Psychiatry

### *The Decline of Manic-Depressive Psychosis**

Manic-depressive psychosis offers a field of inquiry for social psychiatry, for there has been,

* The content of this section and the following one, as well as parts of the previous section on the dynamics of this psychosis, are drawn from the paper, "The Decline of Manic-Depressive Psychosis. Its Significance in the Light of Dynamic and Social Psychiatry," read by the author on May 17, 1957, in Chicago, at the 113th

Downloaded from www.dbraibrary.org.in

in recent times, a marked decrease in the incidence of the disease which seems susceptible of sociological explanations.

The decline in frequency is reflected also by a decline of interest among psychiatrists about the condition. Whereas, at the time of Kraepelin, this psychosis received an amount of consideration equal, or almost equal, to that of dementia praecox, a relative but progressive disinterest has gradually been evident in the last few decades. Books and articles continue to be written,[12, 19, 22, 27, 39, 42, 55, 61, 77] but schizophrenia appears much more often in the literature, particularly in the United States.*

Practicing psychiatrists justify their decrease of interest with the statement that they encounter this disorder much less frequently. The statistics seem to support this observation, made at a clinical level. In 1928, in New York, there were 10 new first hospital admissions of manic-depressive patients per 100,000 inhabitants; in 1947 this incidence had decreased to 3.7 per 100,000. The percentage of first admissions of manic-depressive psychosis in 1928 was 13.5 per cent of all admissions; in 1947 the percentage was reduced to 3.8. Thus, in a period of twenty years, the incidence of manic-depressive psychosis in New York has been reduced to approximately one third. Similar statistical trends are obtained in most of the other states. The statistics point out a definite decrease of this psychosis, but their interpretation is difficult, because, as in all cases of psychiatric vital statistics, there are many variables involved. Bellak[12] offers three possible explanations: (1) an actual lessening of the relative frequency of this disease; (2) greater toleration by the healthy population of milder cases of manic-depressive psychosis; and (3) changing diagnostic trends.

To these three hypotheses a fourth can be added: new therapeutic methods administered at the beginning of the illness produce such improvement or recovery that the patients do not need to be hospitalized. One thinks here of electric shock treatment, which is capable of rapidly ending a manic-depressive attack. But this hypothesis will not withstand close examination. As we know, the first reports on electric shock by Cerletti and Bini appeared in 1938. Electric shock was introduced into the United States in 1939 by Kalinowski and Almansi but did not receive wide application, especially in private offices with nonhospitalized patients, until the year 1942–43. The statistics indicate, on the other hand, that the decline in first admissions of manic-depressive psychoses started in 1928.

There are some factors which tend to weaken Bellak's third hypothesis, that changing diagnostic trends are completely responsible for this decrease. It is correct that many patients with a mixed symptomatology today are classified not as cases of manic-depressive but as cases of reactive depression, senile depression, schizophrenia, obsessive-compulsive psychoneuroses, etc. The pertinent question here is, Why are we reluctant to make the diagnosis of manic-depressive psychosis?

It can be argued justifiably that this reluctance is not merely caprice but is determined by the fact that, in many cases today, the manic-depressive features play only a secondary role, whereas in the past they played the predominant one.

Relevant information has been gathered in other parts of the world. Gold[38] has found a relatively larger incidence of manic-depressive than schizophrenic psychoses in the lands of the Mediterranean basin, as well as in Ireland. He reports that in Oriental countries, especially where Hinduism and Buddhism prevail, manic-depressive psychosis again becomes much less common, but in the Fiji Islands manic-depressive patients are numerous. He writes further that, whereas in India the incidence of manic-depressive psychosis is low and that of schizophrenia higher, the reverse is true for the Indians who have emigrated to Fiji.

I had received the impression when visiting mental hospitals in Italy that manic-depressive patients, not only with mixed but also with

meeting of the American Psychiatric Association. The editor of the *American Journal of Psychiatry* is thanked for having relinquished the publication of the paper and thus permitted its inclusion in this chapter.

* If we examine, as an example, the annual index of the *American Journal of Psychiatry*, official organ of the American Psychiatric Association, for instance Vol. 113, from July, 1956, to June, 1957, we shall find that, whereas under the heading "Schizophrenia" fifteen original articles and five reviews of books are listed, the heading "Manic-Depressive Psychosis" is not even mentioned.

Downloaded from www.dbraulibrary.org.in

classical or pure manic-depressive symptomatology, are more numerous there than in the United States. The official statistics in Italy corroborate this clinical impression. In 1949, in the United States, the rate of first admissions was respectively 4.7 for manic-depressive psychosis and 16.1 for schizophrenia; in Italy it was 10.0 for manic-depressive psychosis and 8.2 for schizophrenia.* Italian psychiatrists,[70, 83] however, state that in Italy, too, manic-depressive psychosis is decreasing in number, especially the manic type, but by no means as rapidly as in the United States.

Another important point to consider concerning diagnostic trends is whether the recent differentiation of the category "involutional psychoses" is responsible for the statistical differences. In other words, patients previously diagnosed as manic-depressive may now be diagnosed as suffering from involutional psychosis. Here again, it is difficult to evaluate all the factors. Previously, involutional patients might have been diagnosed as paranoid conditions, paraphrenia, etc. It is only in the case of pure involutional melancholia that competition with the diagnosis of manic-depressive psychosis exists. It is doubtful whether the cases of pure involutional melancholia, if added to the official figures of manic-depressive psychosis, would reverse the apparent decline or explain the great difference existing today, between the rate of first admissions of schizophrenia and that of manic-depressive psychosis. Again, the trend is demonstrated sharply by the statistics. Bellak reports that, of first admissions to New York civil state hospitals for the year ending March, 1947, 27.7 per cent were diagnosed as dementia praecox, 7.0 per cent as involutional psychosis, and 3.8 per cent as manic-depressive psychosis. (Involutional and manic-depressive combined were 10.8 per cent.)

The second hypothesis of Bellak, that the healthy population has more tolerance for milder cases, is difficult to accept. Bellak states that the "full-of-pep-and-energy" salesman type of person is now an accepted type. He is correct, but, in spite of some similarities, this person corresponds not to the cyclothymic hypomanic, who is liable to become manic-depressive, but rather to the "marketing personality" of Fromm[34] and to the "other-directed" person of Riesman.[81]

These observations and considerations seem to lead to the conclusion offered by Bellak's first hypothesis that the decline in the number of manic-depressive patients is real rather than apparent. Statistics further indicate that, if, in the United States, the same trends continue, manic-depressive psychosis may disappear entirely or reappear later in a near or distant future. Although this decline is not universal, it seems to affect many countries, especially Western countries, but not with the same speed.

It seems apparent that a clear understanding of the reasons for this decline can lead to conclusions relevant to the fields of mental hygiene in particular and of psychiatry in general. In order to understand this, we must resort to social psychiatry, that discipline which, as Rennie[79] has defined it, "is concerned not only with facts of prevalence and incidence . . . [but] searches more deeply into the possible significance of social and cultural factors in the etiology and dynamics of mental disorder."

## *Cultural Factors*

There may be a relation between what David Riesman calls the inner-directed personality and culture, and manic-depressive psychosis. When this type of personality and culture tend to disappear, this psychosis tends also to disappear.

Riesman explains the establishment of the inner-directed society as the result of demographic and political changes. At certain times in history, a rapid growth of population determines a diminution of material goods and a psychology of scarcity. Although this type of society has occurred several times in history, we are particularly concerned with the recurrence which had its beginning at the time of

* Italian statistics were kindly provided by Prof. Francesco Bonfiglio of Rome. To be exact, first admissions of schizophrenics in Italy were 3,541 in the year 1947, 3,780 in the year 1948, and 3,854 in 1949. First admissions of manic-depressives were 4,298 in 1947, 4,562 in 1948, and 4,791 in 1949. The rate of admission for 100,000 represents the annual average of the triennial period 1947–1949.

Downloaded from www.dbraulibrary.org.in

the Renaissance and of the Reformation. As Fromm[33] has clearly illustrated, at this time the security that the individual enjoyed in the Middle Ages by virtue of membership in his closed class system was lost, and he was left alone on his own effort. The religious doctrines of Luther and, indirectly, those of Calvin gave the individual the feeling that everything depended on his own efforts. Deeply felt concepts of responsibility, duty, guilt, and punishment, which, up to that time had been confined to a few religious men, acquired general acceptance and tremendous significance and came to color every manifestation of life. This type of culture, which originated during the Renaissance and developed during the Reformation, sooner or later permeated all Western countries; only recently has it faced replacement by another type of culture, the other-directed.* In some countries, such as the United States, this replacement is taking place at a rapid rate; in others, such as Italy, it is taking place more slowly.

In the inner-directed society the parent is duty-bound and much concerned with the care of the newborn child. It is this duty-bound care and the ensuing burdening of the child with responsibilities and the sense of duty and guilt which may permit the child to develop the strong introjective tendencies that play such a prominent role in the development of manic-depressive psychoses.

The similarities between the pattern of life of the manic-depressive patient and the typical inner-directed person are apparent.

1. Very early in the life of the child, the parent is duty-bound and gives such tremendous care to the child as to determine in the latter strong introjective tendencies.
2. A drastic change will occur later when the child is burdened with responsibility. This change will produce the trauma of the paradise lost.
3. The individual feels responsible for any possible loss. He reacts by becoming compliant, working hard, and harboring strong feelings of guilt. Life becomes a purgatory.*
4. This tremendously burdened life leads to depression, or to inactivity which leads to guilt feelings, or as a reaction, to activity which appears futile. These negative states and feelings are misinterpreted as proof of one's unworthiness and reactivate the expectancy of losing the paradise again, this time forever. A vicious circle is thus formed which repeats itself.

Other social studies point out a relation which is more than coincidental between manic-depressive psychosis and inner-directed society. The recent research by Eaton and Weil on the Hutterites[25,26] may throw additional weight on this hypothesis, although these authors do not speak of inner-directed society. The Hutterites are a group of people of German ancestry who have settled in Dakota, Montana, and the prairie provinces of Canada. Their life is very much concerned with religion, and their birth rate is very high, the average family having ten children. This type of society seems to be a typically inner-directed one. In a population of 8,542 people, Eaton and Weil found only 9 persons who sometime in their life had been suffering from schizophrenia and 39 who had been suffering from manic-depressive psychosis. In other words, among the Hutterites, manic-depressive psychosis was 4.33 times more frequent than schizophrenia, whereas in the general population of the United States the incidence of schizophrenia by far exceeded that of manic-depressive psychosis.†

* The reader is reminded not to confuse the other-directed culture and personality, described by Riesman, with what the present author has described as outer-directed personality (see p. 435). The outer-directed personality is a hypomanic-like defense against, or a reaction-formation to, the inner-directed personality. Reisman's other-directed personality is basically a different type of personality, occurring predominantly in an other-directed society.

* At this point many manic-depressive patients deviate from the inner-directed personality, as they develop instead an excessively dependent or a hypomanic-like outer-directed personality (see p. 435).

† According to statistics from the U.S. Department of Commerce, Bureau of the Census, and reported by Bellak, in 1946 the number of first admissions of manic-depressive psychoses exceeded those of schizophrenics in the states of Tennessee and Alabama. Here the cultural factors seem to play an important role. In other predominantly nonindustrial states, such as

Downloaded from www.libtool.com.cn

There are also historical facts which point to a relation between inner-directed society and manic-depressive psychosis, but these facts, although suggestive, are by no means reliable or scientifically proved. For instance, consider the fact that, among the physicians of the pre-Christian eras, Hippocrates in particular seemed concerned with cases of mania and of melancholia. It is possible to assume from this that his experience with such cases was extensive, making it probable that their incidence was high. Significantly, Riesman's theories postulate that Athenian culture in Hippocrates' time was inner-directed.

Becker, Parker, and Spielberger[11] have recently subjected my hypotheses to studies of their own. According to them, "the character structure of the manic-depressive appears to reflect the unsuccessful resolution of conflicts associated with the stresses of a culture undergoing a transition from inner to other directed." It is the coexistence within a culture of both inner- and other-directed which predisposes to manic-depressive psychosis.

The inner-directed society actually offers a high degree of security to the individual, for it leaves his fate in his own hands rather than in the control of mysterious, omnipotent, and unpredictable forces. Thus, obviously, I do not mean to suggest that the inner-directed culture is "the cause of" manic-depressive psychosis; rather, I speculate that this type of culture tends, in certain cases, to elicit family configurations and interpersonal conflicts that are generally those which lead to manic-depressive psychosis. What is supported here is a psychosocial or biosocial position similar to that expounded by Opler[71] and by Lemkau and his collaborators.[60]

## *Other Social Factors*

Additional cultural factors either add to or detract from the importance of the structure of the society in the formation of various disease entities. Immigration to a foreign country, with consequent problems of maladjustment, seems to elicit a propensity toward this as well as other psychiatric disorders. Some additional explanation for the various incidence of manic-depressive psychosis may be found in ecologic studies.

In 1939 Faris and Dunham[31] published a study, *Mental Disorders in Urban Areas*, in which they found that, whereas schizophrenia is prevalent in the central areas of the cities of Chicago and Providence, that is, in areas of social disorganization (where delinquency, crime, prostitution, and drug addiction are also frequent) and gradually declines in number toward the outskirts of the city, no definite pattern of distribution was found for the cases of manic-depressive psychosis.

The contrast between the ecologic distribution of manic-depressive psychosis and schizophrenia was so marked that Faris and Dunham saw in it another proof of the distinct nature of the two disorders. Faris and Dunham believe that probably precipitating factors have a more important causal relation to manic-depressive psychosis than to other disorders.

Some of Faris and Dunham's conclusions may be integrated with the explanation given by the present author in other sections of this chapter; others are, perhaps, susceptible of different interpretations. We have seen that precipitating factors are undoubtedly important in manic-depressive psychosis (see pp. 435–437). On the other hand, it is my impression that manic-depressive psychosis is not necessarily connected with a milieu which offers "extremely intimate and intense social contacts," but rather with a structural, well-organized inner-directed milieu, removed from the disorganization or relative looseness of organization that we find either in some other-directed societies or, for entirely different reasons, in low economic or socially unstable elements of the population.

A difference in the occurrence of the two major psychoses is also illustrated by the size of the communities involved. The highest proportion of manic-depressives comes from cities of 100,000 to 200,000 population and from rural areas, whereas the largest proportion of schizophrenic cases comes from metropolitan or urban areas.[58]

Maine, Delaware, and Florida, there was very little difference in the incidence of the two conditions, but the total number is too small for conclusions to be drawn.

Downloaded from www.dbraulibrary.org.in

Other studies seem to point out that the economic level of the manic-depressive tends to be higher than that of the schizophrenic. It is debatable, however, whether the low economic condition of the latter is related to the effect of, rather than to the etiology of, the disorder. Manic-depressives are affected by their condition later in life and less seriously.

Summarizing, there is much presumptive evidence that ecological, cultural, and social factors are important in either engendering or at least predisposing to manic-depressive psychosis. It also seems that in the United States, these sociocultural factors, whatever they are, began to decrease sharply in intensity and number in the mid-twentieth century.

## A Study of the Formal Mechanisms of Manic-Depressive Psychosis

As I have stated elsewhere[3, 4, 8, 9] one must study not only the content of psychological conflict but also the form that the conflict assumes—for the form, more than anything else, distinguishes one disorder from the other.

Formulations of the formal mechanisms of manic-depressive psychosis are still at an early stage of development. We can, however, make some preliminary observations.

We have seen how in the premanic-depressive patient there is a tendency to accept, to internalize the interpersonal environment to a more pronounced degree than in the average person. Fairbairn[29] refers to this phenomenon as internalization of objects, but internalization of objects means only acquisition of symbols, symbols which may replace the objects they stand for.

The person who is likely to become manic-depressive has an overdeveloped ability to accept the symbols of the surrounding adults.* Such facility exists even when these symbols are accompanied by an affective tonality which is unpleasant.

We have seen how, in the environment to which the young premanic-depressive is exposed, the symbols acquired from the adults have a tonality consisting predominantly of feelings of guilt, sin, responsibility, and impending loss. The organizations of symbols representing such concepts as family, duty, religion, fatherland, work, etc., are also connected with this unpleasant or burdensome tonality. The affective tonality which accompanies the symbols may become so intense as to overpower the cognitive aspect of the symbols, or to obscure it. The affective component finally may become so powerful, that the cognitive one remains insignificant, or becomes confused or lost, or attached in an unstable way to a vague cognitive ideation of pain and loss.

What are the possible defenses (normal or pathological in degree) against painful or depressive thoughts? They are three: (1) rejection of the symbols of society, (2) acceptance of the depression, and (3) discharge or escape into action. The first possibility (rejection of the symbols of society) ranges from daydreaming activities and fantasy life to schizoid withdrawal; from the new individualistic symbols which the artistic person is able to create to the use of the paleosymbolic or autistic cognition of the schizophrenic.[4, 5, 7]

The premanic-depressive is deprived of this mechanism. He cannot lose the social symbols (or the objects, if we prefer orthodox psychoanalytic terminology) which he has introjected so well. In other words, regression is not available to him, and creativity is not his forte. He must retain the symbols, he must accept them even if they are painful, and by doing so he follows the second possibility. Not only does he accept the unpleasant symbols—he accepts them to an exaggerated degree.

In other words, in the depressed person the cognitive component of the symbol does not change, is not displaced, is not substituted by an autistic or paleosymbolic symbol as in the schizophrenic and in some psychoneurotics: the only thing that changes is the intensity of the emotional tone. Of course, this is not totally true. In depressions too, the symbols may be displaced, but much less than in the other psychiatric disorders, and generally only by some symbols which have similar affective components. We have thus a poverty of neosymbols and a change in the affective component of the

* The reader may remember that the manic-depressive has greater ability than the average person for verbal functions (for instance, learning of foreign languages).

Downloaded from www.freeuniversitylibrary.org.in

old symbols. The affective component is apt to change only quantitatively (unless the manic defense is resorted to, as we shall see later), because emotions, unless accompanied by cognitive components, do not permit as many varieties as do symbols. This limited possibility of responses explains the relative simplicity of the formal mechanisms of manic-depressive psychosis in comparison to those of schizophrenia.

The depression has a purpose, too, not only at a dynamic level but also from a biological and formal points of view. For instance, let us examine the normal depression which we may undergo after the death of a person dear to us.

Why does the loss of such a person produce sorrow? What is sorrow? Why is it unpleasant? Such questions seem to imply intuitional answers or to be self-understood, but they are not. Sorrow, of course, is a form of mental pain.

It is not implied here that depression is the only form of mental pain, but that it is the most typical, and that it is the evolutionary outcome at a human symbolic-interpersonal level of the biologic nociceptive pain. We may even say that the depression is a concrete representation of the loss of a loved object.

As the recuperative properties of the organism attempt to remove physical pain by the histologic healing process, the organism attempts also to heal from mental pain: here lies the teleologic quality of mental pain. Following the example of the death of the person dear to us, for a few days after the death, all thoughts connected with the departed person will bring about a painful, almost unbearable feeling. Any group of thoughts even remotely connected with the dead person will elicit depression. We cannot adjust to the idea that he does not live any more. But if that person was so important to us, almost all our thoughts or actions are directly or indirectly connected with him and therefore will elicit an unpleasant reaction.

Nevertheless, after a certain period of time, we get adjusted to the idea that that person is dead. By the very fact of being unpleasant the sadness has a purpose—it wants to be removed. It will be removed only by forcing the individual to reorganize his thinking, to change his thoughts into different constellations, to search for new ideas so that he can rearrange his life—especially those ideas which were connected with the departed, so that the departed will not be considered indispensable any longer. This process occurs in the normal person, but the manic-depressed person has great difficulties with it.*

When this process fails, another, slightly less normal mechanism occurs. The depression, rather than forcing a reorganization of ideas, slows the thought processes. In this case the teleologic mechanism acts almost with the goal of decreasing the quantity of thoughts in order to decrease the quantity of suffering. At times, the attempt to slow thought processes succeeds so well (as in the state of stupor) that only a few thoughts of a general and vague nature are left; these are accompanied by an overpowering feeling of melancholy. This acceptance of the depressed mood and slowing of thought processes which have an unpleasant emotional tone are self-defeating mechanisms. In a vicious circle they aggravate the situation instead of alleviating it.

The third defense for the individual in the presence of depressive thoughts is the escape into action and fugitive thoughts. This defense is available to the manic-depressive patient, although it is not as frequent as the second. This defense is the formal counterpart of the outer-directed or hypomaniclike personality.

This defense may be so effective as to prevent the occurrence of the psychosis throughout the life of the patient. Thoughts must be very fugitive, must be changed very rapidly, because any constellation of organized thoughts about practically any topic sooner or later bring about the depression. Pleasant thoughts are searched for; actions that may replace ideas are sought.

The patient resorts to this defense either in order to prevent the depression or in order to escape from the depression (as when he slips from the melancholic into the manic state).

At times, he succeeds in using this defense in an acceptable, or at least tolerable way, retaining, or even increasing, normal abilities.

* At other times he will use it too much, as in the manic attack.

Downloaded from www.pdfbooksfree.pk

The ability to recall masses of detail, shown by some hypomanic patients when reporting their experiences, may be useful if channeled into activities that require accurate descriptions. Often however, the wealth of details is useless and irritating. The escape into words, into social symbolism, and into observation of reality almost to a photographic level is obvious.

The following are some excerpts from a woman's conversation during a hypomanic interval. (She had had three previous psychotic depressions.)

The telephone rang; it was the doctor who treated my husband, Dr. B. He told me that I should go to see him right away. I put on my spring coat. It must have been spring, as I remember, because I wore the spring coat. The doctor lived a few blocks away in an apartment in the Hotel Plaza. I went there, took the elevator. They lived at the fourth floor, fourth or fifth, I don't think it makes much difference. I rang the bell. The wife came to open the door. She is such a short woman and her husband, the doctor, was so tall. . . .

These details were, of course, useless and irrelevant to the goal of the conversation. Logicalness, however, was retained. Similar behavior may be tolerated. Often, however, when the looming depression is very intense, the patient must resort to more pronounced manic mechanisms.

The foregoing exposition may create the impression that the manic pleasure consists only in the escape from depression, in the removal of the negative. Not every pleasure, however, is the removal of the negative, or a decrease in the tension which produced pain; it is my impression that the manic does not try only to escape from the pain of depression but tries to gain by extending or enlarging his contacts with the world. Such contacts must remain superficial, however, if depressing connections are to be avoided. A further consideration is the fact that pain elicits in the organism a reaction of *moving away* from the source. At the level of human depression, no movement or moving away is visible, because the moving away is only from depressive thoughts (unless, as we have seen before, the depression is very intense). In pleasure, there is not only a moving away from the source of pain but *also a moving toward* the object which will confer pleasure.[75] And the increased motility of the manic must be considered as an attempt to *move toward* the source of pleasure.

The manic mechanisms, however, fail on account of their pathologic proportions: in order to avoid unpleasant constellations, thoughts must be so rapid that they cannot be organized or, therefore, capable of achieving rewarding actions. The pleasant ideas cannot be sustained and eventually leave the patient with the realization that they are futile. When the manic fervor is exhausted or cannot be sustained any longer, depression ensues or returns.

It is still not clear why some patients are able to avail themselves of the manic defenses and others are not. Perhaps constitutional, cultural, and dynamic factors play roles which cannot yet be ascertained. Studying the literature, however, one gets the impression that in so-called primitive cultures the manic attacks are much more numerous than the depressions.

The incidence of manic attacks is much lower than that of depressions, and many writers today feel that one cannot classify as manic-depressive the many patients who undergo depressions but never have a manic attack.

More conservative psychiatrists, however, tend to retain the syndrome manic-depressive as a unit, a position that can be justified on the grounds that our understanding of its partial manifestations is increased by our acceptance of its unitary concept.

Perhaps, at this point, it is possible to formulate a more complete definition of manic-depressive psychosis:

*Manic-depressive psychosis is a periodical abnormal way of living, dominated by excessive affective tones of exaltation and melancholia. The propensity for this intense affectivity is brought about by childhood experiences which lead to excessive introjections of unpleasant symbolic constellations and to more or less specific defenses against these introjections. These defenses, however, not only are not useful but determine vicious circles which may reproduce the disorder in its totality or its various parts.*

## Biological Factors and Psychosomatic Mechanisms

### *Genetic, Constitutional, and Neurological Factors.*

Many authors are not convinced that the psychodynamic and social factors are the only etiologic agents in manic-depressive psychosis, since people with apparently similar psychological and cultural environments have not developed this disorder. It is difficult either to accept or to reject this type of criticism because of the complexity and the multiplicity of the variables involved. For instance, the defenders of an exclusively cultural psychodynamic point of view reply that obviously these psychodynamic mechanisms must be particularly pronounced and must be accompanied by inadequate compensatory mechanisms in order to lead to the disorder. Inasmuch as it is difficult to differentiate or to evaluate quantatively these compensatory mechanisms, no definite answer can be given at this time.

On the other hand, since constitutional or predisposing factors or a state of receptivity or nonimmunity are to be found in most pathological conditions, by analogic thinking we may assume the possibility of a biological factor in the etiology of manic-depressive psychosis also.

Pollock, Malzberg, and Fuller[74] state that the incidence of the disorder is greater among the siblings of patients than in a sample of the random population. The psychosis, however, does not appear in accord with the laws of simple Mendelian inheritance.

Slater,[85, 86, 87] on the contrary, is a strong advocate of the hereditary nature of manic-depressive psychosis. He thinks that the inheritance follows a dominant type which depends on a single autosomal gene. To explain why the incidence of the psychosis is lower than would be expected from his hypothesis, he states that the dominant gene is a weak one.

Matz and Willhite,[68] who have studied manic-depressive psychosis among ex-service men and reviewed the literature extensively, conclude that inheritance is an outstanding etiological factor in manic-depressive psychosis. In the group of patients that they studied they found a familial history of nervous or mental disease or some other taint in approximately 45 per cent. The most frequent "taints" were alcoholism, manic-depressive psychosis, and "other psychoses." Among "other taints" were psychoneuroses and drug addiction. Since so many conditions are included in the category of taints, one wonders how reliable these statistics are.

Kallmann[46] states that the potentiality for developing manic-depressive psychosis depends "on the mutative effect of a single dominant gene with incomplete penetrance." In a broad-minded conclusion Kallmann states that "the dynamics identified with this specific ability [the ability to develop manic-depressive psychosis] cannot be considered part of a person's normal biological equipment, nor are they out of line with current concepts of psychodynamic phenomena observed in potentially vulnerable persons." In other words, certain psychodynamic phenomena have the ability to elicit the disorder in persons who are potentially vulnerable on account of a hereditary background. Kallmann feels also that the hereditary factor is more important in manic-depressive psychosis than in schizophrenia.

Constitutional factors have also been studied by many authors, following Kretschmer's lead. Kretschmer[56, 59] described a cycloid type of temperament which is accompanied by a pyknic constitution and a schizoid temperament which is accompanied by an asthenic (leptosomatic) or athletic constitution. He stated that approximately two thirds of manic-depressive patients belong to the cycloid temperament and pyknic constitution, pointing thus to a correlation between the body build and the mental disorder. Sheldon[84] continued this study and concluded that manic-depressive patients are generally mesomorphs, or a mixture of endomorphy and mesomorphy, with mesomorphy predominating.

These constitutional factors, if valid, must be interpreted not as necessary prerequisites, but as contributing or aggravating factors. It is a common observation that the pyknic build, assumed to be related to manic-depressive psychosis, is becoming more and more numerous in schizophrenics too.

Another generally neglected consideration is the reverse of this theory. Are these pyknic

Downloaded from www.cerebralpalsy.org.in

patients really constitutionally pyknic from birth or have they become so? Strong receptivity predisposes some premanic-depressive children to overeating and consequently to obesity. We must consider the possibility that personality characteristics may affect the body build.

Studies of general pathology in manic-depressive patients are scarce and do not lead to any conclusions. Lewis,[62] who examined 8 cases of manic-depressive psychosis, post-mortem, found that the circulatory and endocrine systems had reacted "in a compensatory way in excess of what is usually found in those dying at the same age level and that deaths from over-compensation in the circulatory organs are relatively numerous."

Kraines[55] feels that the mechanism of manic-depressive psychosis is to be found in a dysfunction (either increased or decreased function) of the diencephalon. According to him, the psychiatric picture is a "psychic response" to this diencephalic dysfunction. This response depends on the personality of the patient and is a secondary manifestation of the illness, not an etiologic factor. Kraines poses the question about the nature of the pathologic process affecting the diencephalon. Since no toxic, infective, degenerative, neoplastic, or traumatic lesions are found, he postulates that the disturbance must be physiologic and must occur on a hereditary and metabolic basis. According to him, the diencephalon is only part of a larger diencephalic-rhinencephalic-reticular system which mediates the illness. The illness is mediated through this neurological system but may be determined by many factors, such as circulatory alterations, metabolic changes, and especially endocrine dysfunctions, particularly of the gonads.

### *Psychosomatic Mechanisms*

A study of psychosomatic mechanisms in manic-depressive psychosis is premature. In a study of schizophrenia[4, 6] the common trends in the study of that disorder were reversed: the study started with psychology and ended with neurology, demonstrating how psychological conflicts may lead to a rearrangement of cerebral mechanisms even at a physiologic level. A similar study in manic-depressive psychosis is more difficult because the neurology of highly symbolic emotions is even more obscure than that of cognitive processes. If we accept the priority of an interpersonal-psychodynamic etiology and pathogenesis in manic-depressive psychosis, we must also accept the fact that the conflicts that lead to this disorder could not occur without the participation of the neocortical areas which are indispensable in mediating interpersonal relations and symbols. But these relations and symbols have an emotional counterpart which is probably mediated by the archipallium. As Papez[73] and others[37, 65] have indicated, human emotions are probably mediated at a cortical level in the archipallic areas. Such deep emotions as sorrow, sadness, grief, etc., cannot easily be conceived as exclusively hypothalamic or diencephalic functions, although obviously they are also connected with some activities of these structures. They are very different from sham rage and those other emotional expressions which are reported as diencephalic functions. Thus it seems logical to assume that the conflicts of the manic-depressive, which are mediated in the neopallic areas, have functional psychosomatic repercussions in the archipallium. The functional changes in the archipallium, in their turn, may lead to other abnormalities.

To date, a hyperfunctionality of the autonomic nervous system in manic-depressive psychosis has not been sufficiently demonstrated. At a clinical level I have noted rather the opposite —a poverty of autonomic manifestations in manic-depressive patients. In a few patients, who presented intense perspiration, erythema of the skin, and tachycardia when undergoing states of anxiety, all these symptoms disappeared during subsequent attacks of psychotic depression. It seems almost as if the archipallium becomes hyperactive and inhibits lower diencephalic functions.

## ¶ Therapy

### *Choice of Therapy*

The treatment of manic-depressive psychosis should be considered under three headings: (1) hospital treatment, (2) physical treatment, and (3) psychotherapy.

Downloaded from www.dbnet.ir.ac.ir

A discussion of the first two will be confined, in this chapter, to a few general remarks, since they are discussed extensively in other chapters (Chaps. 68, 69, 70, 71 and 85). Here we will consider primarily the psychotherapeutic approach.

Hospitalization must be considered, especially when there is danger of suicide. Whenever there is a tendency toward suicide, the therapist must make sure that the patient can be under proper surveillance at home; if this is not possible, hospitalization becomes necessary. Often it is more difficult to convince the relatives than the patient that hospitalization is necessary. The depressed patient, perhaps in a masochistic spirit, is ready to enter the hospital, whereas the relatives would prefer to send him on vacation. It is more difficult to hospitalize a manic, as he himself prefers to take trips and to escape into actions.

Recently, however, hospitalization could be avoided in many cases because of the efficiency of convulsive therapy in rapidly terminating acute attacks. At times, merely a few electric shock treatments are sufficient to produce a temporary recovery from a depression. A manic attack may require a longer course (see Chap. 69). Electric shock treatment is, at the moment, the best physical therapy for the affective psychoses, and even today is used for these conditions more often than drug therapy, prolonged narcosis, and psychosurgery.

Although convulsive treatment is only a symptomatic treatment, capable of removing the attack but not of preventing recurrences, many psychiatrists (including the writer) feel that it should be instituted in all cases in which the depression or the manic state has gone beyond a mild stage. Not only will a great deal of suffering be prevented by interrupting the attack, but the patient becomes accessible to psychotherapy much sooner. Psychotherapy of manic-depressive patients is always difficult, but during acute attacks it is even more difficult. Either the flight of ideas or the intense preoccupation with depressed thoughts interferes with the attempts to establish contacts. One must be aware, however, of one serious shortcoming in the use of shock therapy for manic or depressed patients. Once freed from symptoms, they are apt to want to forget the illness, with a consequent reluctance to undergo psychotherapy. Careful preparation and cooperation from relatives, however, may help to induce them to accept it. Of course, if the current attack had been preceded by others, the patient knows from experience that the electric treatment alone is not capable of preventing relapses.

It is advisable that electroshock therapy and psychotherapy be administered by different therapists. One of the fantasies of the patient (probably to a certain extent connected with the manifest recovery from the attack after shock treatment) consists in the feeling of having received enough punishment that he can now consider himself redeemed. The psychotherapist should not be seen as the punishing agent.

Psychotherapy should be instituted in the following instances: (1) at the termination of the convulsive treatment, as soon as the organic signs such as forgetfulness, mild confusion, etc. have decreased in intensity; (2) with patients who, because of physical illness, could not receive convulsive treatment; (3) with those patients in whom the depression or hypomanic state is so mild that therapeutic contact may be easily established; and (4) with patients whose acute attacks have ended spontaneously.

In some cases of the third category, the therapist is confronted with a dilemma: a slight possibility of suicide exists; on the other hand, the patient is still able to work and resents hospitalization, for this would mean being cut off from work and from treatment, both of which he considers necessary. The decision, of course, rests not only on the patient but on the therapist. It will depend on the evaluation of the individual case. If the risk of suicide is deemed minimal, it may be worth taking, in view of the fact that long psychotherapy is not possible in the hospital (with a few exceptions), and in view of the fact that the possibility of suicide is not completely eliminated even in a hospital environment. The situation should, however, be discussed with the members of the family.

## *Psychotherapy*

In many cases of mild depression, as Ostow[72] writes, psychotherapy will offer relief to the

Downloaded from www.dbraulibrary.org.in

patient who sees in the therapist a new and reliable love-object. Although the establishment of this transference may be helpful to the subsequent therapy, it cannot be considered a real cure; as a matter of fact, it may be followed by another attack of depression when the patient realizes the limitation of the therapeutic situation. Moreover, this pseudo improvement must be considered as an attempt on the part of the patient to defend himself by assuming the clinging, dependent type of personality.

Kolb,[52] English,[27] and Cohen[22] emphasize this excessive clinging as one of the main problems encountered in intensive psychotherapy with manic-depressives. Some patients do not want to leave at the end of the hour; they claim to remember, suddenly, many things they must say, plead for help, and attempt to make the therapist feel guilty if they are not improving. As Kolb[52] aptly describes, these patients have learned proper or apparently suitable social manners, and, with pleading and tenacity, they are often capable of eliciting in the therapist the reaction they want.

The patient will soon find in the therapist either a person to cling to or to depend on, a love-object, an authority who gives moral assent or disapproval, or a punishing agent. If the patient feels that his needs are satisfied, he will experience a feeling of love for the therapist.

Thus the same situation is repeated in the transference situation that has occurred throughout the life of the patient. He resorts to the same technique: either by clinging and demanding or by complying and seeking approval, he wants acceptance and love. A third method, of course, consists in a flight from the situation which gives the false impression of immersion in reality.

If the life history of the patient has been discussed, it will be possible to point out and explain these mechanisms to him. Sooner or later he will learn to avoid them, as he learns to recognize in them a pseudo solution of his problems and a perpetuation of a vicious circle. The patient will at first have only an intellectual understanding; consequently, the mechanisms will tend to recur even after they have been completely understood. As a matter of fact, even discussion of them will evoke strong emotional reactions which are not congruous with the gained insight but which are the usual affective components of the original symptoms. For, even after the patient has understood the meanings of his symptoms and behavior patterns, he has no other mechanisms at his disposal, no different patterns of behavior.

It must, for example, be pointed out constantly to the patient that he should learn to ask himself what he wants, what he really wishes. Quite often his attempted answer will be only a pseudo answer. He may say, "I wish first of all peace; I wish the happiness of my children." He must learn—and relearn—that peace at any cost implies satisfying others before oneself, and that even the happiness of children, although a natural wish of every parent, is not a wish predominantly related to the individual himself.

In other words, the patient must learn to listen to himself and to reduce the overpowering role of the "Thou." At the same time he must make a voluntary effort to develop inner resources. In the attempt to imitate others, or even to surpass others in proficiency and technique, the patient has never relied on himself. He cannot be alone (unless he is depressed) and alone he cannot do anything that gives him satisfaction; he must work for the benefit of others or take flight into common actions. He must learn that he too has an artistic, individual soul, and if he has the capacity to search for it, he will find it. Creative upsurges in apparently uncreative conventional manic-depressive personalities are a good prognostic sign (with the exception of mixed cases with partial schizophrenic symptomatology).

Summarizing, the patient must first learn to understand all the experiences and mechanisms described in the third part of this chapter; that is, the experienced or expected loss of love, the compliant industrious attempt to recapture it with denial of oneself, the resentment for making strong efforts and consequent aggression, the guilt for failing to recapture love and for having aggression. The early life experiences, remembered, will provide the evidence which the patient needs in order to

Downloaded from www.brainlibrary.ir

understand the patterns which he has developed. Moreover, the therapist must be alert to spot early signs of depressions, at times precipitated even by trivial disappointments or even by chance associations of ideas. As Jacobson[43] and Kolb[53] emphasize, the recurring depression must immediately be related by the therapist to its precipitating cause. In this way full-fledged attacks are aborted.

Jacobson also feels that the patient should be guided to focus on the recent loss or precipitating cause rather than on the early experiences which led eventually to the present symptomatology. On the other hand, one can find in clinical experience that when the triviality of the disappointment or loss that led to the depression is shown to a patient, he may become "depressed" over the fact that such a "minor cause" could evoke such depression. In other words, we have another instance of the vicious circles that tend to occur in all mental disorders and tend to increase the intensity of the symptomatology. If, on the other hand, the patient is made to understand that the present disappointment or loss is symbolic of a much greater disappointment or loss, he is able to understand the unrealistic nature of the incoming depression and is better equipped to fight it.

At the same time, he must learn new patterns of living, patterns which lead to his own independence, individual growth, and self-realization. The learning of new patterns will reduce the tendency of the old ones to recur.

What is advocated here is in a certain way a psychotherapeutic approach which will attempt to reproduce the healthy formal mechanisms described on p. 445 as a normal reaction to depression and to loss—reconstructions of thought constellations rather than the self-perpetuating depression or the manic flight.

The outlined technique may seem, to the reader, a too intellectual approach. But orthodox psychoanalytic procedure, with the use of the couch and free associations, is not indicated in manic-depressive psychosis even during the interval periods. Many failures in treatment of these patients were due to the adoption of the classical psychoanalytic technique. Many therapists feel today that the retarded or hyperactive patients generally should be treated with less frequent sessions—from one to three a week. Many patients, especially elderly ones, seem to do well with one session a week. The therapist must play a relatively active role, not one that conveys to the patient the feeling that he is being pushed or under pressure, but not one in which the passivity of the therapist is too much in contrast with the natural extroversion of the patient. Whenever the therapist feels that he has succeeded in reaching some conclusions or in understanding the feelings of the patient, he should verbalize them freely. Often the patient prefers to keep quiet, not because he is unable to put things together, as in the case of the neurotic or the schizophrenic, but because he feels guilty or ashamed to express his feelings of rage, hostility, and, paradoxically, even of guilt and depression.

Dream interpretations are very useful, especially in depressed patients.

The treatment of hypomanic patients is far more difficult, as the flight of ideas prevents any significant contact. Here an opposite procedure is to be followed. The patient is asked to cut out details, so that irritation and rage are purposely engendered, or he is reminded that he must talk about certain subjects (the subjects that are liable to induce depression). A conversion to a mild depression is therapeutically desirable. In many cases, however, it will not be possible to induce mild depression exclusively with active intervention of the therapist, and chlorpromazine (Thorazine) must be resorted to (see Chap. 77). This drug, either by decreasing the intensity of the manic or hypomanic state or by eliciting a depression, can be a valuable adjunct to psychotherapy.

Needless to say, not every therapist is suitable to treat manic-depressive patients. Some therapists who have been quite competent in treating psychoneurotic or schizophrenic patients have been utterly unsuccessful with manic-depressive patients, especially of the manic-hypomanic type. The verbose, circumstantial talk, or the photographic reproductions with no signs of originality, the lack of any fantasy or of symbolic material, may tire the therapist. The immediate recognition of these characteristics as defense measures, and of their variation in accordance with the

Downloaded from www.dbraibrary.org.in

transference situation, can help the therapist in his trying efforts.

CHAPTER 23

# SCHIZOPHRENIA:

## The Manifest Symptomatology, the Psychodynamic and Formal Mechanisms

Silvano Arieti

Downloaded from www.dbraulibrary.org.in

IN THE LAST TWO DECADES the field of psychiatry has grown in many directions, but schizophrenia retains the first place among psychiatric conditions in claiming the therapeutic dedication and in renewing the searching endeavor of psychiatrists the world over.

The Second International Congress for Psychiatry, held in Zurich in September 1957, which was entirely devoted to this disorder, revealed both the magnitude of the effort and the lack of a satisfactory integrating approach. Despite the mass of data reported by the many participants—results of varieties of research and differing therapeutic approaches—there was not a single concept on schizophrenia that was not rejected or challenged by some other authors. Even the name schizophrenia was disapproved of by several people.

As a preliminary definition of schizophrenia, we shall adopt that offered by Blakiston's *New Gould Medical Dictionary*.[24] This definition is more descriptive than explanatory, but has a great deal of pragmatic value.

> Schizophrenic reaction [is] one of a group of psychotic reactions, often beginning after adolescence or in young adulthood, characterized by fundamental disturbances in reality relationships and concept formations, with associated affective, behavioral and intellectual disturbances in varying degrees and mixtures. These reactions are marked by a tendency to withdraw from reality, inappropriate moods, unpredictable disturbances in stream of thought, regressive tendencies to the point of deterioration, and often hallucinations and delusions.

### ¶ Historical Survey

The concept of dementia praecox as a nosologic entity appeared very late in medical history. Kraepelin is the first writer to structure

this concept. Two precursors of Kraepelin must, however, be mentioned: Morel, was the first author to use the term dementia praecox (*de mence precox*). On page 566 of his treatise published in 1860, he for the first time associates the two words *dementia* and *praecox* to describe a case of "stupidity" in a young man which "degenerated into a state of dementia." Kahlbaum,[97] in 1863, described a special psychiatric condition occurring in puberty and termed it "paraphrenia hebetica"; in 1874 he described catatonia under the name *Spannungsirrsein*. Only in 1898, however, did Kraepelin[105] conclude the synthesis and propose the concept of dementia praecox.

## *The Classical Period*

Kraepelin's insight consisted in including three conditions under one syndrome; (1) catatonia, already described by Kahlbaum, (2) hebephrenia, already partially described by Kahlbaum's pupil Hecker,[81] and (3) "vesania typica," a condition also described by Kahlbaum and characterized by auditory hallucinations and delusions of persecutions. In these different clinical pictures, Kraepelin saw one fundamental nosologic picture characterized by progressive decay and finally by dementia. Thus the outcome, or rather what was supposed to be the outcome—dementia—was the fundamental criterion. By separating the patients who eventually develop dementia from those who do not, Kraepelin was able to differentiate a set of symptoms which he thought were characteristics of dementia praecox, in contrast to another set of symptoms which constitute the syndrome of manic-depressive psychosis. Kraepelin thus could differentiate and define as dementia praecox a symptomatology consisting of hallucinations, delusions, incongruous emotivity, impairment of attention, negativism, stereotyped behavior, and progressive dilapidation in the presence of relatively intact sensorium. He distinguished three types—the hebephrenic, the paranoid, and the catatonic, according to the predominance of certain symptoms over others. Later, following Bleuler's suggestion, he added the simple type.

Kraepelin's descriptive approach, although revolutionary and epoch-making at the time of its development, is outdated today, as it studies and does not lead to psychotherapeutic lacks psychodynamic, sociocultural, and formal possibilities. Kraepelin's aim was to define disease entities based on definite organic pathology, and he always felt that dementia praecox was ultimately based on a faulty metabolism, although he could never prove this belief.

Bleuler is chronologically the second major author who contributed greatly to our understanding of schizophrenia. He probably was the first to understand both the values and limitations of the Kraepelinian conceptions. In 1911 he published a monograph[26] on this subject which has remained a classic in the psychiatric literature.

He accepted the fundamental nosologic concept of Kraepelin but enlarged it to a great extent, because he considered as related to dementia praecox many other conditions such as psychoses with psychopathic personalities, alcoholic hallucinoses, etc. Furthermore, he thought that the largest number of patients are never hospitalized because their symptoms are not severe enough; that is, they are latent cases. He also saw the syndrome described by Kraepelin not as a condition necessarily progressing toward dementia, but as a disorder characterized mainly by an alteration of the faculty of association and by a splitting of the basic functions of the personality. Thus, he felt that the name dementia praecox should be replaced by the name schizophrenia (derived from the Greek words *schizin* [to divide, to split] and *phren* [mind])—a term that has almost completely replaced the older dementia praecox.

Bleuler tried in two ways to overcome the limitations of Kraepelin's system: by accepting the dynamic concepts of Freud, which had already appeared in the literature, and by attempting explanations of the formal processes.

According to him the formal mechanism underlying all the schizophrenic symptoms was the so-called loosening of associations. This loosening is recognizable in various degrees in elisions, blocking, logical errors, etc.

Downloaded from www.dbraulibrary.org.in

Another of Bleuler's major contributions is his concept of autism.[25,26] Autism is a way of turning away from reality; it is a special way of behaving, but predominantly a special way of thinking which is opposed to logical thinking. Autistic thinking reproduces or interprets not external reality, but a world of fantasy, dominated by wishes and fears and mediated by Freudian symbolism. Bleuler felt that, although autistic thinking might occur in many situations, such as when emotions are very strong, or in artistic productions or in the play of children, its most pronounced form appears in schizophrenia.

Adolf Meyer[122-126] accepted the basic nosologic concept of Kraepelin and Bleuler, but gave it a creative twist. He was no longer satisfied with studying the symptomatology of schizophrenia as it presents itself to the psychiatrist after the outbreak of the manifest symptoms, and stressed the fact that this condition should not be studied in "cross-section," but "longitudinally." He felt that the patient should be studied from the beginning of his life, and all the factors that might have contributed to the development of the psychosis should be evaluated. Schizophrenia thus becomes a "schizophrenic reaction," a reaction to the events which gradually prepare the ground for the psychosis. If we study the patient longitudinally, Meyer taught, we see a gradual deterioration of his way of living. Many "faulty habits" such as brooding, excessive fantasy life, decrease of interests seem at first "trivial and harmless subterfuges," but are gradually substituted by more pathologic habits and eventually are transformed into full-fledged schizophrenic symptoms. Meyer is thus one of the first psychiatrists to emphasize the "longitudinal" importance of psychological factors. Although his approach constitutes a definite advancement over the previous ones, it is not entirely dynamic and remains vague for the following reasons: (1) although Meyer takes into consideration the psychological factors, the role that anxiety plays is not suspected and therefore not studied; (2) the "faulty habits" are well described but are accepted on a realistic level—that is, their symbolic meaning is not fully appreciated; (3) by making it appear that the shift from faulty habits to schizophrenic symptoms is only a matter of quantitative transitions, the specific quality of schizophrenia is minimized and the ground is open for attacks on the concept of schizophrenia.

## *The Psychoanalytic Schools*

Although Freud devoted practically his whole life to the study of the psychoneuroses and had only a secondary interest in the psychoses, his contributions to the whole field of psychiatry are so important that the field of the psychoses too has been tremendously enriched by them. Here it is possible to enumerate only the major Freudian contributions pertinent to our understanding of schizophrenia.

The longitudinal study of the patient, advocated by Meyer, acquires full significance only when the role of anxiety is determined. Freud, by disclosing the role that anxiety plays in human life, especially in psychopathologic conditions, indirectly opened up the field of schizophrenia to the psychodynamic approach. In *The Interpretation of Dreams*[58] he describes many processes which also apply to schizophrenia. The symbolic content and the archaic forms of dreams find a counterpart in the schizophrenic symptomatology.

Freud's concept of the unconscious also applies to schizophrenia, not only because of that lack of awareness that accompanies much of the psychodynamic processes which lead to schizophrenia but also, paradoxically, because the "inability to make things unconscious" is one of the important characteristics of this psychosis. In a paper published in 1896,[67] Freud gives the dynamic interpretation of a case which was later recognized as one of the paranoid type of dementia praecox. In this paper, for the first time in the history of psychiatry, the term "projection" is used and this mental mechanism is explained. In another paper on narcissism, published in 1914, Freud gives more details about his interpretation of schizophrenia as a narcissistic neurosis.[66, vol. 1] In this paper he applies the libido theory to schizophrenia. The libido is withdrawn from

Downloaded from www.MedicalLibrary.org.ir

external objects and is directed into the ego, giving rise to a state which is called "narcissism."

In his book, *Psychology of Dementia Praecox*,[94] written in 1903 (nine years before his break with Freud), Jung became the first to apply psychoanalytic concepts fully to schizophrenia. His studies, especially his word association tests, convinced him that delusions, hallucinations, and other schizophrenic symptoms were due to the activity of the autochthonous complex—that is, to a group of ideas which, on account of their disturbing emotional charge, had become removed from consciousness and were maintaining a more or less independent existence. Jung applied to schizophrenia the mechanisms that Freud had described in dreams. He wrote, "Let the dreamer walk about and act as though he were awake and we have at once the clinical picture of dementia praecox."

In 1913 Jung differentiated two psychological types: the extrovert, with an exaggerated emotivity and the psychic energy directed centrifugally toward the environment, and the introvert, with inhibited psychic energy, that is, energy directed away from the environment and toward the self. He thought that the person who is to become schizophrenic has an introvert personality.

Later Jung[93,95] advanced the theory of the collective unconscious. According to him, many symptoms of schizophrenia are the reproductions of the "archetypes" deposited in our "collective unconscious."*

Sullivan[161] introduced a new point of view in psychiatry by shifting the attention of the therapist from the intrapsychic or intrapersonal to the interpersonal.† According to him, schizophrenia is an indirect outcome of unhealthy interpersonal relations between the child and his parents (called by Sullivan the significant adults).[159,160,161] These faulty interpersonal relations do not permit the establishment of enduring patterns of response which eliminate anxiety (that is, they do not permit a normal development of what Sullivan calls self-system). The patient resorts throughout his life to distorted interpretations of interpersonal situations (called parataxic distortions) and finally may lose "consensual validation," that is, recognition from others of the validity of his statements. When the anxiety increases and a state of psychotic panic develops, the early experiences, which had been disassociated from consciousness and were part of what Sullivan calls the "not-me," regain awareness in a symbolic but nevertheless frightening manner.

## *The Phenomenological-Existential School*

The phenomenological-existential school of psychiatry has received much attention from students of schizophrenia in the German-speaking countries, where it originated, as well as in France, Italy, and Japan; but relatively little attention in the United States.

Space limitation will compel us to consider only two authors: Binswanger[20-23] and Minkowski.[128,129]

Binswanger is perhaps the best-known psychiatrist of this school. He has devoted four large works to the study of schizophrenia, which consist of the detailed existentialistic analysis of four patients to whom he has given the names Lola Voss, Ilse, Ellen West, and Suzanne Urban. These works have become classics for students of existential psychiatry.

In the reports of these cases Binswanger is interested not in constitutional or psychodynamic or symbolic or characterologic studies of the patient, but in the underlying *structure* that existed prior to the illness and that explains the way of being-in-the-world of the patient, his pathologic potentialities, and the uniqueness of his experiences.

Binswanger tries to explain the delusional world of the patient as the evolving of a theme (terror, for instance, in the case of Suzanne Urban, who is the prisoner of her own theme of terror and becomes the prisoner of a world of terror). Fear of filling the body and becoming fat in order to compensate for an empty existence is the theme in the case of Ellen

* For the concepts of collective unconscious and of archetypes, see Chap. 72.

† For a larger discussion of Sullivan's concepts, see Chap. 70.

Downloaded from www.dbraulibrary.org.in

West. Undoubtedly these studies enrich our understanding of the schizophrenic patient and will be useful, provided they are complemented by the psychodynamic, formal, and psychosomatic studies. We must mention, moreover, that it was relatively easy for Binswanger to demonstrate this general theme of the delusional world of the patients because the cases he selected, although prognostically serious, did not yet present a segmentation of the personality or regression. Other psychiatrists might consider them cases of paranoia or paranoid conditions rather than rapidly advancing schizophrenic syndromes.

Minkowski, a pupil of Bleuler, added to Bleuler's conceptions the flavor of Husserl's and Bergson's philosophies. In his major work *La Schizophrenie,* he states that the crucial point of the schizophrenic syndrome is "the loss of vital contact with reality."[129] He also adds that such contact can be re-established as a result of therapy, but does not give instructions on how to re-establish such contact. In other studies[128] he focuses his attention on the alteration of the sense of time and space in schizophrenics. Whereas space expands to include the whole category of the objects that are involved in the patient's delusions, time is blocked and limited to the present.

Other important existentialistic studies of schizophrenia were made by Frankl[64] and Wyrsch.[176]

## The Manifest Symptomatology

The clinical symptomatology of schizophrenia, with its various types and stages, presents multiform aspects, but the description of the symptomatology, as reported in this section, will be relatively brief.

### *General Description of the Disorder*

The patient, generally as a young human being (from the time of puberty to his early thirties, but less commonly at any other age of life), starts to show some striking anomalies in his behavior. Although some unconventional traits may have been manifested even earlier, they were apt to be almost unnoticed. Now they become apparent, at times in a slow, insidious, gradual way, at other times more or less acutely.*

The patient seems less interested in life in general and is obsessed instead with some specific problems. Finally he expresses ideas that seem bizarre and are not acceptable to his family or his community. He starts to think that certain things are related to him or have a special meaning (*ideas of reference*). For instance, if he met a person on the street, it was because that person had to spy on him. Finally, the patient gives some interpretation to things that are not supported by the observations made by other persons. (The house is wired, dictaphones are hidden to register the patient's thoughts; poison has been put in the food.) These are false beliefs, or *delusions;* they are generally of negative character, inasmuch as they seem to convince the patient that some people or outside forces want to persecute him, injure him, or at least watch him or plan some future disturbance. At a later stage, however, these delusions may become pleasant in content and even grandiose (the patient is a queen, a millionaire, etc.; a great actor is going to marry her, etc.). Whereas persecutory delusions refer mostly to others, grandiose delusions more frequently refer to the patient himself.

The perceptual functions of the patient seem altered, too, as he sees or hears things in a distorted way. At times things are misidentified (*illusions*). Much more frequent than the illusions, however, are the *hallucinations,* or perceptions occurring without any object or stimulus in the external environment being responsible for them. The patient hears voices which accuse him of being a spy, a homosexual, a murderer, and yet nobody is there to say these things. Hallucinations involve every sense, the auditory being as a rule the most common throughout the course of the disorder. In the beginning, however, especially in very acute cases, visual hallucinations are sometimes as numerous as the auditory. Hallucinations involving smell, taste, and touch are much less

* For a description of the prepsychotic personality see pp. 472–473.

Downloaded from www.dbraulibrary.org.in

frequent. Olfactory hallucinations, generally related to one's body, are relatively frequent in mild cases which do not require hospitalization.

In addition to this content of thought which is definitely psychotic in character, the patient may manifest other symptoms which seem neurotic, especially at the beginning of the illness: asthenia and other hypochondriacal complaints.

At times the general behavior of the patient seems normal and the only apparent symptoms are the abnormal ideas. In the majority of cases, however, the general behavior strikes the examiner as much as the content of thought. The general behavior appears odd in many ways: mannerisms, grimaces, purposeless acts, stereotyped motions, impulsive gestures are observed. In addition in the catatonic type there are particular symptoms to be described later.

The mood and the affective sphere in general are altered. The patient may appear angry, highly emotional, suspicious, cynical, etc., especially when he refers to his delusional complexes; as a whole he is somewhat inadequate emotionally. Often the emotional tone does not seem appropriate to the present situations and almost always a blunting of affect, ranging from a relative coldness to complete apathy, can be detected. The patient seems to have completely lost interest in his surroundings and to be withdrawn into himself. He is often described as being "in a shell," in his own world, as if he had lost not only his understanding of but also his interest in reality. When he presents this picture of withdrawal he is generally underactive. His activities are reduced to a minimum and are often performed in a routine, stereotyped manner. Often he has to be pushed to do things. He may be so unwilling to act that he may become neglectful of his personal appearance. A deterioration in his habits of living is apparent in all advanced cases.

The speech and language show peculiar characteristics, some of which will be examined again in this chapter. If certain questions are asked, the patient seems *evasive*, because he does not answer them directly. At times he seems to beat around the bush—he says something related to what was asked but not exactly what was requested. For instance, to the question, "Who is the President of the United States?" he may reply "White House." At times he seems to use impressive abstract words, but in an empty or inappropriate way. In advanced cases it may be difficult to understand what the patient tries to convey. His sentences consist of a sequence of words which seem unrelated to one another (*word-salad*). At times certain words are used repeatedly in a stereotyped manner (*perseveration*); other words are used which do not appear in the dictionary, and which the patient has coined by condensing or putting together usual words (*neologisms*). In many cases the patient is unable to talk (*mutism*), or able to do so only after overcoming a great resistance (*blocking*).

The sensorium and the intellectual functions are not seriously impaired. Orientation, memory, retention, grasp of general information, calculation, etc., may seem disturbed in many cases. The disturbance is actually the result of the other symptoms described, and may disappear once these symptoms disappear. What seems impaired from the beginning is only an ability for very abstract thought, as we shall see later in more detail. Even this symptom, however, is reversible.

*Insight*, that is, realization of being in an abnormal condition, is absent except in mild or initial states.

### PARANOID TYPE

The cases generally classified as paranoid type present, fundamentally, the picture described above; they also, however, present some characteristics of their own. First of all, the onset of the psychosis may occur a little later in life than in the other types. Although many cases of this type occur even as early as the time of puberty, they are common even in the fourth and even fifth decade of life. The older the patient, the more difficult it will be to decide whether his symptomatology is a schizophrenic one or one which is better classified as paranoid state or paranoia (see Chapter 25).

Paranoid patients are as a rule more intelligent than the other schizophrenic patients, although all types of I.Q. are found. From the

Downloaded from www.dbraulibrary.org.in

beginning they are suspicious and bitter. They may assume the angry, antagonistic, defiant attitude of the person who is unfairly victimized, or the attitude of the submissive person who wants to be helped but does not know what to do because "strange things are happening."

The content of thought of these patients is characterized by ideas of reference and delusions, even more than other types of schizophrenia. Although the delusions are unsystematized in the majority of cases, they are more systematized than in the hebephrenic type and may be quite well systematized at the beginning of the illness.* In American patients they are almost always persecutory in content, especially at the beginning of the illness. Occasionally one finds grandiose delusions from the beginning of the illness. For some undetermined reasons delusions of grandeur are somewhat more frequent in European patients.

Hallucinations, especially auditory, are common. They may, however, be totally absent in cases in which the personality is fairly well preserved and the delusions well systematized. The progression of the illness may be rapid and lead to advanced regression in a short period of time; as a rule, however, the majority of paranoid patients regress less rapidly than the other types, and many of them remain indefinitely at a stage of illness which is not much advanced and may be called the first or primary stage (see later in this chapter). Paranoid patients remain in better contact with the environment and may adjust better to hospital routine. Often their activities can be channeled into useful work. On the other hand, their suspiciousness, ideas of reference, and delusions may make them antagonistic, rebellious, and even violent. Escapes from hospital and homicidal impulses, at times successful, are more common in this group.

*Case 1*

George is a 22-year-old man, the second of two siblings in a middle-class family. Although described as high-strung throughout his life, he never showed gross abnormalities of behavior. During college, however, he found the scholastic work increasingly hard. He finally decided to quit school and accepted a job as a salesman, but found that this occupation too was not satisfactory. He became increasingly preoccupied with certain thoughts. On hearing the word "homo," he understood "homo"; if he heard the word "fair," he felt "fairy" was the word really meant. He became more and more convinced that people thought he was homosexual. When he saw groups of people in his neighborhood he was sure that they were talking about him. He often "heard" them talking about him and making accusations. He became more and more preoccupied, upset, unable to attend to his work. He became somewhat neglectful of his appearance, oblivious of the many usual aspects of life, and more and more involved in thoughts of being accused, spied on, spoken of, ridiculed. In a few weeks it became impossible for him to hold his job and he quit voluntarily. A few days later he became increasingly restless. The psychiatrist who was consulted recommended hospitalization.

### Hebephrenic Type

The hebephrenic type of schizophrenia is probably the most difficult to define and to diagnose. At times the only difference between this and the paranoid type seems to consist in a more rapid disintegration.

The content of thought is characterized by many delusions which are poorly systematized and poorly rationalized. Grandiose delusions are more common than in the paranoid type. Also much more common are hypochondriacal ideas, preoccupations with the body image, and kinesthetic delusions. It is not rare to find a patient who thinks that he has lost his bowels or that his heart has changed place, his brain has melted, etc. Hallucinations are common and, more frequently than in the paranoid type, are pleasing in content.

The mood may be slightly depressed; oftener it is one of apathy and detachment, interrupted now and then by an apparently humorous or jocular attitude. The patient often smiles in situations which seem completely inappropriate. For instance, a question may evoke an incongruous smile instead of a verbal answer.

* Delusions are called systematized when an attempt is made by the patient not to accept them as unrelated beliefs, but to rationalize them, or to explain them more or less logically with the rest of his life, or with other complexes.

Downloaded from www.dbraulibrary.org.in

Language disorders are prominent, especially in cases of rapid regression. Word-salad, clang associations, neologisms are very common.

The dilapidation of personality is soon evident. The neglect of personal habits becomes more pronounced and the patient has to be taken care of.

The prognosis for these cases used to be very unfavorable, as the patient used to sink into an advanced stage of personality disintegration. Today, however, a form of combined treatment succeeds in arresting and recovering many cases.

*Case II*

Gladys is a 17½-year-old white girl, attending high school. Both her parents had psychotic depressions, from which they recovered with the help of shock treatment. Gladys's familial surrounding is characterized by parental conflicts, usually bickering over money matters. Gladys is the third of three children. The other two never received any psychiatric treatment and are described as well adjusted.

Gladys had always done well in school; but, before consultation, she became apprehensive, her marks fell down, and she became afraid to do her home work. On March 7, 1956, she was seen in consultation. She was in a state of great excitement. She said that soon she would have to take the examinations and she was not prepared. She did not know anything. She constantly repeated the same question: "Should I go to school? Shall I pass the examinations?" but no reassurance would help her. She continued to ask the same question incessantly. Apparently she seemed in good contact as she seemed alert and emotionally alive; actually, nothing that the examiner said registered. No delusions or hallucinations were elicited.

During the night, however, Gladys became more excited, expressed suicidal ideas, and was hospitalized. At the time of her admission she was extremely confused, hyperactive, and resistive. At times, when she was asked a question, she seemed unable to speak spontaneously, but would occasionally utter small whimpering sounds, moving her lips as if to pronounce words but being unable to do so.

The second day after her admission she began to masturbate in the presence of the other patients and also to pick at the skin of her face. She was restless, agitated, and screamed a great deal. At other times she sat on one chair in her room and stared vacantly out of the window. She refused to eat and had to be tube-fed. At other times she laughed in an incongruous way, was flighty, talked in an apparently joyful mood, although what she was saying often appeared completely incoherent.

A few weeks later she occasionally expressed the idea that she was in a concentration camp where the Russians had allegedly put her. Later, when she was given electric shock, she misidentified one of the nurses who was leaving the room, believing that this nurse was her mother.

It is out of place to describe here accurately all the sequences of her behavior. It is enough to say that the members of the staff thought she was not suitable for psychotherapy. She was given a course of electric shock and then one of insulin, but there was no improvement in her condition. On the contrary, she seemed to regress rapidly. In August she was treated with large doses of Thorazine. She became more accessible and responsive to psychotherapy. In September she left the hospital, apparently free of the serious symptoms. She remained, however, somewhat flighty and tending to joke in a rather inappropriate way. Since then she has been undergoing psychotherapy. There has been a gradual, slow improvement.

### CATATONIC TYPE

Catatonic schizophrenia, more than any other type, presents characteristics of its own.

After a certain period of excitement, which may even be absent in many cases and which is characterized by agitated, apparently aimless behavior, the patient slows down, reaching sooner or later a state at times of almost complete immobility. The patient may become so inactive as to be unable to move around and take care of his physical needs and must be confined in bed (*catatonic stupor*). The patient in this condition cannot dress or undress himself, does not have the initiative to feed himself in the presence of food or to talk in the presence of other people, even if questions are asked of him. He seems completely paralyzed. At other times, the patient is not so intensely affected, but his activities are still reduced to a minimum. He is not

Downloaded from www.pbookshop.com

really paralyzed. What is disturbed is his faculty to will. He cannot will and therefore cannot will to move. At times he is very obedient and suggestible, because he follows the will of someone else. For instance, if a patient is told, "Show me your tongue, I want to prick it with a pin," the patient may obligingly comply. The examiner may put the body of the patient in the most awkward positions, and the patient will remain in those positions for hours. This is the phenomenon of *flexibilitas cerea* (waxy flexibility). At other times the patient puts himself in an awkward or statuesque position and remains in that position until he is put to bed, to resume the same position the following day. A phenomenon that seems opposite to this suggestibility but is instead related to it is *negativism*. Instead of doing what he is requested to do, the patient does the opposite. For instance, if he is told to show the tongue, he closes the mouth tightly or turns the face away. If he is told to stand, he assumes a reclining position, etc. In many cases a few activities remain, but they are carried out in a routine, stereotyped manner. Any spontaneous or new activity is abolished.

Delusions and hallucinations are present in many cases. They cannot be elicited, however, because the patient cannot communicate to the examiner until he improves. Often they are of a general and cosmic quality. "The world is being destroyed." Attempts to talk to the patient often elicit other symptoms. Echolalia is prominent—that is, instead of answering the questions, the patient repeats the questions. At other times the answers are monosyllabic; at still other times neologisms are numerous. The handwriting manifests a peculiarity of style which is even more pronounced than in other types of schizophrenia. The general behavior is characterized by mannerisms, grimaces, and bizarre acts.

*Case III*

Anthony is a 24-year-old male who, in the past few weeks, had been brooding excessively about his life. He did not feel well but did not know how to explain his malaise. No hallucinations or delusions were elicited. There was an urge to make contact with people, while on the ward, but there was also a sense of disappointment. One morning a few days after his arrival, he was found in a statuesque position, with his legs contorted in an awkward position. Attempts to talk to him were of no avail. He acted as if he could not hear or see anything. His face was completely deprived of any mimic play and did not reveal any emotion. A few days later he could talk a little bit, but in an echolalic way. For instance, to the question, "What is your name?" he would reply, "What is your name?" He had to be taken care of, and spoon-feeding was necessary. Total remission from this episode was obtained with electric shock treatment.

SIMPLE TYPE

Simple schizophrenia almost never occurs in an acute manner. The beginning is slow, insidious, and generally goes back to a time preceding puberty. The major changes, however, occur after puberty, when the family realizes that the patient is not up to par in spite of the expectations that at an earlier age he had evoked in people. The patient becomes quite inactive and limits his life as much as he can. He refuses to go out, to go to school or to work, and gradually his life becomes very restricted. When he talks there is no looseness of ideas or illogical sequence of thought, as in other forms of schizophrenia, but rather *poverty of thought*. The patient is able to talk only about a few concrete things, abstract notions being eliminated. Careful examination of thought processes reveals an impairment of abstract thinking.

Hallucinations, delusions, ideas of reference, and other obvious symptoms are absent. In spite of the absence of these obvious symptoms, the behavior of the patient remains odd, inappropriate, insufficient to the demands of life, and his affect is inadequate. Unless hospitalized or successfully treated, the patients remain a burden to their families. When no family is available, they end up by becoming hoboes, prostitutes, men at the services of gangsters, etc.

*Case IV*

Mary is the older of two sisters. The father was an alcoholic who died when the patient was a child; the mother died when the two daughters were in their teens. Although Mary had never

Downloaded from www.studiesin.org.in

appeared very bright, her inadequacies became more evident after the death of her mother. At that time she became even more dependent on her sister. Mary had several jobs, but could not fulfill them adequately. She was repeatedly fired, or she herself left the job because she felt the work was "too much for her." She refused the few invitations to go out with young men and restricted her life to a minimum. Finally it was agreed that her sister would go to work and she would attend to the care of the household. But even that became "too much for her." She would remain idle for hours and hours and showed no interest in anything. She had to be told what to do, even in relation to her personal needs. Finally the sister decided to hospitalize her. At admission she appeared neat and tidy and able to take care of herself, and accepted hospitalization without protest. On the contrary, it was a relief for her to be away from the world, where she had to make so many efforts. No hallucinations, delusions, or ideas of reference were elicited. Her life became reduced to a few stereotyped acts. The nurses and attendants could not persuade her to do more than a minimum amount of work on the ward. When her sister visited her in the hospital she seemed to sink into a mild state of depression.

### CHANGING ASPECTS OF SCHIZOPHRENIA

In the last few years many clinicians have noticed some changes in the symptomatology of schizophrenia, changes in the incidence of the various types and in the intensity of the symptoms. As far as the intensity of the symptoms is concerned, many psychiatrists, especially those who are in private practice and do not work in psychiatric hospitals, report that they see many patients with symptomatology so mild as not to require hospitalization. These are not latent cases in the sense described by Bleuler, but patients who are actively psychotic, although their symptoms are few and not pronounced. It is difficult to determine statistically whether this increase in mild cases is more apparent than real. The explanation that comes to mind is that today, with the greater understanding of psychiatry and with increased psychiatric facilities, many patients who, because of the relative nonseverity of their symptoms would not have been recognized, are easily diagnosed now. Whether the increase in these mild or oligosymptomatic cases is real or apparent, the fact remains that the psychiatrist in private practice today is bound to see a large number of them and therefore must be able to recognize them.

In addition to the change in the intensity of symptoms, there is also a quantitative change in the percentage of the various types of schizophrenia, a change which is apparent especially to psychiatrists who are associated with hospitals. Until about two decades ago, there was not too marked difference in the incidence of the hebephrenic, paranoid, and catatonic forms (with the simple type trailing); now many admitting psychiatrists feel that the paranoid type is by far the most common.

It is relatively easy to understand the decline in the number of hebephrenics, as possibly many cases previously diagnosed as hebephrenic were paranoid with rapid disintegration. Timely intervention would have arrested them at a paranoid level. More difficult to explain is the decline of full-fledged catatonic patients, who, until fifteen years ago, were much more common. From colleagues working in small hospitals we hear that the admission of a catatonic patient with typical symptoms, such as stupor and waxy flexibility, has become almost a rarity.

### Oligosymptomatic Forms of Schizophrenia

It must be understood that when we refer to mild or oligosymptomatic cases, we are not speaking about the borderline cases described in Chapter 21. A borderline case, as we generally use this term today, is that of a patient who, although presenting a symptomatology so serious as to be classified between the neuroses and the psychoses, generally is not psychotic, does not act as a psychotic, and most probably will never become fully psychotic. The mild cases which are going to be described are considered psychotic.

#### *Paranoid Type*

No definite delusions or hallucinations are found in the oligosymptomatic form of the para-

Downloaded from www.chiranjibrary.org.in

noid type. The patient, however, is suspicious and antagonistic and a *paranoid flavor* characterizes his conversation. Often his parents, siblings, or in-laws are the object of his distortions in thinking. The aim of these relatives or other people is allegedly that of hurting the patient, of spoiling his reputation, etc. Even what the therapist says to the patient is misinterpreted, as the patient often clearly gives it a special twist. This tendency to misinterpret, at first limited to dealings with relatives, later spreads to employers and co-workers, so that finally it becomes impossible for the patient to maintain his occupation. If the patient is not treated, full-fledged psychotic episodes, with definite delusions and hallucinations, may occur.

*Hebephrenic Type*

In the oligosymptomatic form of the hebephrenic type, the patient complains a lot about physical ailments. Often he attributes the responsibility for his troubles to previous physicians who allegedly have treated him badly. At times there is an incongruous euphoria. Odd ideas, either of reference or semi-grandiose, creep in. There is an apparent lack of anxiety.

*Catatonic Type*

There are no motor disorders in the oligosymptomatic form of the catatonic type, but the activities of the patient are reduced to a minimum. It takes the patient an enormous amount of time to do simple things. To get dressed or undressed may require two or three hours, and it becomes a real ordeal. The patient refuses to get out of the house. When he goes out he arrives extremely late. Occasionally, almost catatonic episodes occur. There is no catatonic immobility but the patient is confined to bed for several days, refusing to get up in spite of absence of physical illness. The patient may improve completely, only to develop a full catatonic attack a few years later.

*Simple Type*

It is often difficult to distinguish the oligosymptomatic form of the simple type from that of the mild catatonic type. The patient seems to have more anxiety than the classical form of the simple type. Like the catatonic, he does not want to go out of the house or seek employment, and tells you that he "cannot do it." Activities are reduced to a minimum and are extremely slow. The sleep rhythm is altered. Often he sleeps during the day and stays up until very late at night or the early part of the morning. In quite a few cases he becomes overconcerned with his appearance, or his weight. He may go into periodic eating sprees which alternate with periods of almost total starvation.

It is often difficult to determine to which one of the classical types of schizophrenia these mild cases belong. Often one gets the impression that they are mixed or undifferentiated and that the effort made to recognize in them a particular type is mostly due to our desire to adhere to the kraepelinian terminology.

A type of schizophrenia which is increasingly recognized by many practictioners is that described by Hoch and Polatin in 1949[86] as *pseudoneurotic schizophrenia*. Under this name the authors described a syndrome whose symptoms are not usually considered characteristic of schizophrenia. The diagnosis is made on the subjective evaluation of the constellation of symptoms. The patients present "pan-anxiety" and "pan-neurosis." That is, "an all-pervading anxiety structure . . . does not leave any life-approach of the person free from tension." By "pan-neurosis," the authors mean that the patients do not have only one or two neurotic manifestations, but that "all symptoms known in neurotic illness are often present at the same time." Gross hysterical mechanisms, vegetative dysfunctions such as poor sleep, anorexia, vomiting and palpitations, phobias, obsessions, and compulsions may all be present. The neurotic manifestations shift constantly but are never completely absent. "A considerable number of these patients have short psychotic episodes or later become frankly schizophrenic."

### Atypical Forms of Schizophrenia

In addition to the types of schizophrenia described in classical psychiatry, several other forms which are atypical or rare, have been individualized.

The most important of this atypical form is perhaps *childhood schizophrenia*, first described by DeSanctis under the name Dementia Praecocissima,[51] which has recently received much consideration in the American literature.

Downloaded from www.darolmarg.ir

Since the topic of childhood schizophrenia is presented in Chapter 41, no report of it will be made here.

*Schizoaffective psychoses* are conditions characterized by recurring episodes which present a mixture of schizophrenic and manic-depressive symptomatology. For instance, the patient may present ideational content with delusions, ideas of reference, and hallucinations which seem typically schizophrenic, and yet at the same time show other symptoms such as a mood of depression accompanied by ideas of guilt and self-accusation or a mood of elation with a grandiose overtone. Although at the beginning of the illness the manic-depressive traits appear the predominant ones, in the long run the symptomatology assumes a typical schizophrenic aspect, indistinguishable from the classic types of schizophrenia. If the illness is characterized by several psychotic episodes, generally every successive attack is more and more typically schizophrenic and less and less manic-depressive.

*Schizophrenia in old age* is a condition which is accepted by a few, denied by many. At times we see a paranoid condition in old people which resembles a schizophrenic reaction. The more maladjusted the personality of the patient before the onset of the psychosis, the more schizophrenic or schizophreniclike is the condition. The majority of psychiatrists classify these cases under the heading of *paranoid type of senile psychosis.* In other cases, which present many bizarre delusions of grandeur and hallucinations which are "voices of comfort" to the patient, we must probably deal with latent cases of schizophrenia, of long duration, which become manifest when old age occurs.

*Schizophrenia accompanying other diseases* presents diagnostic problems. Not infrequently we see schizophrenic symptomatologies with patients presenting the serology of general paresis, or epilepsy, Huntington's chorea, postencephalitic conditions, multiple sclerosis, pernicious anemia with nervous complications, cerebellar atrophies, etc. Although in some of these cases the crippling effects of the organic disease may have increased the anxiety of the patient and released a potential schizophrenia, most psychiatrists feel that in the majority of these cases an organic diagnosis should be preferred.

*Propfschizophrenia* is a form occurring in a small minority of mental defectives, generally at the moron or borderline level. It is characterized by paranoid episodes with delusions and hallucinations, which may be followed by slow regression.

*Folie à deux* and *à trois* will be discussed in Chap. 25.

## Course

Schizophrenia distinguishes itself from any other known pathological condition by the great variability of its course. Some patients recover from an acute attack even in a few hours or days, others in several months, others remain sick for the rest of their lives. Those who remain sick may show an arrest of the disorder at a certain stage, whereas others undergo a slow but progressive regression.

This author feels that, in addition to distinguishing schizophrenia from the point of view of types, it is important to differentiate the stages, which he distinguishes thus: the first or initial stage; the second or advanced stage; the third or preterminal stage, and the fourth or terminal stage.[4, 5, 7, 8]

Most of the patients seen by psychiatrists in private practice belong to the first or initial stage. Even if the patients are undergoing a second or third attack, they generally belong in the first stage, as modern types of treatment prevent them from progressing further. After the third attack the patient tends to advance rapidly to subsequent stages. Statistics vary considerably as to the frequency of recurrences.

The first stage of schizophrenia extends from the period when the patient starts to lose contact with reality to the formation of the characteristic symptoms of schizophrenia. The onset may be acute or slow. In acute cases the patient retains great anxiety and restlessness. He seems either to fight his illness and want to return to reality or to fight the external world in an attempt to vindicate his symptoms. There is great variation of symptoms in this period, except in case of the catatonic patient, who may exhibit all the catatonic

Downloaded from www.brainpan.org.in

characteristics from the very beginning. Some catatonic patients, however, may change into a paranoid picture and vice versa.

This first stage is characterized by the presence of anxiety, and lack of a certain equilibrium, in spite of the presence of typical psychotic symptoms. We may distinguish in it three substages:

1. A substage of *panic*—when the patient starts to perceive things in a different way, is frightened on account of it, appears confused, and does not know how to explain "the strange things which are happening."

2. A substage of *psychotic insight*—when he succeeds in "putting things together." By devising a pathological way of seeing reality, he is able to explain his abnormal experiences. The phenomenon is called "insight" because the patient finally sees meaning and relations in his experiences, but the insight is psychotic because founded on mental processes which occur only in a state of psychosis.

3. A substage of *multiplication of symptoms*—when symptoms become more and more numerous as the patient vainly attempts to solve his conflicts and remove his anxiety with them.

The second, or advanced, stage is characterized by an apparent acceptance of the illness. All the classic symptoms are present and they do not seem to bother the patient as much as before. Life has become more and more restricted and lacking spontaneity. Routine and stereotyped behavior are outstanding.

In the third or preterminal stage many symptoms seem to have burned out and the four types of schizophrenia resemble each other so much that it is often difficult to distinguish a paranoid from a catatonic. At this stage primitive habits such as that of hoarding useless objects and of decorating oneself in a bizarre manner are conspicuous.[4,5,7,8] This stage generally occurs from five to fifteen years after the beginning of the illness, but may occur sooner or later.

In the fourth or *terminal* stage the behavior of the patient is even more impulsive and reflexlike. Primitive habits are replaced by others even more primitive. Hoarding of objects is substituted by food grabbing, and later by ingestion of small objects, edible or not (placing-into-mouth reaction).[5,7]

Later, during the fourth stage (although in some cases even at a much earlier one), many patients present what appear to be perceptual alterations. They seem insensitive to pain, temperature, and taste, although they still react to olfactory stimuli. This anesthesia is the cause of many accidents (for instance, burning by sitting too close to a radiator). Although it is pronounced, it may be the result of the fact that the rough sensations are not associated and elaborated to the perceptual level rather than of a definite impairment at the level of sensation.[7]

## *Diagnosis*

Psychodynamic and formal studies, as well as prolonged contacts with patients for psychotherapy, make the diagnosis easier, in the great majority of cases, than the diagnostic studies used in the past.

It is true that there is a group of cases, called latent, borderline, character disorders, etc., where the diagnosis is questionable, but here the diagnosis is apt to be the result of the nosologic concepts held by the psychiatrists rather than of the symptomatology of the patient. Furthermore, in these borderline areas the diagnosis is really less important than the dynamic understanding of the case.

The first rule to be adopted in attempting to diagnose schizophrenia is that an individual symptom or a few symptoms should not be considered absolute proof of the condition, but that the constellation of symptoms should be evaluated in its entirety.

Schizophrenia is at times confused with functional as well as with organic conditions. Of the former, it used to be confused with hysteria, when this neurosis was much more common than it is now. Hysterical attacks occur more suddenly in young adults who generally present an extrovert personality, and are characterized by conversion syndromes. The symptomatology is easily influenced by certain persons in the immediate environment and responds easily to hypnosis.

Not infrequently manic-depressive psychosis

Downloaded from www.dtic.mil/library.org.in

is diagnosed because the symptoms of that psychosis may also appear in schizophrenia. They are, however, eventually replaced by schizophrenic symptoms, and in a second attack the diagnosis is easy. (For differential diagnosis between catatonic stupor and excitement and depressed stupor and manic excitement, see Chapter 22.) The same consideration holds true for psychopathic conditions. At times, early schizophrenics are diagnosed as psychopaths. In patients who eventually reveal themselves as schizophrenic, the apparent psychopathic acts are more bizarre and the general detachment from reality more pronounced.

Organic conditions which may be confused with schizophrenia are the following:

General paresis, but history of syphilis and serological and spinal fluid examinations leads to the diagnosis.

Epilepsy, especially psychomotor. Some schizophrenic attacks seem epileptic, but are generally not accompanied by loss of consciousness. Electroencephalogram generally leads to the diagnosis.

Brain tumors, especially of the prefrontal lobes, and early arteriosclerotic and presenile psychoses may be confused, particularly when at first they manifest themselves with paranoid symptoms. In these cases, however, X-ray, electroencephalogram, pneomoencephalogram, as well as the marked change of the sensorium, lead to the diagnosis. Huntington's chorea is occasionally mistaken for schizophrenia (see Chapter 61).

Mental deficiency may be mistaken for the simple type of schizophrenia, and vice versa. Generally, in mental deficiency the defect was apparent in childhood whereas in the simple type it manifested itself at or after puberty.

Alcoholic hallucinations must be considered every time there is a history of alcoholic addiction.

The catatonic type of schizophrenia may at times be confused with a rare syndrome called akinetic mutism, first described by Cairns[39] and associates in patients having lesions near the third ventricle. These patients cannot move or talk, but generally have other neurological symptoms and are affected by hypersomnia.

## ¶ The Psychodynamics of Schizophrenia

What was described in the previous section is only the last and most apparent phase of a much-troubled life history. Psychodynamic studies reveal that the road leading to schizophrenia has its beginning in the remote past of the patient, perhaps shortly after his birth. Some authors push the beginning further back, to the intrauterine life.[63] Others feel that the parental attitudes which are so important in determining the conflicts of the patients have their roots in sociological, historical, and geographical conditions.

It is generally agreed that the psychodynamic studies should include only the psychological life experiences of the patient. Other experiences such as physical illnesses, unless studied in reference to the psychological impact that they have had, cannot be included among the psychodynamic factors.

Although these psychodynamic studies have revealed nothing that can be considered absolutely specific for the life of schizophrenics, we find that certain constellations of circumstances, events, or factors cluster more frequently in the life of schizophrenics than in that of the average individual. We find, thus, that the troubles of the patient start early in childhood.

### *The Family of the Schizophrenic*

One of the first vivid impressions that we get in dealing with patients and their relatives is that the family of the patient is not a happy one, or at least was not so in the formative years of the patient. The unhappiness, although aggravated at times by realistic situations such as poverty and physical illness, was as a rule determined by psychological factors, predominantly by the unhappy marriage of the parents. The marriage was unhappy not only because of the character incompatibility and

Downloaded from www.PsychiatryOnline.com

personality difficulties of the parents but also because such difficulties, instead of being compensated for or countered by less destructive defenses, were enormously aggravated by the process of living together. This atmosphere of unhappiness and tension, although all-pervading and pronounced, in many cases is not apparent to the casual observer, as an attempt is made by all concerned to conceal it not only from the external world but also from themselves. At times it is almost totally repressed and replaced by psychological insensitivity.

Theodore Lidz has made intensive studies of the family of the schizophrenic and, in collaboration with his associates, has written a number of papers which study such families from every angle.[111-115]

Lidz and his associates found that the role of each spouse in the family cannot be well established and that no attempt is made by them to complement or to help each other. There is no possibility of getting together, of reciprocal understanding and cooperation, no mutual trust, no confidence, but rivalry, undercutting of worth, threat of separation, and enrollment of the children's support against the other. Each partner is disillusioned in the other: the husband sees the wife as a defiant and disregarding person who also fails as a mother. The wife is disappointed because she does not find in her husband the father figure she expected. In this background the family is often split into two factions by the overt *marital schism* of the parents. Generally the children belong to one side of the schism or to the other.

In addition to marital schism Lidz and his associates find "marital skew" a frequent occurrence in the family of schizophrenics. In these skewed marriages, the serious psychopathology of the dominant parent is accepted or shared by the other. This author, too, without using this term, has described several skewed marriages in the families of schizophrenics.[4] He has found that a frequent combination is that of a domineering, nagging, and hostile mother, who gives the child no chance to assert himself, married to a dependent, weak man, too weak to help the child. He found another combination less frequently, but frequently enough: a tyrannical father is married to a weak mother who has solved her problems by unconditionally accepting her husband's rules. These rules do not permit her to give enough love or feeling of acceptance to the child.

Mothers and fathers of schizophrenics have also been studied individually. Many authorities consider the mother the main dynamic factor in the genesis of the child's future psychiatric condition, and have devised the classification "schizophrenogenic mother." She has been described in many ways: overprotective, hostile, overtly or subtly rejecting, overanxious, cold, and distant, etc. In many cases she is found definitely unfit for motherhood. She is unable to give herself to the baby. Sometimes she tries, but does not know how. The author has found that in the majority of cases the mother was either extremely rejecting in the tender years of the patient, or extremely anxious.[6, 11]

The father of the schizophrenic patient was also studied by Lidz and his associates.[114] Whereas previous authors had emphasized the weakness, aloofness, and ineffectiveness of the father in the paternal role, Lidz and associates describe him as insecure in his masculinity, in need of great admiration in order to bolster his shaky self-esteem, not infrequently paranoid or given to paranoidlike irrational behavior, and equating his wife in imperviousness to the feelings and needs of others.

Summarizing these studies, and in particular Lidz's, one may conclude that although nothing has been found which is specific for the families of schizophrenics, presumptive evidence indicates that a tremendous amount of conflict, tension, and anxiety exists and has always existed in these families. It does not matter whether the parents are overtly rejecting or overanxious or irrational and paranoid: the result is the same. They offer to the patient an environment saturated with anxiety, an environment where his attempts to grow psychologically will be thwarted.

Before leaving this topic, however, we must consider two facts to which Lidz and his asso-

Downloaded from www.pdfbooksfree.pk

ciates have given particular importance: the first is that the family operates as a destructive agent not only in the first two or three years of life, but also afterward. The second is that the irrationality of the parents is often transmitted directly to the patient. In other words, some delusional or quasi-delusional conceptions of the parents are accepted by the patients, without further elaboration, just as happens in *folie à deux*. As a matter of fact Lidz speaks of a *folie à famille* in the family of the schizophrenic.

To this writer it seems that to a large extent Lidz and his collaborators are right. Many therapists (Rosen,[148] Benedetti[17]) reached similar conclusions. For instance, a patient kept hearing a voice telling her that she was a prostitute. But she had really been accused by her mother of being a prostitute, because she was wearing lipstick and had been kissed by a boy. We must remember, however, that in the majority of cases the irrationality is not transmitted with such simple mechanisms. The irrationality of the patient, although stemming from that of the parent, undergoes extensive autistic metamorphoses.

## *Childhood*

It is necessary to discuss some phases of normal psychic development in order to understand better what happens in the person who is likely to become schizophrenic. The writings of Sullivan,[161] Buber,[33] George Mead,[121] and a few others have helped the author to formulate these concepts.

The newborn human being needs other members of his own species in order to survive and to grow physically and psychologically. This growth will proceed in accordance with its potentialities if the child, with the help of others, obtains a state of *satisfaction* and a state of *security*.[160] A state of satisfaction of the physical needs, such as food, sleep, rest, warmth, and contact with the body of the mother, is enough for the growth of lower species, and for the growth of the human being in the first months of life. But, in order to continue to grow normally after the first twelve months, the human being needs, in addition to a state of satisfaction, a state of security.

Before the others acquire a "significant" or symbolic importance, the life of the child is almost entirely governed by reflexes, conditioned and unconditioned, and by autonomous mechanisms.

Things are taken for granted by the child; they are expected to occur as they have occurred before. After a certain stimulus, hunger for instance, a subsequent act—the appearance of the mother's breast—is expected. Later the child comes to feel that all things in life are due to others or depend on others. It is up to mother to give him the breast, to keep him on her lap, to fondle him. The child learns to see everything in a teleologic way—everything depends on the will or actions of others. But together with the feeling that everything depends on others there is also the feeling that people will do these wonderful things. In other words, the child expects these wonderful things to happen; he trusts adults. At first, of course, these feelings of the child are vague, indefinite. Since the child is deprived of the use of abstract words to describe these phenomena, his expression of these feelings remains at a primitive level. We may describe them as diffuse feelings, postural attitudes, physiological preparation for what is expected, nonverbal symbolism, and so forth.

Later, the child also expects approval from others. That is, the child expects the significant adults to expect something of him; the child *trusts* that the adults will *trust* him. In other words, there is a reciprocal trust that things are going to be well, that the child will be capable of growing up to be a healthy and mature man. The child perceives this faith of the mother and accepts it, just as he used to accept the primitive responses to the usual stimuli. He finally assimilates the trust of the significant adults, and he *trusts* himself.[11] Thus, things will no longer depend exclusively on others, but also on himself.

This feeling of trust in oneself originates to a large extent from the approval that the others had for the child, or, as Sullivan says, from reflected approvals.[160] This favorable expectancy, which at first is limited to the immediate future, becomes extended to the immediate

Downloaded from www.dbraulibrary.org.in

contingencies of life and then expands into a feeling of favorable anticipation as far as a more or less distant future is concerned. A basic optimism, founded on basic trust, is thus originated. Security consists of these feelings.

This atmosphere, first of satisfaction, and then of security, facilitates the introjection in the child of the symbolic world of the others. It is this introjection that actually permits the emergence and the growth of the self, especially the introjection of the attitudes, feelings, verbal symbolisms, etc., emanating from the mother.

Using Buber's useful terminology and conceptions, we may say that an I-Thou relationship exists. Psychologically, this means that without others and trust in them there would be no I, no development of the self. Buber's "I-Thou" expression corresponds approximately to Sullivan's "me-you" expression.

The development of the self, emerging by the incorporation of the Thou while a state of satisfaction and security exists, permits the child to attain a stable self-image. The self-image consists of (1) the body-image, (2) self-identity, and (3) self-esteem. As to the body-image, the child will have a realistic appraisal of himself and will be able to identify with his own sex. As to self-identity, the child will become aware of his role in the family and in society. As to self-esteem, he will trust himself and will have a sense of confidence and optimism.

It is obvious that in the families of schizophrenics this normal development cannot take place. We find, instead of a state of satisfaction and security, an atmosphere of anxiety. Anxiety occurs in absence of a state of satisfaction or security or both. The anxiety due to lack of satisfaction would not alone lead to schizophrenia, because it is based on mechanisms more primitive than those involved in the pathogenesis of this disorder. Some schizophrenics were not deprived of satisfaction during the first year of life, but of security later, for many parents are capable of functioning as such when the child is a baby, who has not yet developed a will of his own and is completely dependent. In many other cases, however, the patient was deprived of both his early need for satisfaction and his later need for security.

In the families of schizophrenics there is at first no emotional detachment: all are involved with each other without helping each other, but the little child cannot entirely accept the others, or the Thou, because the Thou is too threatening, is a carrier of too much anxiety. This is the beginning of the schizophrenic cleavage, this never-complete acceptance of the Thou, or the social self, of that part of the self that originates from others. This Thou tends to remain unintegrated or to become dissociated, like a foreign body which is easily externalized in forms of projection and hallucination.

These difficulties in accepting the Thou are manifested by the reluctance of these children to acquire the language and ways of the surrounding adults and by the emergence of such autistic ways and expressions as neologisms. Autistic tendencies exist even in normal children to a minimum degree, but they are more pronounced in pathological conditions—that is, when the child is afraid of the first interpersonal relations. In some cases autistic manifestations become so pronounced as to offer the picture of childhood schizophrenia or of "early infantile autism," as described by Kanner.[100,101] In most cases, however, even of preschizophrenics, these autistic tendencies are repressed and the individual acquires the symbols of the others, but a propensity to lose them and to return to one's private autistic ways will persist.

A second characteristic in the childhood of preschizophrenics, found from the second to the fifth year of life, is a certain inconsistency in what is repressed from consciousness. To use Sullivan's terminology, the "not-me" threatens to come back to awareness, as the normal mechanism of removing unpleasant things from consciousness seems to be less efficient in these children. At times the child succeeds in repressing the bad images that he forms of the parents, especially of the mother. But these repressed images tend to become conscious again or to be transformed into symbolic forms later on in life. In a minority of cases, the bad image of the mother is totally repressed and replaced by the image of the good, omni-

Downloaded from www.dbraulibrary.org.in

potent mother, corresponding to the image the child had built during babyhood, when his needs *for satisfaction* were well taken care of. This image of the mother, however, predisposes to regression and total dependency. If the child should become a baby again, mother will love and protect him.

The self-image, too, is based on unstable foundations. Because the patient is rejected or feels rejected by both parents and cannot identify with either one, he may have difficulty in identifying with either sex. Later he may not be able to find a complete heterosexual or homosexual integration, and may maintain some unconscious uncertainty about his sexual identification. Being unable to take or to visualize roles, he will have an unstable sense of self-identity, and being unable to introject trust, will have low self-esteem.

Often, the parents perceive that things are not right with the child. This realization increases their anxiety, leading not to constructive remedies, but to increased unhealthiness in the atmosphere. It is a two-way stream, a reverberation of anxiety from the parent to the child and from the child to the parent.

Children who are raised in disturbed homes nevertheless succeed in finding "compromises" or remote defenses which permit them to deal with others. With much more difficulty than normal children, they develop what Sullivan calls enduring patterns of response, or a workable "self-system." There is another important handicap in the formation of the self-system—the inconsistency of the parents. The children cannot learn effective defensive measures, because the unpredictability of the parents may render these defenses inadequate. Nevertheless, some kind of integration occurs even in the most unfavorable situations. We have thus the formation of a personality, although a prepsychotic one. It is in this prepsychotic personality or character structure, rather than in typical psychoneurotic symptoms, that the psychotic-to-be finds his defenses.

Another difficulty in the formation of a workable self-system lies in the presence of the double-bind type of communication, which Bateson[13,14] has found prevalent in preschizophrenics. The future patient receives, predominantly from his mother, a message with two or more logical meanings so related to each other as to induce painful conflict. In the words of Donald Jackson,[91] "It's a sort of game, or gambit, set up by mother so that the child is damned if he does and damned if he doesn't"; he does not know to which of the messages to respond. Bateson gives the following example as an illustration: the child cries and the mother goes to him. Her impulse is to get rid of the child, perhaps to kill him, but her feelings about this impulse compel her to feign acceptance or love. The child perceives the original impulse and the simulated love (the double-bind) and becomes confused and anxious.

Such situations undoubtedly occur oftener in the childhoods of schizophrenics than in the childhoods of other people and may be considered one of the factors responsible for the general state of anxiety that eventually leads to the disorder.[11]

## *The Prepsychotic Personality*

The most common preschizophrenic psychotic personalities are the schizoid and what the author calls the stormy personality.

The schizoid personality is found not only in people who are liable to become schizophrenic but also in neurotics, in people with character disorders, and in a mild form even in people who are considered normal. In the potential schizophrenic, however, it is particularly pronounced and has additional characteristics.

The person who has a schizoid personality appears aloof, detached, less emotional than the average person, and less involved. This emotional detachment originated as a defense against those intense interpersonal relations which occurred in early childhood and which proved destructive. Neurotic children may find defenses in other ways against similar family situations—that is, they may become compliant and submit to the parents unconditionally or become aggressive and fight the parents, and/or develop several neurotic symptoms, such as phobias, compulsions, etc. The person who is becoming schizoid selects instead a pattern similar to the one Horney[87] described as

Downloaded from www.dbraulibrary.org.in

"moving away from people." Emotional detachment will permit the child to be less concerned or to suffer less on account of the bad images he has formed of his parents, and on account of his self-image and of the general difficulties in life.

In addition to this emotional detachment, or rather as a consequence of it, the schizoid person limits his life experiences—his social contacts, his activities, his usual functions. The "object-relationships" are decreased in number.

It is important to remember that this schizoid personality is only a character armor, a defense the patient has evolved in order to fight the anxiety in living. Actually, the schizoid person is very sensitive; it is because of his oversensitivity that he has to defend himself with this character armor. By decreasing his contacts with society, he shows paradoxically how involved he is with society, and how afraid he is of people.

Although this defense may protect the patient so that he can remain schizoid for the rest of his life, it may also become more destructive than constructive unless treatment or other circumstances change his basic attitudes. When the patient had to contend only, or predominantly, with his family, this character armor may have been an adequate defense, but at about the time of puberty the patient discovers that not only his family but the world at large makes demands on him. He feels "pushed around" when environmental forces compel him to do things in spite of his detachment. On the one hand, reduction of his experiences in living has made him unprepared, hesitant, awkward, fearful; on the other, the early unhealthy experiences, which he may have forgotten, continue to alter or to give a particular flavor to his present experiences. Symbolically, and unconsciously, every interpersonal situation is experienced as a reproduction of the old parent-child relationship. As a matter of fact, a compulsive attitude often compels the patient to make this reproduction more like the original situation than it actually is.

At times the patient himself is not satisfied with his withdrawal and harbors strong desires to make excursions into life, but every time he tries, he is burdened with anxiety, is awkward and ineffective, and meets defeat. Defeat in its turn reinforces his inferiority feelings, and a vicious circle is thus perpetuated.

In addition to the schizoid personality, which is well known in the psychiatric literature, the present author has described another type of personality frequently found in persons who are apt to become schizophrenic. This is the *stormy* personality.[4]

People with a stormy personality did not find a defense in emotional detachment or withdrawal. They tried many possible ways; at times extreme submissiveness, at other times aggressiveness, at other times even schizoid detachment. This variety of responses to people was generally determined by the inconsistency of the parents. These patients have developed an even less workable enduring pattern of response than have the schizoids. Their self-images and self-identifications are even more indistinct than those of the schizoid. They keep trying to reach people, but each attempt leads to hurt. In a certain way they are like schizoid persons who have been deprived of the character armor of indifference and therefore experience a tremendous amount of conscious anxiety. They are very vulnerable; every minor event can unchain a crisis. Life is generally a series of crises, frequently precipitated by little happenings which are magnified by the patients, who unconsciously see in them symbolic reproductions of original anxiety-producing situations. At other times the patients seem actively to precipitate crises. They search actively for a meaningful way of living, but the inappropriateness of their actions (bizarre marriages, love affairs, absurd jobs, etc.) lead them to repeated crises. They actually live a stormy life: often they resort to excessive use of drugs and alcohol in order to abate the storms.

### *Precipitating Factors and Psychotic Episodes*

As we have already mentioned, in many cases the prepsychotic personality actually hastens a state of overt disequilibrium. At times a slow change in inner and overt behavior oc-

Downloaded from www.dbraunlibrary.org.in

curs, and we have that deterioration of habits described by Adolf Meyer.[124] At other times, we find that new situations strain the already tenuous defenses of the patient. A new situation, such as a marriage hastily made in spite of psychological unpreparedness, a reunion with a person who elicits great anxiety, a change or a loss of a job, etc., may increase the anxiety and precipitate the actual psychotic episode. In these cases one has the impression that a challenge presents itself which the patient has to accept and which is liable to disrupt the weak defenses. Frequently the birth of a child is such a challenge, precipitating a psychosis in the mother. These psychoses, which Zilboorg[176] called postpartum psychoses, are actually either schizophrenic or manic-depressive attacks, much oftener the former. The woman, as a result of a double identification with her own mother and with the child, experiences a state of panic. At times she would like to leave husband and child, but she cannot; she accepts the challenge, but the challenge proves too much for her and she develops a psychosis.

### *Social Factors*

Sociological, historical, and geographical factors have important connections with the incidence of schizophrenia, but space limitations prevent us from giving an adequate account of this subject. The volumes by Faris and Dunham,[56] Malzberg,[129] Weinberg,[169] and Rose[147] deal more specifically with these subjects. See also Chapter 6 of this book for ecological factors and Chapter 7 for statistical data.

Only fundamental issues will be briefly mentioned here.

Schizophrenia is believed to occur in every country and under any type of culture. Studies of comparative incidence rates, however, are even more difficult in schizophrenia than in other conditions because of the different concepts of schizophrenia adopted in the various schools of psychiatry and because of the large number of mild cases which may or may not be hospitalized, according to such varying factors as opportunity for treatment, therapeutic policies, and attitudes of the community.

Although the following statements have not been established with any scientific or statistical rigor, they are probably accurate:

1. The incidence of schizophrenia seems to have increased everywhere.

2. Schizophrenia occurs more frequently: in urban areas than in rural areas; in industrial areas than in nonindustrial; among foreign-born than among native-born; among immigrants than among people born in the place where they reside; among ethnic minorities than among the majorities.

3. Faris and Dunham[56] found that the rates of schizophrenia vary in different areas of the city. In the center of the city there is the highest incidence, with progressive decline going toward the periphery. They are, however, also the areas where delinquency, crime, prostitution, and drug addiction are more frequent. It would seem thus that schizophrenia tends to occur more frequently in areas of extreme social disorganization.

4. The present writer has the impression (not statistically proved) that, although schizophrenia may occur in every type of society, it tends to be more common in that type of society which Riesman[141] calls other-directed. In other words, it would have a distribution different from that of manic-depressive psychosis. It is much more difficult, however, to prove this impression than it is in the case of manic-depressive psychosis, and the point of view must remain a mere hypothesis.

The recognized importance of these social, and cultural factors does not lessen the importance of personal and dynamic factors. Cultural factors generally affect the individual in two ways:

1. By their impact on the internal organization of the family, on the assignment of specific roles and emotional values and, more specifically, on the determination of most of the methods by which children are raised. For instance, in an industrial, urban society, the woman to some degree loses the traditional role of homemaker; some of her roles may then become uncertain, less satisfactory, especially her role of mother, and she may have more chance of becoming a schizophrenogenic

Downloaded from www.dbraibrary.org.in

mother. The same could be repeated for the father, who loses some of his older prerogatives and roles.

2. By certain specific mores which may inflict adverse psychological pressure on the individual, putting him under greater strain and depleting the psychic reserves which might have compensated for the forces leading to schizophrenia.

## ¶ The Formal Psychological Mechanisms

### *The Progressive Teleologic Regression*

Although the psychogenic conflicts described in the preceding section are necessary in the genesis of schizophrenia and indeed constitute an important part of what has to be studied in its connection, only when they assume a particular form do they constitute the disorder. In other words, what is specific in schizophrenia is not the content or the nature of the conflict, but the *form* the conflict assumes. I call the particular form assumed in schizophrenia, a progressive teleologic regression.

Regression, as the term is used here, is not limited to the Freudian concept of return to earlier levels of adaptation, but includes the Jacksonian concept of return to lower levels of functionality. Whereas the *content* of symptoms may reproduce, in either identical or symbolic fashion, earlier ontogenetic experiences and their derivatives, the *forms* that the symptoms assume may use even mechanisms that appeared in earlier phylogenetic levels. In the schizophrenic's psychological structure, an attempt is made *to fit a higher content into a lower form.*

The second term, teleologic, implies that the regression is purposeful, having the purpose of removing excessive anxiety and re-establishing some kind of psychic equilibrium. This is not a completely vitalistic or animistic concept; it is an additional application of concepts developed in general medicine by Claude Bernard and in psychiatry by Freud. It is not a denial that psychological and psychopathological phenomena are removed from physical determinism (according to which causes have effects, not purposes) but an additional affirmation that the human being, as we are able to understand him today, seems to be subjected to both mechanical and teleologic causalities.[3,4,6] Cybernetics today tries to find a reconciliation between a deterministic and a teleological interpretation of biological phenomena (see Chapter 87).

We visualize the process as an excessive state of anxiety which produces an impairment of the highest mental processes, perhaps a partial functional paralysis. At the same time, the lower levels tend to be disinhibited in accordance with the mechanisms described by Jackson,[1014] and to show manifestations of their own. One possibility now open to the organism is that of maintaining this state of unrest and disequilibrium. The organism will tend, however, to readjust at the re-emerging lower levels, because these lower levels seem to remove part of the conflicts. The lower-level exerts a strong pull, or some "kind of fascination." It is easy for the individual to "succumb to its charm," and to attempt to re-establish an equilibrium at that low level. How much of this is teleologic and how much is deterministic, only further studies will be able to establish.

The regression is *progressive* because, although it is purposeful, with few exceptions it fails of its purpose and tends to repeat itself. An individual who is deprived of the highest level of integration can be compared to an animal experimentally deprived of the cerebral cortex. This animal will not be in a physiological condition comparable to that of an organism of a low species which does not possess the cerebral cortex. Rather, it remains in an abnormal condition, because its whole organism is attuned to the cerebral cortex, or integrated with the functions of the cerebral cortex.

In similar way the schizophrenic patient will *regress to*, but not *integrate at*, a lower level: he will remain disorganized. The organism then defends itself from this disorganization

Downloaded from www.libtibet.com

with further regression to an even lower level. The process repeats itself in a vicious circle that can lead to complete dilapidation.

A limited regression from the highest levels of functionality may be a preserver of normality in sleep, convalescence, neurotic conditions, and some overwhelming circumstances, but it is pathological in schizophrenia because it resorts to mechanisms usually repressed and discordant with the state of normalcy of the individual.

We must now examine the specific aspects of this schizophrenic regression. We shall take into consideration only the fundamental ones: (1) the concretization of the concept; (2) the paleologic way of thinking and related phenomena; (3) the desymbolization and desocialization, and (4) the motor dysfunctions. Actually all these aspects are related and probably different manifestations of the same basic phenomenon, but we shall take them into consideration separately for didactical purposes.

### THE CONCRETIZATION OF THE CONCEPT

The process of concretization may be best illustrated in the paranoid type of schizophrenia.

Immediately prior to the outbreak of the psychosis, the patient experiences feelings of despair and inadequacy and an impression that the whole world is hostile toward him. Some of these feelings are abstract, all-pervading, indefinite, and imperceptible. They represent the culmination of his disastrous life history, particularly in presence of a new challenge with which he knows he cannot cope. After the onset of the psychosis, the indefinite feelings become finite, the imperceptible becomes perceptible, the vague menace becomes a specific threat. It is no longer the whole horrible world which is against him; "they" are against him. It is no longer a feeling of being under scrutiny, under the eyes of the world; no longer a mild sense of suspiciousness toward his unfriendly neighbors. The sense of suspiciousness becomes the conviction that "they" follow him. We have thus a reduction of the conceptual and abstract to the concrete, the perceptual. The "they" is the concretization of feeling; later, "they" are more definitely recognized as F.B.I. agents, neighbors, or other persecutors. A return to a situation similar to that of the childhood, when a few powerful people (members of the family) were responsible for the difficulties of the patient, undergoes a displacement in the attribution of responsibility. In by far the majority, but by no means all of these cases, not the members of the family but other people are considered the wrong-doers.

In different patients we see all the possible transitional stages from abstract feeling to definite perceptions. Some patients say that they have the feeling that people follow and speak about them. Other patients say that they see and hear people following them and talking about them. In the latter the process of concretization of the concept has reached its most advanced stage: that of perceptualization of the concept.

Goldstein[76] was one of the first to see the schizophrenic process as an expression of the concrete attitude (see Chapter 65). According to him, the schizophrenic abandons the realm of the abstract and withdraws into the concrete.

Although Goldstein's conception is extremely useful, I feel that it does not encompass the whole process of concretization of concept. This process involves, in addition to withdrawal from the abstract into the concrete, active concretization. Especially at the beginning of the psychosis, the schizophrenic not only loses the abstract; he transforms the abstract into the concrete.

The patient still experiences the abstract conceptualizations because to some degree they continue to exist for him—the abstract level is impaired but not completely lost. The feelings cannot be sustained or coped with in the impaired abstract level and are immediately channeled into lower levels where they acquire a different representation.

Hallucinations are perhaps the most typical examples of perceptualization of the concept. For example, a patient who, before the onset of the psychosis, had a very low opinion of himself, especially on account of his homosexual desires, now has an olfactory hallucina-

Downloaded from www.psychlibrary.org

tion. He smells an awful odor emanating from his body. Here again we have a perceptualization of the feeling he has toward himself: he is a rotten character, he stinks.

In the intermediary stages between the abstract level and the perceptualization of the concept, the patient undergoes peculiar experiences. At times, but especially at the beginning of the first psychotic attack, these subjective experiences are felt as a struggle, "a fight against a tendency to give in." The patient tries to resist the temptation of accepting this limited, perceptual world and is afraid that sooner or later he will succumb. Succumbing would somewhat relieve a state of confusion and panic.

At other times the opposite process occurs: the patient searches actively for this corroborative perceptual evidence.

In patients who have auditory hallucinations and, through psychotherapy, have acquired some understanding of their symptoms, three stages could be recognized in the hallucinatory experience: First, the patient is in a state of anxiety. (A situation that would not arouse too much anxiety in an ordinary person has acquired a particular meaning for the patient and provokes great turmoil—for instance, returning to a lonely home from a party, after having vainly hoped for a date.) Second, the patient puts himself in the *"listening attitude."* He expects to hear something derogatory. (This would be the evidence he searches for.) For instance, he must try to listen to what the neighbors say. Third, the patient actually hears; he *hallucinates*.

Most patients are aware only of the third stage. As a rule, only during intense psychotherapy do they acquire awareness of the first two stages.

Let us now examine hallucinations in their three important characteristics: (1) perceptualization of the concept; (2) projection to the external world of the inner experience; and (3) the extremely difficult corrigibility of the experience.

The perceptualization of the concept is an extreme degree of concretization. It is not the only type of perceptualization of concept, dreaming being another important one. In dreams, thoughts acquire the form of visual perceptions. In hallucinations, they acquire the forms of many types, but predominantly of the auditory. Thoughts, which ordinarily consist of images (verbal, visual, auditory, etc.), use a lower mechanism—the mechanism of perception.

The second important characteristic of hallucination, projection to the external world of the inner subjective experience, also exists in dreams. The dreamer believes that the action of the dream actually takes place in the external world. This characteristic may be easily understood if we remember that this characteristic is also present in every normal perception. If I see an object in front of me, the perception of that object occurs inside me, around my calcarine fissure, but my organism projects this perception again into the external world. Thus, in hallucination, the most important fact is not that the subjective experience is externalized, because this externalization or projection occurs in every perception, but that an abstract thought has been perceptualized and follows the law of perception instead of those of thinking.

In a previous publication I called the third characteristic the incorrigibility of the experience. I think now that the term difficult corrigibility is more appropriate, because patients in psychotherapy learn to recognize and correct the hallucinatory experiences, although with great difficulty. In the majority of patients, however, hallucinations are not corrected. The patient not only has the dynamic wish to believe the content of the hallucination but also the need to interpret experiences in accordance with the levels of mentality to which he regresses.

The concretization and perceptualization of the concept (for instance, in the case of the patient who smells an awful odor emanating from his body) may seem metaphorical and symbolic. Let us remember, however, that these experiences are metaphorical and symbolic only for us, who retain our usual way of thinking or at least the possibility of shifting from one to another of different ways of

Digitized for http://www.cirnfu.org.in

thinking. But these experiences are not metaphorical for the patient. They are intensely lived; they are his reality.

### PALEOLOGIC THOUGHT

The patient struggling in his attempts to resist the "fascination" of the lower levels is in a very unpleasant state of mental confusion. Often, in this state, he suddenly experiences what has already been described as "psychotic insight." For instance, given a sequence of events such as noticing, during the course of a few days, that several people glance at him and then hearing his doorbell ring twice in an evening, the patient will suddenly realize that these are not coincidences—there is a relation between the events; agents of the F.B.I. are watching him in order to prove that he is a spy.

If the patient were resorting only to that process called concretization of the concept, he would not begin to use this method of interpretation. But here he regresses to a lower level of rationality; he no longer operates with Aristotelian logic but rather uses a logic *sui generis* which has been called paleologic. Paleologic is, to a great extent, based on a principle enunciated by Von Domarus.[166, 167] This author, as a result of his studies on schizophrenia, formulated a principle which, in slightly modified form, is as follows: "*Whereas the normal person accepts identity only upon the basis of identical subjects, the paleologician accepts identity based upon identical predicates.*"

For instance, if a normal man is told, "All men are mortal; Socrates is a man," this normal person will be able to conclude, "Socrates is mortal." This conclusion is valid because the subject of the major premise (all men) contains the subject of the minor premise (Socrates). If, on the other hand, a schizophrenic happens to think: "The President of the United States is a person who was born in the United States; John Doe is a person who was born in the United States," in certain circumstances he may conclude, "John Doe is the President of the United States." This conclusion, which to a normal person appears delusional, is reached because the identity of the predicate of the two premises "a person who was born in the United States" makes the schizophrenic accept the identity of the subjects, "the President of the United States" and "John Doe." Of course, two additional factors permit him to reach such a conclusion: first, the over-all state of anxiety makes the use of the highest levels of mentation less efficient; second, he has an emotional need to believe that John Doe is the President of the United States, a need which will arouse additional anxiety if it is not satisfied. It is not difficult, then, to see how, in a teleologic way, the patient grasps the re-emerging paleologic level in order to reach the conclusion that he desires.

It must be emphasized that the schizophrenic does not necessarily adopt paleologic for all or even most of his thinking processes. Especially in the early stages of the illness, paleologic thought is found only when it involves the complexes of the patient. Later, however, it tends to extend to other areas. In this early selectivity for the emotionally determined complexes, paleologic thinking differs from organically determined mechanisms which apply indiscriminately to any content. In the light of Von Domarus's principle,[4, 7, 8] even bizarre and complex schizophrenic delusions can be interpreted.

Occasionally, the schizophrenic has insight into his mode of thinking and makes his deductions consciously. Usually, however, this process is as automatic as the normal person's application of Aristotelian logic.

The application of Von Domarus's principle extends far beyond schizophrenia. The whole phenomenon of Freudian symbolism may be interpreted from a formal point of view as an application of this type of logic. The symbol is not only something which stands for something else but also something which has at least a common characteristic (predicate) with the thing it symbolizes. Freud demonstrated that a person or object A, having certain characteristics of B (that is, a common predicate with B), may appear in dreams as B or a composite of A and B. The wife of a dreamer may appear in a dream as having the physical appearance of the dreamer's boss. The two persons are identified in the dream because the

Downloaded from www.dbraulibrary.org.in

dreamer is concerned with a characteristic common to them (domineering attitude).

Of course, we do not attribute to the word predicate only the meaning usually given to it in logic or grammar. The term, as used here, refers to an attribute of the subject, in the broadest sense. It may also be a tangible part of the subject. Thus, in this type of thinking there is a tendency to identify a part with the whole—e.g., a room with the house to which the room belongs. Expressed differently, $a = a + b + c$ because the two terms of the equation have $a$ in common. The predicate, furthermore, may refer not only to a quality inherent in the objects but also to spatial and temporal contiguity. The predicate which leads to the identification is called the *identifying link*.

Often, what should be only an *associative link* becomes, for the schizophrenic, an *identifying link*. According to my own studies,[4] this mechanism underlies the disturbances of association in schizophrenia. It is beyond the purpose of this chapter to describe and to interpret all alterations of association which may occur in schizophrenia. Here it will be enough to mention that regressed schizophrenics substitute associative words for those actually appropriate. For instance, if a regressed schizophrenic is asked the name of the President of the United States, he may reply, "White House." The idea of "White House" is a normal association to the idea of President of the United States, but in the regressed schizophrenic, associated ideas are identified and substituted for one another. The understanding of this transformation of associative links into identifying links will lead to the interpretation of word-salad, which otherwise appears an incomprehensible phenomenon.

Cameron[42] has made important studies of *disorganized* language and talk in disorganized schizophrenics. He characterizes the talk of these patients as: (1) *asyndetic*—lacking essential connectives; (2) *metonymic*—lacking precise definitive terms for which approximate but related terms or phrases are substituted (for instance, a patient said that he had three menus instead of three meals); (3) *interpretative*—having parts of one theme appearing as intrusive fragments; (4) *overinclusion*—including material only remotely related; (5) *noncorrespondence*—lacking relationship between what is done and what is said; (6) calling for *transformation in the rules* of procedure to justify failures; and (7) shifting verbal *generalizations* concerning solutions, hypotheses which were inadequate.

### Desymbolization and Desocialization

The individual during his childhood introjects symbols and roles from the surrounding adults. During the schizophrenic psychosis, he tends to lose these introjected symbols and roles. Desocialization or withdrawal in the schizophrenic means much more than being at a physical distance from the interpersonal environment and living in an ivory tower (as the schizoid does). For the schizophrenic patient, desocialization implies a change in the process of symbolizing, change which will permit the loss of the introjected symbols which originate from others and the replacement with more primitive ones.

In order to understand this process, a brief discussion of the process of symbolization in the human mind is necessary.*

The symbolic property of the mind permits the human being *to go beyond* what is given by the perceptual apparatus. Sense perceptions give information about what is here and now, that is, present in the spatiotemporal world in which the subject lives and by which he is stimulated, but symbols and the symbolic apparatus will permit him to become aware even of what is not given.

We may recognize a hierarchy of symbols. The simplest is the sign, which we have in common with infrahuman animals. The smell of a mouse, which is not seen, is, for the cat, the sign that the mouse is around. The physician sees a rash on the skin of the child and he realizes that that rash is the sign of measles. Signs are parts or cues of objects or situations which stand for the whole objects or situations which are *present* or *about to be present*. We may even say that the *sign* is that

* For a more adequate discussion of this subject the reader is referred to Cassirer,[45] Langer,[107] R. Spiegel (Chapter 46 of this book), and, in relation to schizophrenia, Arieti.[4]

Downloaded from www.pnaulay.org

predicate of the subject which makes the observer become aware of the presence or imminent presence of the subject. *Symbols* must be considered as belonging to higher levels than signs because they stand for something which is not present.

The image is the most primitive form of symbol. The external object is no longer present, but the individual retains an internal image which tends to reproduce the past perception of the object. Thus, the image of the mother may be with the child even when the mother is not present.

The image, however, tends to be private and cannot be externalized. In phylogeny the next step occurs when an individual succeeds in equating an external event or thing for something which is not present. (A sound or a thing [fetish] or a gesture may be equivalent for the object which is not present.) The thing that is taken as equivalent of the absent object is originally perceived as part or predicate of the missing object and becomes a paleosymbol. But paleosymbols too are individualistic, and private. Paleosymbols (and the higher types of symbols) may be auditory, visual, tactile, etc., but, for the sake of simplification, we shall consider only the auditory.

When an auditory paleosymbol, for instance the sound *ma-ma*, uttered casually or accidentally by a primitive man in connection with his mother, is understood by a second man (for instance, a sibling) as referring to the mother, we have the occurrence of a *verbal symbol* (called also *common* or *social symbol*). The verbal symbol evokes in the person who pronounces it the same reaction that it evokes in others,[121] it elicits "consensual validation."

The verbal symbol is something which not only replaces the missing object but also is shared by many people. Thus, it is no longer a paleosymbol, even for the person who used it for the first time, because the person now knows the reaction that the symbol will elicit from others, and knows that this reaction is approximately similar to his own.

The evolution of the word from the paleosymbol to the most abstract levels cannot be described here in detail but a brief summary will be presented. A word, when it is created by primitive men, has at least two characteristics: first of all denotation (not connotation).* The denotation is the object meant. The denotation of the word *ma-ma*, of our example, is the mother of the primordial siblings. Second, it has *verbalization*. The verbalization is the word applied to the object; it is the word as a word, that is, as a verbal entity, independent of its symbolic value. In primitive societies the emphasis is on these two aspects of terms. The word is so strictly tied to the object it denotes that it is often confused with that object. We have thus "word magic": the word applied to an object assumes the same quality that the object itself has. A great deal of attention is paid to the word, from the point of view of sound, rhythm, rhyme, assonance, homonymy, etc.

Later on, however, the word acquires *connotation* (or enlarges the primitive connotation); that is, it represents the concept of the object it stands for. It refers not only to a particular embodiment of the object but to the whole category of the object. Thus, in the example given, the sound *ma-ma* came to refer not only to the particular mother of the primordial siblings but to any mother, and came to assume the meaning, "female who begets offspring."

At high levels of development new symbols and roles are continuously created. The child is immediately exposed not only to many already made words, which have denotations and connotations, but to groups or configurations of words which reproduce or represent concepts and roles.

At the same time that he learns new words, he learns new relationships and concepts and the roles that he must assume. The image of himself, which consists predominantly of the body image, self-esteem, and self-identification, needs words, concepts, and roles reflected to the self from the human environment.

In schizophrenia, we have an approximate reproduction in reverse order of all the stages of symbolization and socialization. Furthermore, all of these stages may overlap, be

*This is not entirely correct. A primitive connotation may coexist.

Downloaded from www.dcpublishers.com

mixed in several proportions, so that what results is a very confusing picture.

The process of desocialization starts first with the progressive loss of those organizations of symbols which are referred to the self. There is thus a tendency to reject, or to divest the self of, those attitudes and tendencies which were reflected from others and became part of the self, and a tendency also to project, or give back the introjected attitudes. For example, the nagging, scolding attitude of the parent is originally introjected by the child, who will acquire a critical, condemnatory attitude toward himself. When the patient becomes psychotic, this attitude is projected, or given back to a parent-substitute—an authority or a person paleologically conceived as a persecutor because he seems to have one of the persecuting traits of the parent.

Thus, projection is not only attributing an idea to others but also giving back, restoring to the people who built it, an unpleasant part of the self. The patient no longer accepts self-condemnation as a part of the self; condemnation now comes from the persecutor. This mechanism is greatly complicated and obscured by the fact that what is given back is returned not to the original givers but to persons who symbolize them. Thus, paleologic mechanisms will transform the condemnatory quality of a parent into the persecutory actions of an F.B.I. agent.

We may distinguish three successive stages: First, the stage of introjection. The action or attitude of the parent is still external, actual, and is being introjected. Second, the stage of assimilation. The child has accepted the attitude of the parent, which has become his own attitude toward himself. He accuses, hates, or controls himself as the parents did. Third, the stage of projection (the psychotic stage). The patient projects back to symbolic parents those attitudes toward himself that he now rejects.

This mechanism of projection may be viewed as the expression of a changing interpersonal relation between the *I* (the patient) and the *Thou*. In the first stage the *Thou* is the parent or parent-substitute; in the second stage the *Thou* has become that component of the patient himself which may be called super-ego, if we adopt Freud's terminology, and includes the self-image of the bad child. In the third stage the *Thou* is the persecutor.

The stage of introjection is represented by the early life of the patient, when the unpleasant experiences took place. These unpleasant experiences are repressed but continue to act on the patient during the second stage by unconsciously motivating him toward awkward actions and distorted interpersonal relations. They participate in making the derogatory self-image much more pronounced and more difficult to tolerate. During the third stage the psychosis tries to eliminate this self-image.

At the same time that delusional formations occur, or later, other processes take place which are more directly related to language. Although the healthy person in a wakened state is concerned mainly with connotation and denotation of a symbol, he can shift his attention from one to another of its three aspects; the regressing schizophrenic, however, is concerned more and more with denotation and verbalization, and experiences a partial or total impairment of his ability to connote. This is what I have called *reduction of the connotation power*. For example, when regressed schizophrenics are asked to interpret proverbs, they do so literally. (A patient, asked to explain the proverb, "When the cat's away, the mice will play," replied that the mice felt free to play when the cat was away. He could not give to the word cat the special connotation, "a cruel person in authority.")

At the same time that the connotation power is decreased, denotation and verbalization become more important.

The verbal characteristics of schizophrenics are well known. The patients pay much attention to the sound, alliteration, and repetition of words. They seem to enjoy writing or pronouncing words which have sound associations —as, for instance, in the following series of words written by patients: "C, see, sea." "I know it, you know it. Chuck, luck, luck, Buck. True-two. These are it. I know it. I know it, you know it." "Are you pure? Sure. Yes! Yes!

Downloaded from www.dvaipublications.com

Yes! Frame! Name! Same! Same! Same! Came."

In the course of the illness, the patient gradually relinquishes common symbols and reverts to paleosymbols—that is, to symbols which he himself creates and which have no consensual validation. The paleosymbols represent a return to the level of the autistic expression of the child. As it happens in children, however, these paleosymbolic expressions are not completely original and private, but use remnants of common symbols. Often we recognize, in neologisms, common symbols which have undergone autistic or paleosymbolic distortions.

This process of desocialization and desymbolization is sometimes delayed or arrested by restitutive phenomena (see Reference 4, pp. 303–309). With the progression of the schizophrenic process, however, the process of desocialization increasingly impoverishes the patient's repertory of common symbols. With the advancing impoverishment of common symbols it becomes progressively more difficult for the patient to assume his own role and to visualize the roles of others. This process reveals how much of man is actually made of social life. When what was obtained from others is eliminated, man remains an insignificant residue of what he used to be.

### CAUSALITY AND ACTION: MOTOR DYSFUNCTIONS

Man uses two forms of causality to explain the universe and himself. The first is mechanical or deterministic causality; "Each cause has an effect." The necessary antecedent A is the cause of a necessary, consequent B. The second is teleologic causality. Things occur because of their purpose. B (reading a book) takes place because of A, the reader's *purpose* (learning a subject). Psychological causality is a variety of teleologic causality.

In pathological conditions or primitive thinking, mechanical causality plays a very little role. Instead of finding a physical explanation for an event, the paleologic thinker looks for a cause in a personal motivation or an intention. Every act, every event occurs because it is willed or wanted either by the person himself who seeks an explanation or by another person or by something which becomes personified. In other words, causality by logical deduction, often implying concepts involving the physical world, is replaced with causality by psychological explanation: *the necessary antecedent of any event is an act of will.* The study of primitive concepts of causality consists of the study of what is attributed to the will. For studies of anthropomorphization in primitive men or children, see Arieti,[4] Piaget,[139,140] Werner.[170] This method of interpreting the world—called *projected psychological causality*—is always found in paranoiacs and paranoids who interpret almost every occurrence as expressions of psychological intentions related to their delusional complexes.

More difficult to understand, perhaps, is the concept of *introjected psychological causality*, which is pronounced in catatonics. Although this type is psychological causality related to the thinker himself, and therefore not essentially dissimilar from projected psychological causality, it requires the study of other aspects of the problem. Here one's own will becomes the antecedent of events.

The symptomatology of catatonia consists not of motor disorders but of will disorders. The patient cannot move, not because he is paralyzed, but because he cannot will to move. The human action is not a simple motion, it is also an act of will. One of the first things primitive man became aware of was that he was able to will. He became aware of this long before he was able to evolve the concept of physical (deterministic) causality.

Human action is a very complicated phenomenon. Just as symbolism includes an elaborate transformation of what the posterior human brain (temporal, occipital, and parietal lobes) receives from the external world, willing and acting include the elaborate transformation of motor impulses, which take place in the anterior brain (frontal lobes). At the same time, of course, other noncortical mechanisms permit the precise execution of the movement as a neurological function.

What seems to be the first clear-cut manifestation of willed action is the inhibition of the reflex response. The toilet-trained baby is a clear example of this. Because of rectal distention,

Downloaded from www.dbraun-library.org

he has the impulse to defecate, but he learns to inhibit the response. He learns, by using cortical mechanisms, to control his sphincters. The will of the child is necessary: the child must want not to defecate. He develops the capacity and the will to resist. But if the child wants not to defecate, although it would be pleasant to do so, it is because he learns to please his mother. Thus, even in the first volitional acts, which imply choices, a new dimension enters: the interpersonal (the Thou). From a philosophical point of view it seems almost a contradiction in terms: the first acts of volition are acts of obedience, or of submission to the will of others. Choice, this new, portentous tool which emerges in phylogenesis with the human race, in the early ontogenetic stages requires support from others before it can be exercised independently.

Individual primitive man, as an independent doer, often feels guilty.[4] To do is to be potentially guilty, because, after all, you cannot know what event will follow what you are doing. It might have an effect on the whole tribe; its repercussions might be enormous, such as an epidemic or a drought. Kelsen[102] has illustrated well the relations between *to do* and *to be guilty* in the primitive. In order to diminish their feelings of guilt, primitive men refrain from acting freely; they perform only those acts which are accepted by the tribe. The tribe teaches the individual what act to perform for any desired effect. Ritualism and magic thus originate. By performing each act according to ritual, primitive man removes the anxiety that arises from the expectation of possible evil effects. The ritual ensures that the effect will be good.

From a certain point of view, the subsequent development of humanity can be seen largely as a gradual freedom from this reliance on the support of the group and as an expansion of the individual will. This act of liberation from the influence or suggestion of others ontogenetically is seen during the negativistic stage of children, who refuse to do what they are told to do. By disobeying, they practice their newly acquired ability to will; but they do so with the most primitive method (volition of resistance).

The phylogenetic history of human action may be summarized diagrammatically:

ACTION
- Resistance to reflex response or volition of resistance
- ↓
- Volition with introjected guilt causality
- ↓
- Volition with compliance to { mother / tribe / ritual }
- ↓
- Volition

This is, of course, a simplified scheme, and many intermediate stages have probably been omitted. Furthermore, many stages overlap and coexist. In normal human beings, all possible stages are found, but in pathological conditions we find a preponderance of earlier stages and partial or total loss of others—for instance, in neurotic persons, neurotic compliance to others; in obsessive-compulsives, volition with compliance to ritual. But the most pathological forms of volition are found in catatonic patients.

Dynamic studies reported elsewhere[4] indicate that people who are apt to become catatonic are those who in their early childhood have been prevented from developing confidence in their own actions and reliance on their capacity to will. The parents or parent substitutes have forced these patients either not to will or to follow parental decisions. When the patients later had to make their own choices, they found themselves unable to act; if they acted, they were criticized and made to feel guilty. In catatonia, the typical schizophrenic childhood struggle with significant adults is connected particularly with the actions and choices of the patient.

The eventual catatonic may try to remove the anxiety which accompanies his actions by compliance or obsessive-compulsiveness. In precatatonic patients, in fact, we find strong ambivalent attitudes, pseudocompliance, and compulsions. But if the symptoms are not sufficient to protect the patient from excessive anxiety, or if they cannot be built up rapidly enough to dam the anxiety, catatonia develops.

Downloaded from www.brainlibrary.org.in

Catatonia is a removal of action in order to remove the panic connected with the willed action. Sometimes this panic is generalized. When it is extended to every action, the patient may lapse into a state of complete immobility (stupor).

In less advanced cases, one clearly recognizes the impairment of the function to will. For instance, as an answer to an order, the patient starts a movement, but then stops, as if a counterorder had prevented him from completing the movement. Having decided to obey, he is then afraid to will the act involved, and he stops. At other times there is a series of alternated opposite movements, rather like a cogwheel movement, superficially similar to that observed in postencephalitic patients affected by muscular rigidity. In the middle of a movement the patient becomes afraid of willing that act, decides not to perform it, and arrests his arm. But to decide not to perform the act is also a volition. The patient becomes afraid of it and starts to make the movement again. To do this is also volition and he is again afraid. This series of attempted escapes from volition may go on for a long time; it is a horrifying experience, which only a few patients are able to relate.[4]

This fear of volition accounts for other characteristics encountered in cases of catatonic schizophrenia. In order to avoid anxiety and guilt, the patient cannot will any act, but he may passively follow orders given by others because the responsibility will not be his—there is a complete substitution of someone else's will for his own. Waxy flexibility or the retention of body positions, no matter how uncomfortable, in which the patient is passively put, can also be explained in this way. When the patient is put in a given position, the will or responsibility of someone else is involved. If he wants to change positions, he has to will the change, and this engenders anxiety or guilt.

Quite often the reverse seems to occur. The patient will resist the order, or will do the opposite. This is the phenomenon of negativism which has baffled many investigators. This action of willed disobedience is sometimes present in the normal person and in the negativistic child, as if unwillingness to obey or to follow an order automatically engenders an action of resistance. Perhaps we may understand this phenomenon of negativism if we interpret it as a return to the most primitive act of volition, or volition of resistance.

There seems to be a correlation, although not yet statistically proved, between the decline in the catatonic type of schizophrenia and the decline of manic-depressive psychosis. Perhaps a cultural environment which emphasizes the concept of guilt predisposes to these two conditions (see Chapter 22). But, whereas generally the premanic-depressive feels guilty for not acting, the catatonic feels guilty for acting. Actually, this is not the only difference between the guilt of the manic-depressive and that of the catatonic. The guilt feeling of the catatonic is much more primitive; it is a syncretic feeling of guilt-fear and is associated with the elementary concept of action, rather than with the higher concepts of sin and atonement.

At times the catatonic loses this inhibiting guilt-fear complex and acts in an opposite way—that is, as if he were not concerned at all with responsibility or as if he were defying previous feelings of fear and responsibility. His behavior manifests a maniclike sequence of aimless acts. He may become violent and homicidal. This is the state of *catatonic excitement.*

Other patients who remain in a catatonic stupor for a long time develop what I have called a feeling of *negative omnipotence,* or an alleged expansion of will power. They feel that, if they move, the whole world will collapse or all mankind will perish.
